Williams OBSTETRICS

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

DEDICATION

These are the times that try men's souls.

—Thomas Paine, *The American Crisis,* 1776–1783

This 23rd edition of *Williams Obstetrics* arrives at a time of economic uncertainty for our country—indeed, for the world. There is especial anxiety provoked by the anticipated tumultuous reorganization of our healthcare system. We dedicate this book to those who are fair minded and who strive to bring about these changes with equanimity. We include all those who work to construct a system that is the best for all, includes those who are disadvantaged, but does not diminish the quality of healthcare for those who will ultimately finance the system—a tall order indeed. We echo the philosophy of the American College of Obstetricians and Gynecologists that all women and their unborn children should have access to obstetrical care and family planning services.

PREFACE

In this 23rd edition of *Williams Obstetrics*, we continue to emphasize the science-based underpinnings and evidence-based practices of our specialty. Most professional and academic organizations embrace these principles, and while some promulgate guidelines and recommendations, others provide funding for such investigations. Our policy is to cite these whenever possible. A major impetus for these studies comes from the *Eunice Shriver Kennedy* National Institute of Child Health and Human Development—also called the NICHD. For many decades, this Institute has supported basic and clinical research to improve healthcare for women and children. We especially rely on investigations performed through NICHD-sponsored Maternal-Fetal Medicine Units and Neonatal Units Networks. There is also fiscal support for young investigators in obstetrics and allied specialties that comes from a number of societies and organizations. Among others, these include the American College of Obstetricians and Gynecologists, the American Gynecological and Obstetrical Society, the Society for Maternal-Fetal Medicine, the Society for Gynecological Investigation, and the American Board of Obstetrics and Gynecology.

A major objective of this book is to provide a convenient source that will aid the busy practitioner—those "in the trenches." To this end, we summarize new data that has influenced evidence-based management to improve pregnancy outcomes. And while we cite numerous sources to accomplish this, we again mention some important caveats. For example, while we try to avoid—or at least soften—dogmatism that creeps into obstetrical practice, we often cite our combined clinical experiences drawn from large teaching services. We remain convinced that these are disciplined examples of evidence-based obstetrics. Importantly, we do not represent that these constitute the sole method of management.

To succeed in these self-imposed mandates, we have again added new editors with especial expertise in important areas to ensure accurate interpretation of recent scientific and clinical advances. To allow for this, two editors who have served with distinction for several editions of this book have passed their pens on to others. Dr. Larry Gilstrap has traded the Chair of Obstetrics, Gynecology, and Reproductive Sciences at the University of Texas-Houston Medical School to become Executive Director of the American Board of Obstetrics and Gynecology. Dr. Kathy Wenstrom has left the University of Alabama at Birmingham to become Chief of Maternal-Fetal Medicine at Brown University. We will miss them both and value their contributions. To fill their shoes, two associate editors have assumed their duties. Dr. Dwight Rouse from the University of Alabama at Birmingham continues to lend his expertise in many areas of obstetrics, maternal-fetal medicine, and epidemiology. He also has many years of experience as a leading investigator in the Maternal-Fetal Medicine Units Network. Dr. Catherine Spong continues her ever-increasing duties as Chief of the Pregnancy and Perinatology Branch of the *Eunice Shriver Kennedy* National Institute of Child Health and Human Development. Cathy also serves as program scientist for the vitally important Maternal-Fetal Medicine Units Network cited above. A third vacancy in the associate editorship is Dr. William Rainey, who left UT Southwestern and is a Regents' Professor of Physiology at the Medical College of Georgia. Bill performed a fantastic job for the 22nd edition in dissecting basic science principles of human reproduction in a textbook written primarily for clinicians.

Dr. George Wendel remains on the team as associate editor. He is internationally recognized for his expertise in obstetrical, perinatal, and sexually transmitted infections. He is widely published in these fields and has mentored numerous fellows who have followed in his footsteps. Also joining us from UT Southwestern as associate editor is Dr. Diane Twickler, Professor of Radiology as well as Obstetrics and Gynecology. Her incredible wealth of knowledge and clinical and research experience with a variety of imaging techniques used during pregnancy have been unsung contributions for many previous editions of this book.

Reflecting the rapidly accruing knowledge in clinical obstetrics is the further addition of six extremely talented contributing editors, all from UT Southwestern Medical Center. Dr. Jodi Dashe uses her extensive experience and incredible skills with obstetrical sonography, fetal diagnosis, and prenatal genetics to provide input for this 23rd edition as she has namelessly done now for many previous ones. Dr. Barbara Hoffman has widespread clinical expertise with contraception and sterilization issues, embryology and anatomy, and especial interest in congenital and acquired genital tract anomalies. Equally importantly, she has served as the in-house production editor for the 22nd and 23rd editions and has spent countless evenings and weekends applying her considerable editorial talents and creative illustration production. Dr. Mala Mahendroo is a basic scientist who performs a magnificent job of providing a coherent clinical translational version of basic science aspects of human reproduction. To do so, she draws from her own research experience with cervical remodeling during pregnancy and initiation of human labor. Dr. Jim Alexander brings his expertise with the conduct of normal as well as abnormal labor and delivery, cesarean delivery, conduction analgesia, preeclampsia, and obstetrical hemorrhage. Dr. Brian Casey lends his in-depth clinical and research experience with diabetes, fetal growth disorders, and thyroid physiology. Dr. Jeanne Sheffield joins us as a vital member of the obstetrical infectious diseases group. In addition to her wealth of clinical and research experience with maternal, perinatal, and sexually transmitted infections, she also has extensive experience in managing drug dependency as well as a

host of other medical and surgical disorders that complicate pregnancy.

We continue to rely heavily on other colleagues for their intellectual and clinical input and the use of photographs and other illustrations that improve immensely the readability of this 23rd edition. Although these colleagues are too numerous to mention individually, we attempt to thank those with especial contributions. From UT Southwestern and Parkland Hospital, we cite the entire faculty of the Maternal-Fetal Medicine Division, who, in addition to providing expert content, graciously helped us cover clinical duties when writing and editing were especially time consuming. These include Drs. Oscar Andujo, Morris Bryant, Susan Cox, Jennifer Hernandez, Robyn Horsager, Julie Lo, Mark Peters, Scott Roberts, Vanessa Rogers, Patricia Santiago-Munoz, Steve Shivvers, Ed Wells, Kevin Worley, and Mike Zaretsky. Also in the division, our special thanks go to Dr. Don McIntire, who retrieved and tabulated electronically stored data for Parkland Hospital obstetrical outcomes that are shown in numerous tables and figures throughout this book. Dr. Barry Schwarz shared his extensive knowledge of contraceptive management for preparation of that chapter. Dr. Kelly Carrick of the Department of Pathology contributed numerous photographs illustrating both normal and abnormal features of the female reproductive tract. Dr. Gerda Zeeman from the University of Groningen in The Netherlands—but who remains in Dallas in spirit—graciously provided magnetic resonance images from women with eclampsia. We also thank the fellows of our Maternal-Fetal Medicine Division and our many residents in obstetrics and gynecology. Their vigilant search for perfect examples of normal and abnormal findings has led to many of the photographs in this edition. We specifically thank Drs. Mina Abbassi-Ghanavati and Laura Greer for their time-consuming efforts to provide the first-ever appendix of normal values during pregnancy for common and uncommon laboratory tests. We predict that this will be a priceless resource for practitioners.

From the University of Alabama at Birmingham, Ms. Suzanne Cliver provided material for tables and figures from the perinatal database. Drs. Ona Marie Faye-Peterson and Michael Conner of the Department of Pathology generously contributed pictures and photomicrographs of placental pathology. From Bethesda, Dr. Rosemary Higgins of the Neonatal Units Network provided expert input for disorders of the fetus and newborn.

Thanks to generous funding from The McGraw-Hill Companies, this 23rd edition has full-color photographs and illustrations. Many were either replaced or redrawn for consistency of style. More than 200 of the new color illustrations were created by two talented medical illustrationists. Ms. Marie Sena was one of the major artist contributors to the inaugural edition of *Williams Gynecology*. To even further her experiences for the current book, she logged countless hours in labor and delivery, in the anatomy laboratory, and in model simulations. Ms. Erin Frederikson, also a veteran of our art team, added insightful images depicting cesarean delivery, peripartum hysterectomy, and fetal development. Additional artwork was generously provided by Mr. Jordan Pietz and Ms. Jennifer Hulsey. All of these talented artists trained on campus under the stimulating leadership of Mr. Lewis Calver, who is Chair of the Biomedical Communications Graduate Program. More artistic support came from Mr. Joseph Varghese and his team at Thomson Digital, who provided the full-color graphs and line art that completes this edition's art program. They were aided by medical content expert Dr. Anuradha Majumdar, who precisely translated our academic vision to each image. Both tirelessly coordinated efforts between our authors and their art team and graciously accommodated our numerous changes and tweaks. In addition to these artists, we were grateful for photographic contributions from academic giants in their field. We boast seminal placental images generously donated by a dear friend, Dr. Kurt Benirschke, laparoscopic images of ectopic pregnancies from Dr. Togas Tolandi, and fetal surgery images from Dr. Timothy Crombleholme.

Production of the 5,000-page typewritten manuscript would be impossible without a dedicated team to bring these efforts together. Once again, we are deeply indebted to Ms. Connie Utterback for her untiring efforts as production coordinator for Dallas, Birmingham, and Washington, D.C. She received able assistance with manuscript production from the Dallas group that included Ms. Minnie Tregaskis, Ms. Melinda Epstein, Ms. Mary Kay McDonald, Ms. Dina Trujillano, and Ms. Ellen Watkins. From Birmingham, production coordination and manuscript preparation were ably provided by Ms. Belinda Rials and Ms. Sue Capps. Ms. Cherry Neely coordinated database analysis and presentation with help from research nurses Ms. Allison Northen and Ms. Rachel Copper. Graphic illustration for the Birmingham group was provided by Ms. Jo Taylor.

It again has been a privilege and a pleasure to work with the dedicated personnel from McGraw-Hill. A number of individuals were crucial to the success of this 23rd edition. Dr. Anne Sydor helped us to conceive the project, and she provided the inspiration and obtained financial support to present this full-color edition. Ms. Marsha Loeb served as senior editor during the bulk of its production, and she was an efficient and steadfast advocate who frequently went above and beyond to accommodate our needs. Her responsibilities were assumed in the "home stretch" by Ms. Alyssa Fried, who has ably led us to completion. We appreciate her efforts and thank her for her help and her patience. Integral to a project of this scope and complexity is attention to detail. This 23rd edition would have never seen the light of day without the considerable talents of Mr. Phil Galea, Mr. John Williams, and Mr. Armen Ovsepan. They have been long-standing members of the *Williams* team and have lent their considerable talents to several editions. An especially warm thank you is extended to a long-time colleague, Ms. Karen Davis, who coordinated production of this edition. Karen has been a tireless and committed member of our *Williams* family. Over the many years that we have worked with her, she has always handled problems quickly and expertly as soon as they arose. Her dedication to creating the best textbook possible equaled our efforts, and we are in awe of her unflappable, gracious, and effective style. Finally, McGraw-Hill enlisted Aptara Inc. for composition. We thank Ms. Satvinder Kaur for her talents in coordinating and overseeing composition. Her attention to detail and organization skills were vital to completion of our project.

Our goal at the outset of this 23rd edition was to create a visual landmark to equal the written content. To this end, almost 90 percent of images in this edition have been upgraded or revised. Of these, 220 images were rendered by our medical illustrators cited above. It will also be apparent that almost all previous black-and-white photographs have been replaced by those in vivid color. This is supplanted by a thorough canvass of the literature with stated efforts to emphasize evidence-based management. To do this, almost 2000 new journal and textbook references were added, and more than 400 of these were published in 2009. All of this talent and hard work has come to fruition in what we hope is the best edition so far of *Williams Obstetrics*. We further hope that the reader will enjoy studying its content as much as we have enjoyed conveying it.

SECTION 1

OVERVIEW

CHAPTER 1

Overview of Obstetrics

VITAL STATISTICS 2
PREGNANCY IN THE UNITED STATES 4
MEASURES OF OBSTETRICAL CARE 4
TIMELY TOPICS IN OBSTETRICS 7

According to the Oxford English Dictionary, the word *obstetrics* is defined as "that branch of medicine that deals with childbirth and the care and treatment of the mother before and after birth." Its derivation is from the Latin *obstetrix*, meaning midwife—from "mid"—with, and "wif"—meaning woman. Petraglia (2008) describes evidence of midwifery from records found in ancient Egypt and the Roman Empire. The Egyptian Ebers Papyrus (1900 to 1550 BC) recognized midwifery as a female occupation concerned with obstetrics and gynecology, and specifically with the acceleration of parturition and the birth process. Petraglia further reports that midwifery services were described through the Middle Ages and into the 18th century, at which time the role of the surgeon superseded that of the midwife. It was at this time that medicine began to assert that its modern scientific processes were better for mothers and infants than those of folk-medical midwives.

In the contemporaneous sense, obstetrics is concerned with reproduction of humans. The specialty promotes health and well-being of the pregnant woman and her fetus through quality prenatal care. Such care entails appropriate recognition and treatment of complications, supervision of their labor and delivery, ensuring care of the newborn, and management of the puerperium to include follow-up care that promotes health and provides family planning options.

The importance of obstetrics is attested to by the use of maternal and neonatal outcomes as an index of the quality of health and life in human society. Intuitively, indices that reflect poor obstetrical and perinatal outcomes would lead to the assumption that medical care for the entire population is lacking. With those thoughts, we now provide a synopsis of the current state of maternal and newborn health in the United States as it relates to obstetrics.

VITAL STATISTICS

The National Vital Statistics System of the United States is the oldest and most successful example of intergovernmental data sharing in public health. The National Center for Health Statistics (NCHS) collects and disseminates official statistics through contractual agreements with vital registration systems operated in various jurisdictions legally responsible for registration of births, fetal deaths, deaths, marriages, and divorces. Legal authority resides individually with the 50 states; two regions—the District of Columbia and New York City; and five territories—American Samoa, Guam, the Northern Mariana Islands, Puerto Rico, and the Virgin Islands. Schoendorf and Branum (2006) provide a thoughtful review of the use of these statistics to conduct obstetrical and perinatal research.

Standard certificates for the registration of live births and deaths were first developed in 1900. An act of Congress in 1902 established the Bureau of the Census to develop a system for the annual collection of vital statistics. The Bureau retained authority until 1946, when the function was transferred to the United States Public Health Service. It is presently assigned to the Division of Vital Statistics of the NCHS, which is a division of the Centers for Disease Control and Prevention (CDC). The standard birth certificate was extensively revised in 1989 to include more information on medical and lifestyle risk factors and also obstetrical care practices.

Further revisions were initiated in some states in 2003, but full implementation in all states will not be completed for several more years. The 2003 revision focuses on fundamental changes in data collection aimed at improving accuracy.

Changes also include a format conducive to electronic processing, to collect more explicit parental demographic data, and to improve selection of information regarding antepartum and intrapartum complications. Some examples of new data to be collected include those related to uterine rupture, blood transfusion, and pregnancy resulting from infertility treatment.

Definitions

The uniform use of standard definitions is encouraged by the World Health Organization as well as the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007). Such uniformity allows comparison of data not only between states or regions of the country, but also between countries. Still, not all of these definitions are uniformly applied, as illustrated by the example of definitions of inclusive fetal birthweights. To wit, these two organizations recommend reporting to include all fetuses and neonates born weighing at minimum 500 g, whether alive or dead. But not all of the 50 states follow this recommendation. For example, 28 states stipulate that fetal deaths beginning at 20 weeks' gestation should be recorded as such; 8 states report all products of conception as fetal deaths; and still others use a minimum birthweight of 350 g, 400 g, or 500 g to define fetal deaths. To further the confusion, the National Vital Statistics Reports tabulates fetal deaths as those 20 weeks' gestation or older (Centers for Disease Control and Prevention, 2009). But the 50th percentile for fetal weight at 20 weeks approximates 325 to 350 g—considerably less than the 500-g definition. Indeed, a birthweight of 500 g corresponds closely with the 50th percentile for 22 weeks.

Definitions recommended by the NCHS and the CDC are as follows:

Perinatal period. The period after birth of an infant born after 20 weeks and ending at 28 completed days after birth. When perinatal rates are based on birthweight, rather than gestational age, it is recommended that the perinatal period be defined as commencing at 500 g.

Birth. The complete expulsion or extraction from the mother of a fetus after 20 weeks' gestation. As described above, in the absence of accurate dating criteria, fetuses weighing <500 g are usually not considered as births, but rather are termed abortuses for purposes of vital statistics.

Birthweight. The weight of a neonate determined immediately after delivery or as soon thereafter as feasible. It should be expressed to the nearest gram.

Birth rate. The number of live births per 1000 population.

Fertility rate. The number of live births per 1000 females aged 15 through 44 years.

Live birth. The term used to record a birth whenever the newborn at or sometime after birth breathes spontaneously or shows any other sign of life such as a heartbeat or definite spontaneous movement of voluntary muscles. Heartbeats are distinguished from transient cardiac contractions, and respirations are differentiated from fleeting respiratory efforts or gasps.

Stillbirth or fetal death. The absence of signs of life at or after birth.

Early neonatal death. Death of a liveborn neonate during the first 7 days after birth.

Late neonatal death. Death after 7 days but before 29 days.

Stillbirth rate or fetal death rate. The number of stillborn neonates per 1000 neonates born, including live births and stillbirths.

Neonatal mortality rate. The number of neonatal deaths per 1000 live births.

Perinatal mortality rate. The number of stillbirths plus neonatal deaths per 1000 total births.

Infant death. All deaths of liveborn infants from birth through 12 months of age.

Infant mortality rate. The number of infant deaths per 1000 live births.

Low birthweight. A newborn whose weight is < 2500 g.

Very low birthweight. A newborn whose weight is < 1500 g.

Extremely low birthweight. A newborn whose weight is <1000 g.

Term neonate. A neonate born anytime after 37 completed weeks of gestation and up until 42 completed weeks of gestation (260 to 294 days).

Preterm neonate. A neonate born before 37 completed weeks (the 259th day).

Postterm neonate. A neonate born anytime after completion of the 42nd week, beginning with day 295.

Abortus. A fetus or embryo removed or expelled from the uterus during the first half of gestation—20 weeks or less, or in the absence of accurate dating criteria, born weighing < 500 g.

Induced termination of pregnancy. The purposeful interruption of an intrauterine pregnancy with the intention other than to produce a liveborn neonate, and which does not result in a live birth. This definition excludes retention of products of conception following fetal death.

Direct maternal death. The death of the mother that results from obstetrical complications of pregnancy, labor, or the puerperium and from interventions, omissions, incorrect treatment, or a chain of events resulting from any of these factors. An example is maternal death from exsanguination after uterine rupture.

Indirect maternal death. A maternal death that is not directly due to an obstetrical cause. Death results from previously existing disease or a disease developing during pregnancy, labor, or the puerperium that was aggravated by maternal physiological adaptation to pregnancy. An example is maternal death from complications of mitral valve stenosis.

Nonmaternal death. Death of the mother that results from accidental or incidental causes not related to pregnancy. An example is death from an automobile accident or concurrent malignancy.

Maternal mortality ratio. The number of maternal deaths that result from the reproductive process per 100,000 live births. Used more commonly, but less accurately, are the terms *maternal mortality rate* or *maternal death rate.* The term *ratio* is more accurate because it includes in the numerator the number of deaths regardless of pregnancy outcome—for example, live births, stillbirths, and ectopic pregnancies—whereas the denominator includes the number of live births.

Pregnancy-associated death. The death of a woman, from any cause, while pregnant or within 1 calendar year of termination of pregnancy, regardless of the duration and the site of pregnancy.

Pregnancy-related death. A pregnancy-associated death that results from: (1) complications of pregnancy itself, (2) the chain of events initiated by pregnancy that led to death, or (3) aggravation of an unrelated condition by the physiological or pharmacological effects of pregnancy and that subsequently caused death.

PREGNANCY IN THE UNITED STATES

Data from diverse sources have been used to provide the following snapshot of pregnancy in the United States during the first decade of the 21st century.

Pregnancy Rates

According to the Centers for Disease Control and Prevention (2009), and as shown in Table 1-1, the fertility rate in 2006 of women aged 15 to 44 years was 68.5 live births per 1000 women. This rate began trending downward in 1990 and decreased even lower than that for replacement births, indicating a population decline (Hamilton, 2004). However, this was offset by considerable net migration into the United States that is discussed further on page 10. For example, there were more than 1 million migrants each year from 2000 to 2002.

There were nearly 4.3 million births in 2006, and this constituted a birth rate for the United States of 14.2 per 1000 population. This rate was up from that in 2002, which was the lowest rate ever recorded—13.9 per 1000 population. Hispanic women accounted for more than 1 in 5 births. The average American woman has 3.2 pregnancies in her lifetime, and 1.8 of these are considered wanted pregnancies (Ventura and colleagues, 1999). After exclusion of fetal losses and induced terminations, American women on average deliver 2.0 live births in a lifetime. By way of example, Table 1-1 includes more than 5.1 million pregnancies in the United States that were classified as live births or induced abortions. Assuming another 15 percent for spontaneous abortion, there are approximately 6 million pregnancies in this country each year.

TABLE 1-1. Some Statistics Concerning Reproductive Outcome for the United States in 2005 or 2006

Statistic	Number or Rate
Births	
Total	4,265,555
Birth rate	14.2 per 1000 population
Fertility rate	68.5 per 1000 women aged 15–44 years
Abortion	
Total	820,151
Birth rate	223 per 1000 live births
Fertility rate	15 per 1000 women aged 15–44 years

Data from Centers for Disease Control and Prevention (2008, 2009).

Pregnancy-Related Care

This is a major component of health care. In 2001, delivery was the second leading cause of hospitalization behind heart disease (Hall and DeFrances, 2003). The average length of hospital stay for all deliveries was 2.5 days. Prenatal care was the fourth leading reason for office visits to physicians and accounted for nearly 20 million visits in 2001 (Cherry and associates, 2003). Nondelivery hospitalizations have decreased substantially since the late 1980s due to efforts to minimize expenditures. The leading indication for hospitalization unrelated to delivery is preterm labor. Nicholson and co-workers (2000) estimated that the total national cost of hospitalization for preterm labor that did not eventuate in delivery was $360 million in 1996 dollars. This sum increased to $820 million when women with preterm labor who actually delivered early were added.

MEASURES OF OBSTETRICAL CARE

There are a number of indices—several among the vital statistic definitions described above—that are used as a yardstick of obstetrical and perinatal outcomes to assess quality of care.

Healthy People 2010 and 2020

Objectives for maternal and infant health for the decade now ending were promulgated by the Centers for Disease Control and Prevention and the Health Resources and Service Administration (2000) and included in the nationwide goals termed *Healthy People 2010*. Progress toward some of these goals has been disappointing. Notably, one major objective was to lower the number of preterm births, but these have actually increased since 2000. Also, the disparity in pregnancy outcomes between whites and racial/ethnic minorities has persisted, and the infant mortality rate in African-American women is now almost twice that of white mothers. Other objectives were concerned with decreasing the rates of maternal, perinatal, and infant morbidity and mortality.

Planning for Healthy People 2020 began in 2008 guided by the Office of Disease Prevention and Health Promotion (2009). Goals are being determined using science-based findings that have accrued over the current decade with launch expected in 2010.

Perinatal Mortality

As previously defined, the perinatal mortality rate includes the numbers of stillbirths and neonatal deaths per 1000 total births. According to the National Vital Statistics Reports by MacDorman and Kirmeyer (2009), in 2005 there were 25,894 fetal deaths of 20 weeks' gestation or more. As shown in Figure 1-1, the fetal death rate declined gradually from 1999 but plateaued in 2003. Most of the improvement was a decrease in fetal deaths between 20 and 27 weeks.

Fetal deaths after 20 weeks are an important public health issue. Although there is appropriate concern concentrated on infant mortality—death in the first year of life—a focus on fetal mortality may provide further opportunities for prevention. For

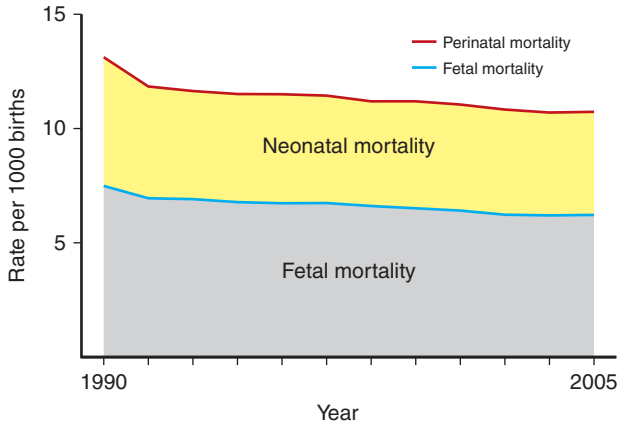

FIGURE 1-1 Fetal mortality rates from 1990 through 2005 in the United States are depicted by the blue line. Fetal mortality (*gray area*) and neonatal mortality rates (*yellow area*) are combined to reflect the total the perinatal mortality rate, which is shown by the red line. (Data points estimated from National Vital Statistics Reports by MacDorman and Kirmeyer, 2009.)

example, racial and ethnic disparity associated with fetal death is obvious as shown in **Figure 1-2**. In 2004, approximately a fourth of the 18,593 neonatal deaths were due to preterm delivery and approximately a fifth was caused by a congenital malformation (Heron, 2007). Worldwide, approximately 4 million babies are stillborn each year, and another 4 million die in the first 4 weeks of life (Lawn and colleagues, 2005).

Infant Deaths

There were 28,384 infant deaths in 2005, a rate of 6.9 per 1000 live births compared with 6.8 in 2001 (Mathews and MacDorman, 2008). The three leading causes of infant death—congenital malformations, low birthweight, and sudden infant death syndrome—accounted for 44 percent of all deaths. Infants born at the lowest gestational ages and birthweights have a large impact on these mortality rates. For example, 55 percent of all infant deaths in 2005 occurred in 2 percent of infants born before 32 weeks' gestation. Indeed, the percentage of infant deaths related

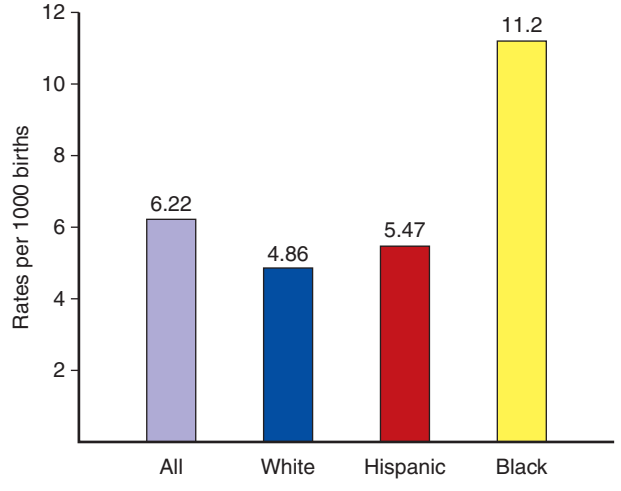

FIGURE 1-2 Fetal death rate for various populations in the United States in 2005. (Data from National Vital Statistics Reports by MacDorman and Kirmeyer, 2009.)

to preterm birth increased from 34.6 percent in 2000 to 36.5 percent in 2005. When analyzed by birthweight, two thirds of infant deaths were in low-birthweight neonates**.** Of particular interest are those birthweights less than 500 g, for which neonatal intensive care can now be offered. In 2001, there were 6450 liveborn infants weighing less than 500 g, but 86 percent of these infants died during the first 28 days of life. Of the 1044 who survived the first 28 days of life, there were 934 who lived for at least 1 year. Thus, only 11 percent of all neonates weighing $<$ 500 g survived infancy. Importantly, developmental and neurological sequelae are common in the survivors (see Chap. 36, p. 807).

St. John and associates (2000) have estimated the total cost of initial care in the United States for all newborns as $10.2 billion annually. Almost 60 percent of this expenditure is attributed to preterm births before 37 weeks, and 12 percent is spent on neonates born between 24 and 26 weeks.

Maternal Mortality

Pregnancy and childbirth have never been safer for women in the United States. In fact, pregnancy-related deaths are so uncommon as to be measured per 100,000 births. Still, some women die from early pregnancy complications related to ectopic pregnancy, miscarriage, and induced abortion and later complications such as hypertensive disorders, hemorrhage, and infection. Kung and colleagues (2008) reported for the National Vital Statistics System that there were 623 pregnancy-related deaths in the United States in 2005. Some of the more common causes of pregnancy-related maternal deaths are shown in **Table 1-2**. Hemorrhage and infection cause half of deaths associated with ectopic pregnancy and abortion. Taken together, embolism, hemorrhage, hypertension, and infection accounted for 65 percent of maternal deaths after midpregnancy. It is also important to consider the role that the increasing cesarean delivery rate has on maternal mortality risks (Clark and associates, 2008; Deneux-Tharaux and co-workers, 2006; Lang and King, 2008).

There are a number of other factors important to the discussion of maternal mortality. First, maternal deaths are notoriously underreported, possibly by as much as half (Koonin and colleagues, 1997). Even so, there is no doubt that a major accomplishment of obstetrical care is the markedly decreased risk of death from pregnancy complications. As shown in **Figure 1-3**, maternal mortality rates decreased by two orders of magnitude—almost 99 percent—in the United States during the 20th century. Still, it is unfortunate that mortality rates have plateaued since 1982 (Lang and King, 2008). This may be due in part to an artificial increase caused by a classification system change. For example, new International Statistical Classification of Diseases and Related Health Problems, 10th Revision (ICD-10) codes were implemented in 1999.

A second important consideration is the obvious disparity of increased mortality rates in indigent and minority women as shown in **Figure 1-4**. The disparity with indigent women is exemplified by the study of maternal deaths in women cared for in a third-party payer system, the Hospital Corporation of America. In this study of nearly 1.5 million pregnant women, Clark and associates (2008) reported an impressively low maternal mortality rate of 6.5 per 100,000.

TABLE 1-2. Causes of Pregnancy-Related Maternal Deaths in the United States[a] Compared with Those of Pooled Data from Developed Countries[b]

Cause of Death	United States 1991–1999[c] (n = 4200) Percent	Pooled Data for Developed Countries after 1990[d] (n = 2047) Percent
Embolism	19.6	20.5
Hemorrhage	17.2	18.5
Gestational hypertension	15.7	22.2
Infection	12.6	2.8
Other pregnancy-related	34.1	29.4
Cardiomyopathy	8.3	
Stroke	5.0	
Anesthesia	1.6	
Others[e]	19.2	
Unknown	0.7	6.6

[a]Data from Centers for Disease Control and Prevention reported by Chang and colleagues (2003).
[b]Data from the World Health Organization reported by Khan and associates (2006).
[c]Includes abortion and ectopic pregnancy.
[d]Excludes abortion and ectopic pregnancy.
[e]Includes cardiovascular, pulmonary, neurological, and other medical conditions.

The third important consideration is that many of the reported maternal deaths are considered preventable. According to Berg and colleagues (2005), this may be up to a third of pregnancy-related deaths in white women and up to half of those in black women. And even in the insured women described above and reported by Clark and co-workers (2008), 28 percent of 98 maternal deaths were judged preventable. Thus, although significant progress has been made, measures to prevent more deaths are imperative for obstetrics in the 21st century.

Severe Maternal Morbidity

The concept of "near miss" maternal mortality has led to development of statistical data systems that measure indicators of *severe maternal morbidities*. This evolution followed inadequacies in hospitalization coding to reflect the severity of maternal complications. Thus, coding indicators or modifiers are used to allow analysis of clinical "near misses." Such a system has been implemented in Britain and is termed the UK Obstetric Surveillance System—UKOSS (Knight and colleagues, 2005, 2008).

Ad hoc studies of severe maternal morbidity for the United States have been reported. From the Centers for Disease Control and Prevention, Callaghan and colleagues (2008) analyzed nearly 425,000 records from the National Hospital Discharge Summary (NHDS) from 1991 through 2003. *Selected International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM)* codes were used to tabulate a number of severe morbidities, and some of those most commonly encountered are listed in Table 1-3. These investigators reported that 5 per 1000 of these 50.6 million pregnant women had at least one indicator for severe

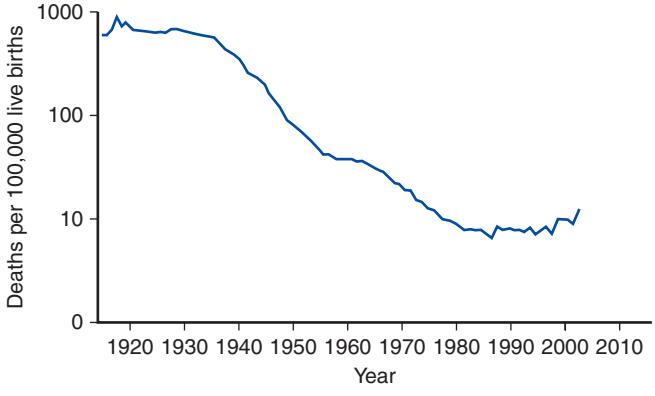

FIGURE 1-3 Maternal mortality rates for the United States from 1915 to 2003. (From the National Center for Health Statistics reported by Hoyert, 2007.)

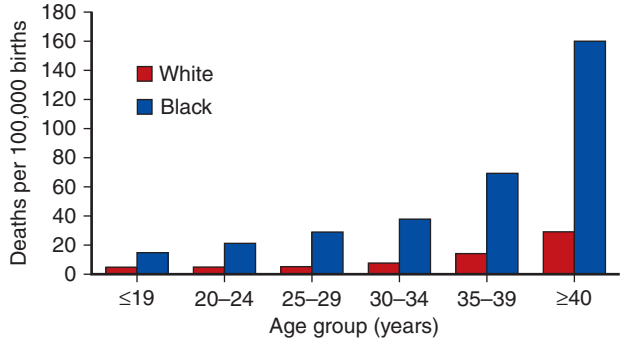

FIGURE 1-4 Maternal mortality ratio (deaths per 100,000 live births) by age and according to race for the United States, 1991 through 1999. (Data from the Centers for Disease Control and Prevention as reported by Chang and co-workers, 2003.)

TABLE 1-3. Severe Obstetrical Morbidities Identified[a] During Delivery Hospitalizations–United States, 1991–2003

Category	Percent of Morbidities[b]
Transfusions	48
Eclampsia	14
Hysterectomy	12
Cardiac events	7.6
Respiratory failure	6.7
Anesthesia complications	4.6
Mechanical ventilation	4.2
Septicemia	4.2
Renal failure	2.5
Stroke	2.5
Invasive monitoring	1.8
Hemorrhagic shock	1.5
Pulmonary embolism	0.8

[a]Identified by International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) codes.
[b]Percent exceeds 100 because some patients had multiple diagnoses.
Data from the Centers for Disease Control and Prevention reported by Callaghan and colleagues (2008).

morbidity. Said another way, for every maternal death, approximately 50 women experience severe morbidity.

A similar study was recently reported by Kuklina and associates (2009) from the National Institutes of Child Health and Human Development and the Centers for Disease Control and Prevention. They performed a cross-sectional study of severe obstetrical complications identified from the 1998–2005 National Inpatient Sample of the Healthcare Cost and Utilization Project that included more than 32 million discharges. Severe complications similar to those shown in Table 1-3 were identified with a rate of 6.4 per 1000 in 1998-1999 and 8.1 per 1000 for 2004–2005.

These rates of 5 to 8 per 1000 deliveries have been reported from other developed countries. From Canada, Wen and associates (2005) surveyed 2.54 million deliveries between 1991 and 2000 and reported an overall rate of severe morbidity of 4.6 per 1000 deliveries. From the Netherlands, Zwart and co-workers (2008) studied nearly 325,000 deliveries and reported an overall incidence of severe morbidity of 7.1 per 1000 deliveries. As with maternal deaths, these morbidities can be studied to discover and correct systemic errors and to improve substandard care (Pearlman, 2006).

TIMELY TOPICS IN OBSTETRICS

A variety of topics have been in the forefront for obstetrical providers in the 4 years since the last edition of this textbook. Our purpose here is to review some of these topics selected because of their likely impact on our specialty in the coming years.

Rising Cesarean Delivery Rate

In the preceding edition we noted that in 2002, the cesarean delivery rate climbed to the highest level ever reported in the United States—26.1 percent. Since that time, this record has subsequently been broken each year with the new record of 31.1 percent in 2006 (Martin and colleagues, 2009). This rise in the total rate is a result of upward trends in both the primary and the repeat cesarean rate. Indeed, more than 90 percent of women with prior cesarean deliveries now undergo repeat procedures. The forces involved in these changes in cesarean delivery rates are multifactorial and complex. We cite a few examples:

1. As discussed in Chapter 20 (p. 465), the major indication for primary cesarean delivery is dystocia, and there is evidence that this diagnosis has increased.
2. As discussed throughout Chapter 26, the sharp decline in vaginal births after cesarean—VBAC—deliveries is likely related to the uterine rupture risk associated with VBAC.
3. As discussed in Chapter 25 (p. 548), a new and controversial factor is *cesarean delivery on maternal request—CDMR*. This is defined as a cesarean delivery at term for a singleton pregnancy on maternal request in the absence of any medical or obstetrical indications (Reddy and Spong, 2006). The magnitude of the CDMR phenomenon in American obstetrics has been difficult to quantify. Meikle and co-workers (2005) estimated that the rate of such elective procedures increased from 20 percent of all primary cesareans in 1994 to 28 percent in 2001. Thus, such elective cesarean deliveries constitute between 3 and 7 percent of all deliveries to women without a previous cesarean delivery (Menacker and colleagues, 2006). To address this issue, the National Institute of Child Health and Human Development (NICHD) convened a State-of-the-Science Conference in 2006 to provide an in-depth evaluation of the evidence, raise public awareness, identify research goals, and guide practitioners in assessing risks and benefits. According to Dr. James Scott, editor of *Obstetrics & Gynecology*, more than 500 people attended, and it was apparent that there were numerous advocacy groups concerned about and opposed to the direction that CDMR has taken. In a summary of the meeting—*NIH State-of-the-Science Conference Statement on Cesarean Delivery on Maternal Request (2006)*—it was concluded that there was insufficient evidence to evaluate fully the benefits and risks of CDMR versus planned vaginal delivery. Importantly, CDMR was not recommended for women desiring several children because the risks of placenta previa and accreta increase with each cesarean delivery. Moreover, it was concluded that CDMR should not be performed before 39 completed weeks' gestation or before verification of fetal lung maturity. It is hoped that some evidence-based guidelines will soon be available.

Measuring Healthcare Outcomes

Much publicity followed the report by the Institute of Medicine entitled *To Err Is Human* (Kohn and colleagues, 2000). The report greatly increased interest in measuring healthcare outcomes and adverse events (Grobman, 2006). Even the U.S. Congress has determined that reimbursements by Medicare and Medicaid should be indexed to selected healthcare outcomes. Specifically, wide and often dizzying spectra of benchmarks have

TABLE 1-4. Recommended Adjustments to Current ACGME Resident Guidelines for Work Hours

	2003 ACGME Guidelines	2008 IOM Recommendations
Maximum hours of work per week	80 hours, averaged over 4 weeks	No change
Maximum shift length	30 hours (admitting patients up to 24 hours then 6 additional hours for transitional and educational activities)	• 30 hours (admitting patients for up to 16 hours, plus 5–hour protected sleep period between 10 p.m. and 8 a.m. with the remaining hours for transition and educational activities) • 16 hours with no protected sleep period
Maximum in–hospital on–call frequency	Every third night, on average	Every third night, no averaging
Minimum time off between scheduled shifts	10 hours after shift length	• 10 hours after day shift • 12 hours after night shift • 14 hours after any extended duty period of 30 hours and not to return until 6 a.m. of next day
Maximum frequency of in–hospital night shifts	Not addressed	• 4 night maximum; 48 hours' off after 3 or 4 nights of consecutive duty
Mandatory time off duty	• 4 days off per month • 1 day (24 hours) off per week, averaged over 4 weeks	• 5 days off per month • 1 day (24 hours) off per week, no averaging • One 48-hour period off per month
Moonlighting	Internal moonlighting is counted against 80-hour weekly limit	• Internal and external moonlighting is counted against 80-hour weekly limit • All other duty hour limits apply to moonlighting in combination with scheduled work
Limit on hours for exceptions	88 hours for select programs with a sound educational rationale	No change
Emergency room limits	12-hour shift limit, at least an equivalent period of time off between shifts; 60-hour workweek with additional 12 hours for education	No change

ACGME = Accreditation Council for Graduate Medical Education; IOM = Institute of Medicine.
From the Institute of Medicine (2008).

been proposed for measurement of the quality and safety of obstetrical care. Pearlman (2006) reviewed the present state of quality outcome measures in obstetrics and provided an agenda for the future. In our view, the greatest impediment to deriving meaningful measures of obstetrical care is the continued use of administrative and financial data—instead of clinical data—to set benchmarks for outcomes such as rates of perinatal deaths, cesarean delivery, or third- or fourth-degree perineal lacerations.

Residency Training Work Hours

In 2003, the Accreditation Council for Graduate Medical Education (ACGME) set a national standard restructuring the resident physician workweek to a maximum 80 hours per week averaged over 4 weeks and limiting the longest consecutive period of work to 30 hours. These and other 2003 ACGME guidelines are shown in Table 1-4. Following this, the Institute of Medicine (IOM) (2008) commissioned a study to determine factors of patient safety vis-a-vis resident work hours. The Institute recommended changes that are also listed in Table 1-4. These investigators concluded that costs incurred would range annually from $1.1 to $2.5 billion in 2006 dollars, but with unknown effectiveness.

As expected, some disagree with the IOM recommendation for swift implementation of these changes. Citing lack of evidence-based efficacy, inflexibility of the guidelines, and possible adverse effects on resident training, Blanchard and associates (2009) called for studies to determine factual effects before implementation. Indeed, there is evidence that the guidelines will likely adversely affect residency training in neurosurgery (Grady and colleagues, 2009; Jagannathan and co-workers, 2009).

At least in 2009, the plan is for the ACGME Duty Hours Congress to review available data as well as responses from various professional societies and boards. In 2010, the ACGME plans to revise Common Program Requirements. After this, individual Residency Review Committees will revise these for

their own specialty specific requirements, which likely will be implemented in July 2011.

Electronic Medical Records

Rising costs and inconsistent quality are both significant challenges in the delivery of healthcare in the United States. Electronic health records have been identified as a means of improving the efficiency and effectiveness of healthcare providers (Jha and co-workers, 2009). Methods to speed the adoption of health information technology have received bipartisan support in Congress, and the American Recovery and Reinvestment Act of 2009 has made such a system a national priority. Jha and colleagues (2009) surveyed hospitals nationwide and found that only 1.5 percent had a comprehensive electronic records system. And only 17 percent of physicians reported using some type of electronic records system (DesRoches and colleagues, 2008). Obviously, implementation of an interconnected national system is a daunting task that will require many years.

Conflicts of Interest

According to Brennan and colleagues (2006), physician commitment to altruism, putting the interests of patients first, scientific integrity, and an absence of bias in medical decision making are regularly in conflict with financial interests. Although physician groups have instituted self-regulation, it is now widely perceived that more stringent regulation is necessary. To this end, the American College of Obstetricians and Gynecologists (2008b) has published a *Committee Opinion* that details recommendations for relationships between physicians and industry.

Research

It has become increasingly recognized that although per capita healthcare expenditures in the United States are the highest in the world, healthcare outcomes not infrequently lag behind those in nations spending far less. A major factor in this disparity is thought to be expenditure overuse, underuse, and misuse driven by rationale- instead of evidence-based health care. To this end, the National Institutes of Health began a nationwide research program of Clinical and Translational Science Awards (CTSA) to enhance evidence-based health care. (National Center for Research Resources, 2009). The neutral premise of this approach is that successful healthcare interventions require systematic translation of developments from the basic sciences. We applaud this decision.

Medical Liability

The American College of Obstetricians and Gynecologists periodically surveys its fellows concerning the impact of professional liability on their practice. The 2006 Survey on Professional Liability is the ninth such survey since 1981 (Wilson and Strunk, 2007). The survey reflects experiences of more than 10,500 members, and some of these findings are listed in Table 1-5.

TABLE 1-5. 2006 Survey of Fellows on Professional Liability by the American College of Obstetricians and Gynecologists

Since 2003 Survey	Responses[a]
Practice change(s)	70 percent overall with one or more changes 30 percent increased number of cesarean deliveries 26 percent stopped performing VBACs 26 percent decreased number of high-risk patients 12 percent decreased number of deliveries 7 percent stopped all obstetrics
Open or closed claims	55 percent overall with one or more claim (62 percent obstetrics, 39 percent gynecology) • 31 percent—neurologically impaired infants • 16 percent—stillborn or neonatal death • 16 percent—shoulder dystocia • 11 percent—electronic fetal monitoring • 9 percent—resident physicians
Average paid claims	$505,000 all paid claims $1,150,000 for neurologically impaired infants $477,000 for other infant injury—major $259,000 for stillbirth or neonatal death
Co-defendants	42 percent—hospital 29 percent—partners 15 percent—residents 12 percent—nurses 11 percent—nonpartner OB-GYN 7 percent—anesthesiologists 4 percent—nurse midwives

[a]Percentages rounded off.
VBAC = vaginal birth after cesarean.
Data from Wilson and Strunk (2007).

Importantly, 70 percent of fellows responded that some aspect(s) of liability had changed their practice since last surveyed in 2003. Some of these changes undoubtedly were not positive.

Thus, by all accounts, there is still a "liability crisis" that is complex. Because it is largely driven by money and politics, a consensus seems unlikely. Although some interests are diametrically opposite, other factors contribute to its complexity. For example, each state has its own laws and opinions of "tort reform." Meanwhile, liability claims remain a "hot button" in obstetrics because of their inherent adversarial nature and the sometimes outlandish plaintiff verdicts that contribute to increasing liability insurance premiums. In some states, annual premiums for obstetricians approach $300,000—expenses that at least partially are borne by the patient, and certainly by the entire healthcare system. Liability issues are daunting, and in 2002, all tort costs in the United States totaled $233 billion—an astounding 2.2 percent of the *gross domestic product* and averaging $890 per citizen (Tillinghast-Towers Perrin, 2009).

Related to plaintiff awards, Hankins and co-workers (2006) reported that only 6 percent of premium payments will be used to underwrite medical expenses for a patient! This is in contrast to 22 percent for plaintiff lawyers' expenses and contingency fees. According to the *New York Times*, "The very phrase 'trial lawyer' has become associated with unadulterated greed; the Association of Trial Lawyers of America now calls itself the 'American Association for Justice'" (Glater, 2008). In their review, Berkowitz and colleagues (2009) compared them with Willie Sutton, the (in)famous bank robber who stole more than $600 million in his prolific career from the 1920s until the early 1950s.

The American College of Obstetricians and Gynecologists has taken a lead in adopting a fair system for malpractice litigation—or *maloccurrence litigation*. The Committee on Professional Liability has produced a number of related documents that help fellows cope with the stresses of litigation (2008a), provide advice for the obstetrician giving expert testimony (2007c), and that outline recommendations for disclosure of adverse events (2007b).

National liability reform likely will come in some form with the push for universal medical insurance coverage. President Obama, in his 2009 address to the American Medical Association, indicated that national malpractice liability reform was negotiable. U.S. Congressman Michael Burgess asked the president to reaffirm this commitment. We applaud their efforts and wish for their success.

Births to Immigrants

Persons born outside the United States comprised an estimated 11 percent of the population—more than 30 million people (Gold, 2003). Approximately a third are undocumented—here illegally or with an expired visa—and this proportion has increased tenfold over the past 30 years (Goldman and colleagues, 2006). According to the Pew Hispanic Center (2009), 57 percent of immigrants are from Mexico, 24 percent from Latin America, and the remainder from Asia, Europe, and Africa. The American College of Obstetricians and Gynecologists (2009a) has taken the position that all immigrants within our borders should receive basic health care.

Family Planning Services

Politics and religion over the years have led to a variety of governmental interferences with the reproductive rights of women. These interferences have disparately affected indigent women and teenagers. An example from the recent past is the consideration by Congress in 1998 of the Title X Parental Notification Act to mandate parental notification for minors seeking contraception at federally funded clinics. Reddy and colleagues (2002) reported that this would have dissuaded almost half of girls younger than 17 years from seeking contraceptive services and testing or treatment for sexually transmitted disease. The increased number of unintended teenage pregnancies and abortions that would inevitably ensue are discussed subsequently.

A recent example is the tug-of-war over emergency contraception, and more specifically over the *morning-after pill* (see Chap. 32, p. 692). The 2004 decision by the Bush Administration to override the 23 to 4 vote to approve *Plan B* for over-the-counter sales to 17-year-old women was decried appropriately by editorials in the *New England Journal of Medicine* (Drazen and colleagues, 2004; Steinbrook, 2004). This was overturned in April 2009 by a federal district court in New York that ordered the Food and Drug Administration (FDA) to make emergency contraception available over the counter to women 17 years or older. The American College of Obstetricians and Gynecologists (2009b) lauded the decision, citing the more than 800,000 yearly teenage pregnancies in this country and the fact that many are terminated. Also cited were data showing that most adolescents have sex for the first time at age 17.

Perhaps the most egregious example of both federal and state governmental intrusion into women's reproductive rights is the often poor availability of federally funded family planning services for indigent women. This is despite all reports of the overwhelming success of such programs. According to the Guttmacher Institute (2009), publicly funded family planning services in 2006 prevented nearly 2 million unintended pregnancies and 800,000 abortions in the United States (**Fig. 1-5**). They conclude that without such funding the abortion rate would be nearly two thirds higher for all women, and nearly twice as high for poor women.

Teenage Pregnancy

In 2006, there were almost a half million births to women aged 15 to 19 years (Centers for Disease Control and Prevention, 2009). The national rate was 42 births per 1000 females aged 15 to 19 years. Although this rate is substantively reduced compared with 77 per 1000 in 1990, measures to lower it further should remain a

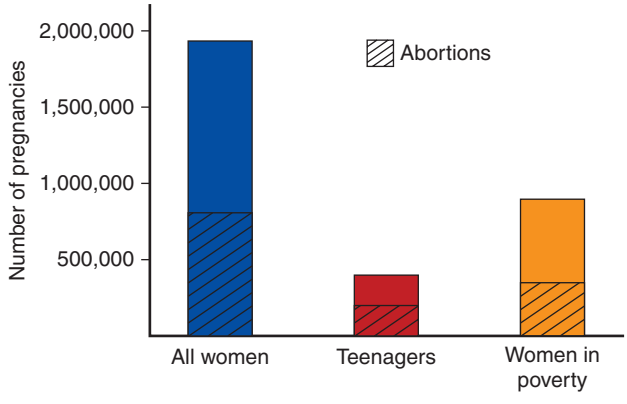

FIGURE 1-5 Number of unintended pregnancies including elective abortions prevented in 2006 by publicly funded clinics. (Data approximated from reports by the Guttmacher Institute, 2009.)

top priority. Like abortion, teen pregnancy is a complex situation and is influenced by strong opinions and religious ideology that have in some cases resulted in blocked access to family planning services for teenagers. Another confounding factor is that it is related to the prevalence of sex education in schools.

Despite the successes of family planning programs described above, and usually driven by sociopolitical concerns, a number of states have linked funding to "abstinence-only" counseling and to exclusion of family planning counseling that include abortion topics. Writing in *Newsweek*, Anna Quindlen (2009) concluded that "Congress has poured $1.5 billion into what is essentially anti-sex ed, abstinence-only programs, despite the following facts: They don't work. They're actually counterproductive."

Even worse, some states have diverted funds from family planning services and put them into programs for abstinence-only counseling. In this regard, Texas may serve as the worst-case example. According to the *Dallas Morning News* (2009), 96 percent of Texas school districts, yielding to pressure from the Board of Education, either teach abstinence-only counseling or avoid talking about sex entirely. It is thus not surprising to many that Texas has been ranked in the top five states for teenage-pregnancy rates over the past several years. In 2006, according to the Centers for Disease Control and Prevention as reported by Ventura (2009), Texas ranked number one with 63 births per 1000 females aged 15 to 19 years. This compared with the national average of 42 per 1000. And Alaska—another state that has recently showcased its abstinence programs—led the nation with a 19-percent increase in the teenage birth rate from 2005 to 2006.

Abortion

It continues to be a sad fact that up to a fourth of pregnancies in this country are terminated by elective abortion. According to the American College of Obstetricians and Gynecologists (2007a): "The most effective way to reduce the number of abortions is to prevent unwanted and unintended pregnancies." Importantly, the negative attitudes, beliefs, and policies toward family planning services and sex education discussed above have helped to contribute to the 1 million or so abortions performed yearly in the United States.

The history of legislative regulation and federal court decisions regarding abortions is considered in Chapter 9 (p. 227). At the time of the 22nd edition of this book, the *Partial Birth Abortion Ban Act of 2003* had been signed into law. In 2007, the United States Supreme Court ruled that the ban—officially known as *Gonzales v. Carhart*—is constitutional. This again caused editorialists in the *New England Journal of Medicine* to decry the intrusion of government in medicine (Charo, 2007; Drazen, 2007; Greene, 2007). Since that time, negative effects on abortion services and training have been reported (Haddad and colleagues, 2009; Weitz and Yanow, 2008).

Healthcare Reform

Many readers of this textbook can remember when the Clinton administration was unsuccessful in passing healthcare reform legislation. Now, more than 15 years later, healthcare reform once again has been made a priority by the Obama administration. By mid-2009, momentum was building for policies that would move the United States toward universal health insurance (Mello and associates, 2009, Oberlander, 2009).

TABLE 1-6. Four Key Factors Implicated in the High Costs of Health Care in the United States

1. Higher administrative costs
2. Higher wages for healthcare workers and professionals
3. Greater use of expensive technological interventions
4. Unnecessary or inappropriate care

From Sessions and Detsky (2009).

To put pregnancy-related health care into perspective, a fifth of the $875 billion charged by U.S. hospitals in 2005 was for treatment of five conditions: (1) pregnancy and childbirth, (2) infant care, (3) coronary artery disease, (4) heart attack, and (5) congestive heart failure (Andrews and Elixhauser, 2009). Health care is the largest industry in this country, employing 13.5 million workers—10 percent of the total workforce (Sessions and Detsky, 2009). And importantly, 5.5 percent of the gross domestic product (GDP) went to health care 50 years ago compared with 16 percent currently.

Four key driving forces considered responsible for the escalating cost of health care in the United States are shown in Table 1-6. Like other healthcare providers, we too have had to increasingly grapple with layer upon layer of bureaucracy. No wonder that 27 percent of the total jobs in the healthcare workforce are devoted to administrative functions! In the midst of all this, given its large role in the healthcare economy, it seems clear that perinatal care will figure prominently in any reform movement. Along with others, we nervously await implementation.

SECTION 2

MATERNAL AND FETAL ANATOMY AND PHYSIOLOGY

CHAPTER 2

Maternal Anatomy

ANTERIOR ABDOMINAL WALL 14
EXTERNAL GENERATIVE ORGANS 15
INTERNAL GENERATIVE ORGANS 21
MUSCULOSKELETAL PELVIC ANATOMY 29

An understanding of the anatomy of the female pelvis and lower abdominal wall is essential for obstetrical practice. There may be marked variation in anatomical structures in individual women, and this is especially true for major blood vessels and nerves.

ANTERIOR ABDOMINAL WALL

The anterior abdominal wall confines abdominal viscera, stretches to accommodate the expanding uterus, and provides surgical access to the internal reproductive organs. Thus, a comprehensive knowledge of its layered structure is required to surgically enter the peritoneal cavity.

Skin

Langer lines describe the orientation of dermal fibers within the skin. In the anterior abdominal wall, they are arranged transversely. As a result, vertical skin incisions sustain increased lateral tension and thus, in general, develop wider scars. In contrast, low transverse incisions, such as the Pfannenstiel, follow Langer lines and lead to superior cosmetic results.

Subcutaneous Layer

This layer can be separated into a superficial, predominantly fatty layer—*Camper fascia,* and a deeper, more membranous layer—*Scarpa fascia.* These are not discrete layers but instead represent a continuum of the subcutaneous tissue layer.

Rectus Sheath

The fibrous aponeuroses of the external oblique, internal oblique, and transversus abdominis muscles join in the midline to create the *rectus sheath* (**Fig. 2-1**). The construction of this sheath varies above and below a demarcation line, termed the *arcuate line.* Cephalad to this line, the aponeuroses invest the rectus abdominis bellies above and below. Caudal to this line, all aponeuroses lie anterior to the rectus abdominis muscle, and only the thin transversalis fascia and peritoneum lie beneath.

In the lower abdomen, transition from the muscular to the fibrous aponeurotic component of the external oblique muscles takes place along a vertical line through the anterosuperior iliac spine. Transition from muscle to aponeurosis for the internal oblique and transversus abdominis muscles takes place more medially. For this reason, muscle fibers of the internal oblique are often noted below the aponeurotic layer of the external oblique during creation of low transverse incisions.

Blood Supply

Femoral Artery Branches

The *superficial epigastric, superficial circumflex iliac,* and *external pudendal* arteries arise from the femoral artery just below the inguinal ligament in the region of the femoral triangle (see Fig. 2-1). These vessels supply the skin and subcutaneous layers of the anterior abdominal wall and mons pubis. The superficial epigastric vessels course diagonally toward the umbilicus. During low transverse skin incision creation, the superficial epigastric vessels can usually be identified at a depth halfway between the skin and the rectus fascia, several centimeters from the midline.

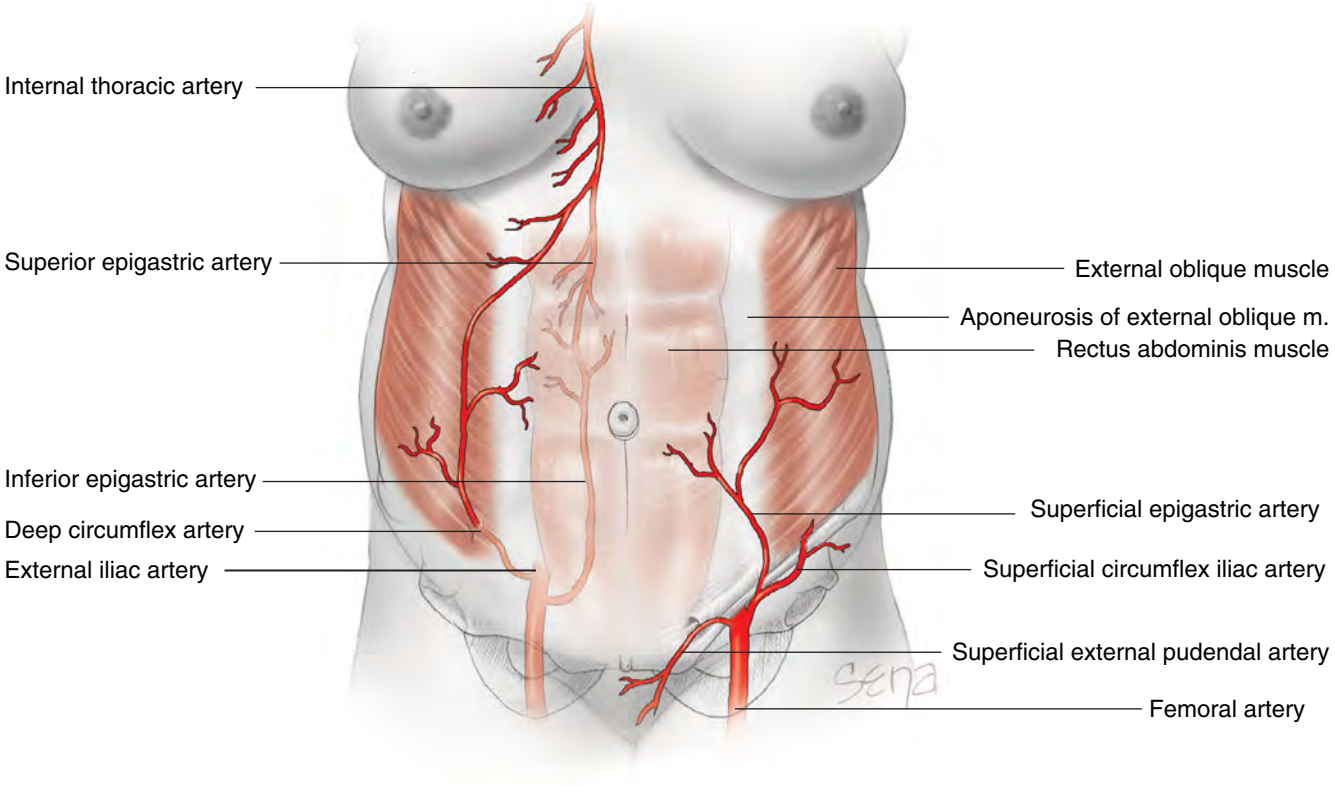

FIGURE 2-1 Muscles and blood vessels of the anterior abdominal wall.

External Iliac Artery Branches

The *inferior "deep" epigastric vessels* and *deep circumflex iliac vessels* are branches of the external iliac vessels. They supply the muscles and fascia of the anterior abdominal wall. The inferior epigastric vessels initially course lateral to, then posterior to the rectus muscles, which they supply. They then pass anterior to the posterior rectus sheath and course between the sheath and the rectus muscles. Near the umbilicus, the inferior epigastric vessels anastomose with the superior epigastric artery and veins, branches of the internal thoracic vessels.

Hesselbach triangle is the region in the anterior abdominal wall bounded inferiorly by the inguinal ligament, medially by the lateral border of the rectus muscles, and laterally by the inferior epigastric vessels. Direct hernias protrude through the abdominal wall in Hesselbach triangle, whereas indirect hernias do so through the deep inguinal ring lying lateral to this triangle.

Innervation

The anterior abdominal wall is innervated by the abdominal extensions of the intercostal nerves ($T_{7\text{-}11}$), the subcostal nerve (T_{12}), and the iliohypogastric and the ilioinguinal nerves (L_1). The T_{10} dermatome approximates the level of the umbilicus.

The iliohypogastric nerve provides sensation to the skin over the suprapubic area. The ilioinguinal nerve supplies the skin of the lower abdominal wall and upper portion of the labia majora and medial portion of the thigh through its inguinal branch. These two nerves pass 2 to 3 cm medial to the anterior superior iliac spine and course between the layers of the rectus sheath (Whiteside and colleagues, 2003). The ilioinguinal and iliohypogastric nerves can be entrapped during closure of low transverse incisions, especially if incisions extend beyond the lateral borders of the rectus muscle. These nerves carry sensory information only, and injury leads to loss of sensation within the areas supplied.

EXTERNAL GENERATIVE ORGANS

Vulva

The *pudenda*—commonly designated the *vulva*—includes all structures visible externally from the pubis to the perineal body. This includes the mons pubis, labia majora and minora, clitoris, hymen, vestibule, urethral opening, and greater vestibular or Bartholin glands, minor vestibular glands, and paraurethral glands (Fig. 2-2). The embryology of the external genitalia is discussed in Chapter 4 (p. 98).

Mons Pubis

Also called the *mons veneris*, this fat-filled cushion overlies the symphysis pubis. After puberty, the skin of the mons pubis is covered by curly hair that forms the *escutcheon*. In women, it is distributed in a triangular area, the base of which is formed by the upper margin of the symphysis. In men and in some hirsute women, the escutcheon is not so well circumscribed and extends onto the anterior abdominal wall toward the umbilicus.

Labia Majora

Embryologically, the labia majora are homologous with the male scrotum. These structures vary somewhat in appearance,

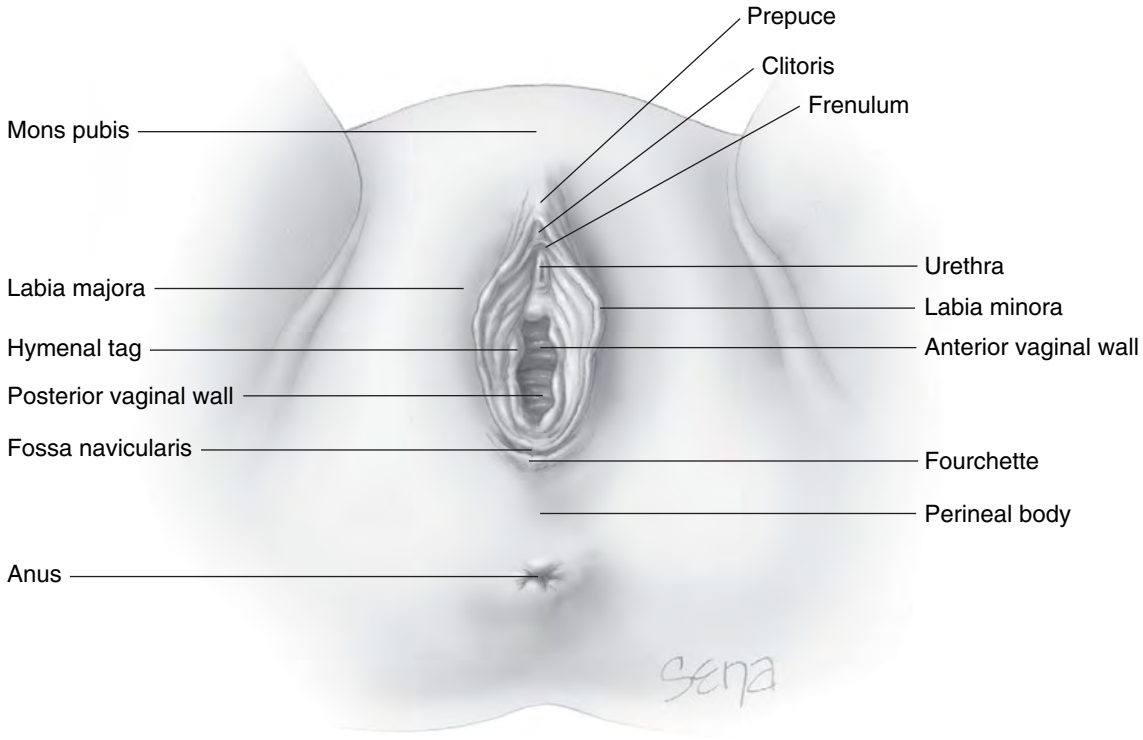

FIGURE 2-2 External female reproductive organs.

principally according to the amount of fat they contain. They are 7 to 8 cm in length, 2 to 3 cm in depth, and 1 to 1.5 cm in thickness. They are continuous directly with the mons pubis superiorly, and the round ligaments terminate at their upper borders. Posteriorly, the labia majora taper and merge into the area overlying the perineal body to form the *posterior commissure.*

The outer surface of the labia majora is covered with hair, whereas on their inner surface, it is absent. In addition, apocrine and sebaceous glands are abundant. Beneath the skin, there is a dense connective tissue layer, which is nearly void of muscular elements but is rich in elastic fibers and adipose tissue. This mass of fat provides bulk to the labia majora and is supplied with a rich venous plexus. During pregnancy, this vasculature commonly develops varicosities, especially in parous women, from increased venous pressure created by advancing uterine weight. They present as engorged tortuous veins or as small grapelike clusters but are typically asymptomatic.

Labia Minora

Each is a thin fold of tissue, which lies medial to each labia majora. In males, its homologue forms the ventral shaft of the penis. The labia minora extend superiorly, where each divides into two lamellae. The lower pair fuses to form the *frenulum of the clitoris*, and the upper pair merges to form the *prepuce.* Inferiorly, the labia minora extend to approach the midline as low ridges of tissue that fuse to form the *fourchette.*

Structurally, the labia minora are composed of connective tissue with many vessels, elastin fibers, and some smooth muscle fibers. They are supplied with a variety of nerve endings and are extremely sensitive. The epithelia of the labia minora vary with location. Stratified squamous epithelium covers the outer surface of each labium. The lateral portion of the inner surface is covered by stratified squamous epithelium to a demarcating line—the *Hart line.* Medial to this line, each labium is covered by squamous epithelium that is nonkeratinized. Although the labia minora lack hair follicles, eccrine glands, and apocrine glands, there are many sebaceous glands.

Clitoris

This principal female erogenous organ is the erectile homologue of the penis and is located beneath the prepuce and above the urethra. It projects downward between the branched extremities of the labia minora, and the free end points downward and inward toward the vaginal opening.

The clitoris rarely exceeds 2 cm in length and is composed of a glans, a corpus or body, and two crura. The *glans* is usually less than 0.5 cm in diameter, is composed of spindle-shaped cells, and is covered by stratified squamous epithelium that is richly innervated. The *clitoral body* contains two corpora cavernosa. Beneath the ventral surface of this body, homologues of the corpora spongiosa unite to form a commissure. These homologues are anterior extensions of the vestibular bulbs (O'Connell and DeLancey, 2006). Extending from the clitoral body, each corpora cavernosa diverges laterally to form the long, narrow *crura.* These lie along the inferior surface of the ischiopubic rami and deep to the ischiocavernosus muscles.

Vestibule

The vestibule is the functionally mature female structure derived from the embryonic urogenital membrane. In adult women, it is an almond-shaped area that is enclosed by Hart line laterally, the external surface of the hymen medially, the

clitoral frenulum anteriorly, and the fourchette posteriorly. The vestibule usually is perforated by six openings: the urethra, the vagina, two Bartholin gland ducts, and at times, two ducts of the largest paraurethral glands—the Skene glands (see Fig. 2-2). The posterior portion of the vestibule between the fourchette and the vaginal opening is called the *fossa navicularis*. It is usually observed only in nulliparous women.

Vestibular Glands

The pair of *Bartholin glands,* also termed greater vestibular glands, are the major glands. They measure 0.5 to 1 cm in diameter. They lie inferior to the vestibular bulbs and deep to the inferior ends of the bulbocavernosus muscle on either side of the vaginal opening. Their ducts are 1.5 to 2 cm long and open distal to the hymenal ring at 5 and 7 o'clock. Following trauma or infection, either duct may swell and obstruct to form a cyst or if infected, an abscess.

The *paraurethral glands* are collectively an arborization of glands whose ducts open predominantly along the entire inferior aspect of the urethra. The two largest are called *Skene glands*, and their ducts typically lie distally near the urethral meatus. Inflammation and duct obstruction of any of the paraurethral glands can lead to urethral diverticulum formation. The *minor vestibular glands* are shallow glands lined by simple mucin-secreting epithelium and open along Hart line.

Urethral Opening

The lower two thirds of the urethra lie immediately above the anterior vaginal wall. The urethral opening or meatus is in the midline of the vestibule, 1 to 1.5 cm below the pubic arch, and a short distance above the vaginal opening.

Vestibular Bulbs

Embryologically, the vestibular bulbs correspond to the corpus spongiosum of the penis. These are almond-shaped aggregations of veins, 3 to 4 cm long, 1 to 2 cm wide, and 0.5 to 1 cm thick, which lie beneath the bulbocavernosus muscle on either side of the vestibule. The bulbs terminate inferiorly at approximately the middle of the vaginal opening and extend upward toward the clitoris. Their anterior extensions merge in the midline, below the clitoral body. During childbirth, the vestibular bulbs may be injured and may even rupture to create a vulvar hematoma.

Vaginal Opening and Hymen

The vaginal opening is rimmed distally by the hymen or its remnants. In adult women, the hymen is a membrane of varying thickness that surrounds the vaginal opening more or less completely. It is composed mainly of elastic and collagenous connective tissue, and both outer and inner surfaces are covered by stratified squamous epithelium. The aperture of the hymen ranges in diameter from pinpoint to one that admits the tip of one or even two fingers. *Imperforate hymen* is a rare lesion in which the vaginal orifice is occluded completely, causing retention of menstrual blood (see Chap. 40, p. 892).

As a rule, however, the hymen is torn at several sites during first coitus. Identical tears may occur by other penetration, for example, tampons used during menstruation. The edges of the torn tissue soon re-epithelialize. In pregnant women, the epithelium of the hymen is thick, and the tissue is rich in glycogen. Changes produced in the hymen by childbirth are usually readily recognizable. Over time, the hymen consists of several nodules of various sizes, also termed *hymenal caruncles*.

Vagina

This musculomembranous structure extends from the vulva to the uterus and is interposed anteriorly and posteriorly between the bladder and the rectum. The upper portion arises from the müllerian ducts, and the lower portion is formed from the urogenital sinus (see Fig. 40-1, p. 891). Anteriorly, the vagina is separated from the bladder and urethra by connective tissue—the *vesicovaginal septum.* Posteriorly, between the lower portion of the vagina and the rectum, there are similar tissues that together form the *rectovaginal septum.* The upper fourth of the vagina is separated from the rectum by the *recto-uterine pouch,* also called the *cul-de-sac of Douglas.*

Normally, the anterior and posterior vaginal walls lie in contact, with only a slight space intervening between the lateral margins. Vaginal length varies considerably, but commonly, the anterior and posterior vaginal walls are, respectively, 6 to 8 cm and 7 to 10 cm in length. During her lifetime, the average woman may have a shortening of her vagina by 0.8 cm (Tan and associates, 2006). The upper end of the vaginal vault is subdivided into anterior, posterior, and two lateral fornices by the cervix. These are of considerable clinical importance because the internal pelvic organs usually can be palpated through their thin walls. Moreover, the posterior fornix provides surgical access to the peritoneal cavity.

At the midportion of the vagina, its lateral walls are attached to the pelvic walls by visceral connective tissue. These lateral attachments blend into investing fascia of the levator ani muscles. In doing so, they create the anterior and posterior lateral *vaginal sulci*. These run the length of the vaginal sidewalls and give the vagina an H shape when viewed in cross section. There are numerous thin transverse ridges, known as *rugae*, found along the length of the anterior and posterior vaginal walls.

Histology

The vaginal lining is composed of nonkeratinized stratified squamous epithelium and underlying lamina propria. Below this there is a muscular layer, which consists of smooth muscle, collagen, and elastin. Beneath this muscularis lies an adventitial layer consisting of collagen and elastin (Weber and Walters, 1997). There are no vaginal glands. Instead, the vagina is lubricated by a transudate that originates from the vaginal subepithelial capillary plexus and crosses the permeable epithelial layer (Gorodeski, 2005). Due to increased vascularity during pregnancy, vaginal secretions are notably increased. At times, this may be confused with amnionic fluid leakage, and clinical differentiation of these two is described in Chapter 17 (p. 392).

After birth, fragments of stratified epithelium occasionally are embedded beneath the vaginal surface. Similar to its native tissue, this buried epithelium continues to shed degenerated cells and keratin. As a result, firm *epidermal inclusion cysts,* which are filled with keratin debris, may form.

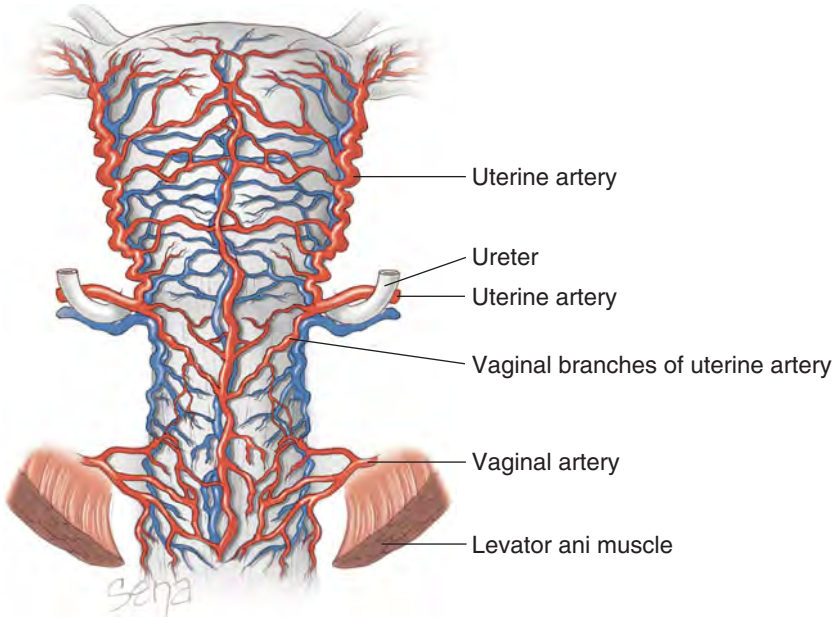

FIGURE 2-3 Uterine and vaginal blood supply. The origin of the vaginal artery varies and may arise from the uterine, inferior vesical, or internal iliac artery.

Vascular and Lymphatic Supply

The vagina has an abundant vascular supply (Fig. 2-3). The proximal portion is supplied by the cervical branch of the uterine artery and by the vaginal artery. The latter may variably arise from the uterine, inferior vesical, or directly from the internal iliac artery. The middle rectal artery contributes to supply the posterior vaginal wall, whereas the distal walls receive contributions from the internal pudendal artery. At each level, blood supply from each side anastomoses on the anterior and posterior vaginal walls with contralateral corresponding vessels.

An extensive venous plexus immediately surrounds the vagina and follows the course of the arteries. Lymphatics from the lower third, along with those of the vulva, drain primarily into the inguinal lymph nodes. Those from the middle third drain into the internal iliac nodes, and those from the upper third drain into the external, internal, and common iliac nodes.

Perineum

The perineum is the diamond-shaped area between the thighs. The anterior, posterior, and lateral boundaries of the perineum are the same as those of the bony pelvic outlet: the pubic symphysis anteriorly, ischiopubic rami and ischial tuberosities anterolaterally, sacrotuberous ligaments posterolaterally, and coccyx posteriorly.

Anterior Triangle

An arbitrary line joining the ischial tuberosities divides the perineum into an anterior triangle, also called the *urogenital triangle*, and a posterior triangle, termed the *anal triangle* (Fig. 2-4). The anterior triangle is bounded by the pubic rami superiorly, the ischial tuberosities laterally, and the superficial transverse perineal muscle posteriorly.

The anterior triangle is further divided into superficial and deep spaces by the *perineal membrane*. This is a sheet of dense fibrous tissue and was previously known as the *inferior fascia of the urogenital diaphragm*. The perineal membrane attaches laterally to the ischiopubic rami, medially to the distal third of the urethra and vagina, and posteriorly to the perineal body. Anteriorly, it attaches to the arcuate ligament of the pubis.

Superficial Space of the Anterior Triangle. This space is bounded deeply by the perineal membrane and superficially by Colles fascia. It is a closed compartment, and infection or bleeding within it remains contained. The anterior triangle contains several important structures that include the ischiocavernosus, bulbocavernosus, and superficial transverse perineal muscles; Bartholin glands; vestibular bulbs; clitoral body and crura; and branches of the pudendal vessels and nerve (see Fig. 2-4).

The *ischiocavernosus muscle* attaches to the medial aspect of the ischial tuberosities inferiorly and the ischiopubic rami laterally. Anteriorly, it attaches to the crus of the clitoris. This muscle may help maintain clitoral erection by compressing the crus to obstruct venous drainage. The *bulbocavernosus muscles* overlie the vestibular bulbs and Bartholin glands. They attach to the body of the clitoris anteriorly and the perineal body posteriorly. The muscles constrict the vaginal lumen and aid release of secretions from the Bartholin glands. They also may contribute to clitoral erection by compressing the deep dorsal vein of the clitoris. The bulbocavernosus and ischiocavernosus muscles also pull the clitoris downward. The *superficial transverse perineal muscles* are narrow strips that attach to the ischial tuberosities laterally and the perineal body medially. They may be attenuated or even absent, but when present, they contribute to the perineal body (Corton and Cunningham, 2008).

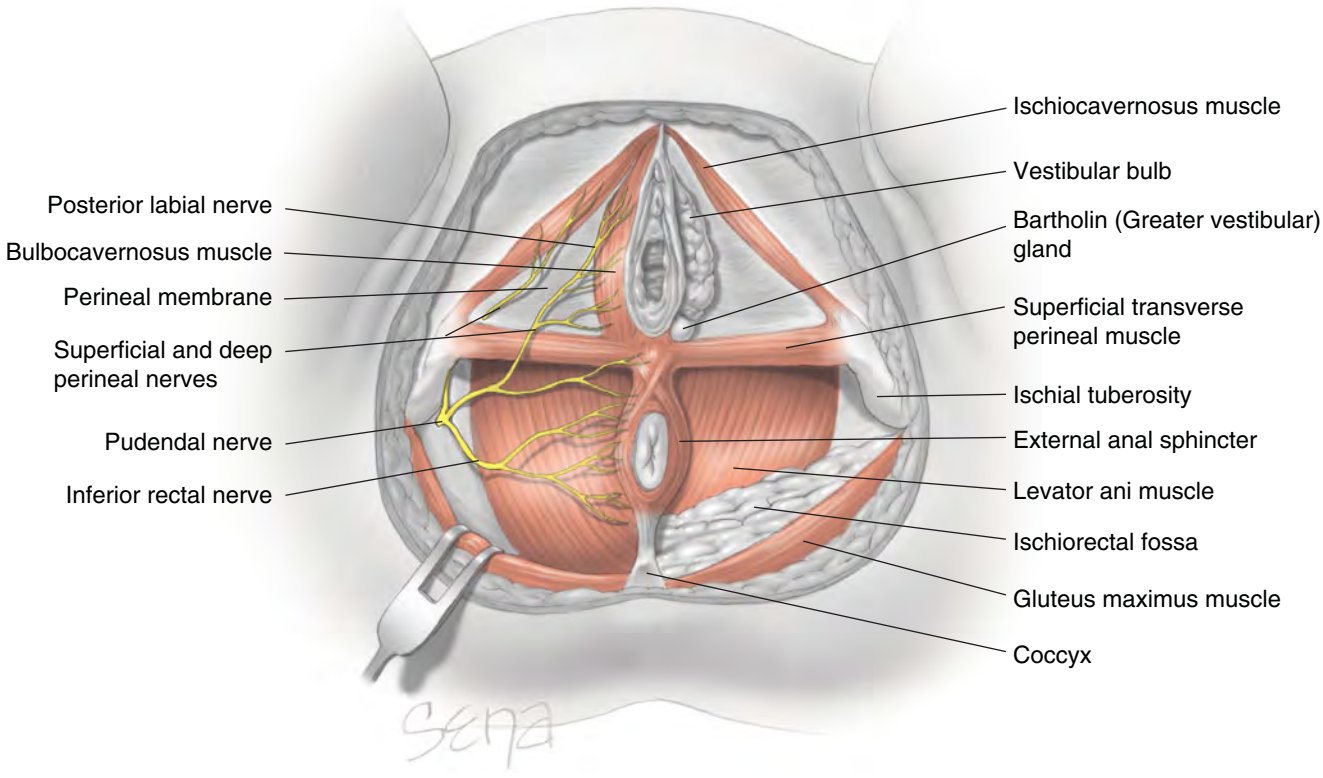

FIGURE 2-4 Perineal anatomy. Anterior and posterior triangles are defined by a line drawn between the ischial tuberosities. The superficial space of the anterior triangle and its contents are shown above this line.

Deep Space of the Anterior Triangle. This space lies deep to the perineal membrane and extends up into the pelvis (Mirilas and Skandalakis, 2004). In contrast to the superficial perineal space, which is a closed compartment, the deep space is continuous superiorly with the pelvic cavity (Corton, 2005). It contains the compressor urethrae and urethrovaginal sphincter muscles, external urethral sphincter, parts of urethra and vagina, branches of the internal pudendal artery, and the dorsal nerve and vein of the clitoris (Fig. 2-5).

Posterior Triangle

This triangle contains the ischiorectal fossa, anal canal, anal sphincter complex, and branches of the internal pudendal vessels and pudendal nerve (see Figs. 2-4 and 2-5).

Ischiorectal Fossae. These are two fat-filled wedge-shaped spaces found on either side of the anal canal and comprise the bulk of the posterior triangle (Fig. 2-6). Their structure reflects their function. They provide support to surrounding organs, yet allow distension of the rectum during defecation and stretching of the vagina during delivery.

The anal canal and sphincter complex lie in the center of these fossae. Deeply, there is no fascial boundary between the fossa and the tissues above the perineal membrane. Thus, the two fossae communicate posteriorly, behind the anal canal. This continuity of the ischioanal fossa across perineal compartments allows fluid, infection, and malignancy to spread from one side of the anal canal to the other as well as into the areas deep to the perineal membrane. This can be clinically important if episiotomy infection extends to involve either fossa.

Pudendal Nerve and Vessels

The pudendal nerve is formed from the anterior rami of the second through fourth sacral nerves. It courses between the piriformis and coccygeus muscles and exits through the greater sciatic foramen in a location posteromedial to the ischial spine (Barber and colleagues, 2002). This anatomy is important when injecting local anesthetic for a pudendal nerve block. The ischial spine serves an easily identifiable landmark for anesthetic infiltration around this nerve (see Chap. 19, p. 450).

The pudendal nerve then courses along the obturator internus muscle. Along this muscle, the nerve lies within the *pudendal canal*, also known as *Alcock canal*, which is formed by splitting of the obturator fascia (Shafik, 1999). The pudendal nerve leaves this canal to enter the perineum and divides into three terminal branches (see Fig. 2-4). The *dorsal nerve of the clitoris* supplies the skin of the clitoris. The *perineal nerve* serves the muscles of the anterior triangle and labial skin. The *inferior rectal* branch supplies the external anal sphincter, the mucous membrane of the anal canal, and the perianal skin (Mahakkanukrauh and associates, 2005).

The major blood supply to the perineum is via the internal pudendal artery and its branches. These include the inferior rectal artery and posterior labial artery.

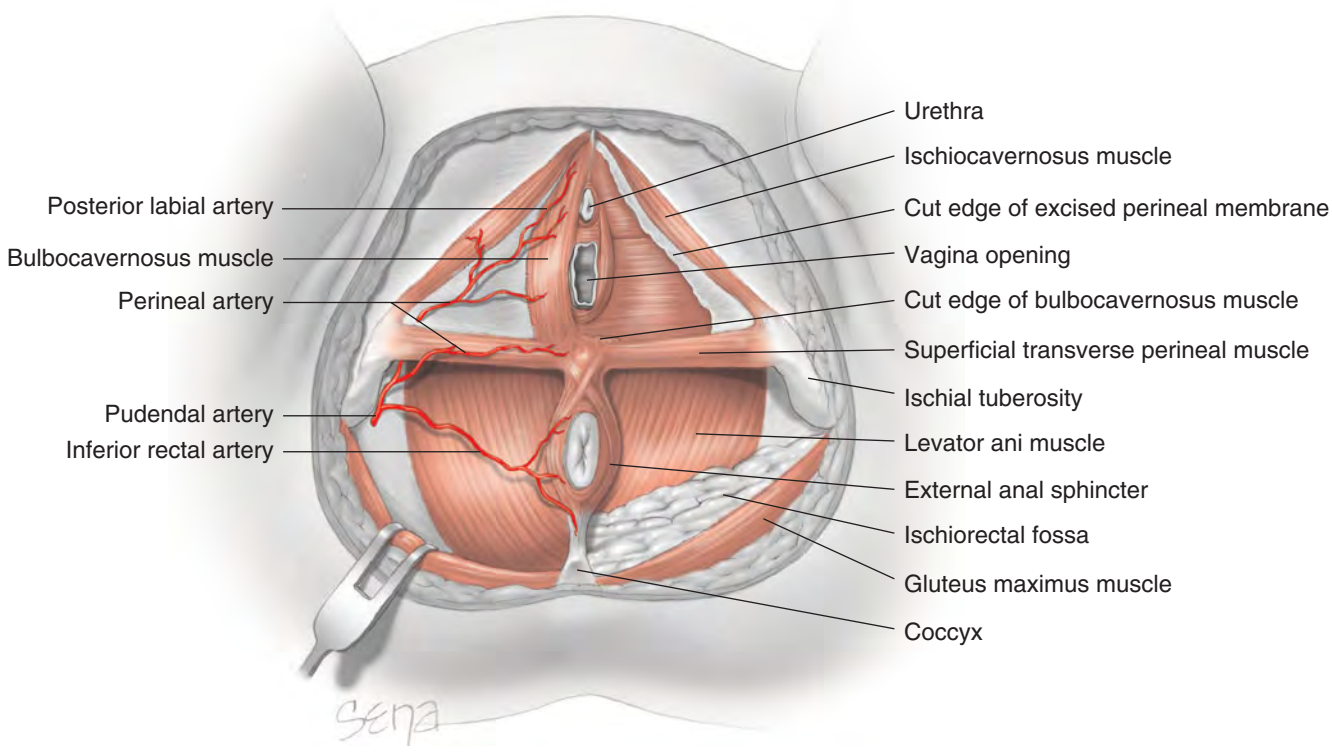

FIGURE 2-5 Perineal anatomy. Anterior and posterior triangles are shown. Within the anterior triangle, the contents of the deep space are shown on the image's right, whereas those of the superficial space are on the left.

Anus

Anal Sphincters

Two sphincters surround the anal canal to provide continence—the *external* and *internal anal sphincter* (Fig. 2-6). Both lie proximate to the vagina, and one or both may be torn during vaginal delivery. Of these disruptions, many are not clinically identified at delivery. For example, Sultan (1993) performed endoanal sonography 6 weeks following delivery and found that 28 of 79 primiparas—35 percent—had sphincter defects, more commonly involving the internal sphincter. Clinically, these defects can have functional consequences. Oberwalder and colleagues (2003) performed a meta-analysis of 717 women after a vaginal delivery and found that almost 80 percent of those with anal sphincter defects had impaired control of stool or flatus.

External Anal Sphincter (EAS). This ring of striated muscle attaches to the perineal body anteriorly and the coccyx posteriorly. It maintains a constant state of resting contraction that provides increased tone and strength when continence is

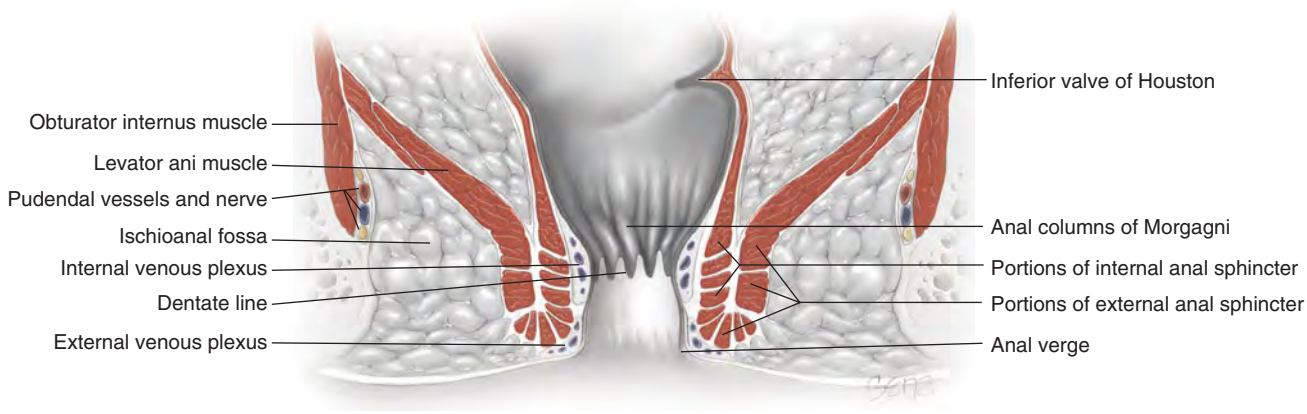

FIGURE 2-6 Anatomy of the anorectum, drawn to show relations of the internal anal sphincter, the external anal sphincter, and the levator ani muscles. The boundaries of the ischiorectal fossa are shown. The ischiorectal fossa is bounded deeply by the inferior fascia of the levator ani muscles, superficially by the perineal skin, anterolaterally by the fascia of the obturator internus muscles and ischial tuberosities, posterolaterally by the gluteus maximus muscles and sacrotuberous ligament, and medially by the anal canal and sphincter complex.

threatened, and it relaxes for defecation. Hsu and colleagues (2005) studied structure of the EAS using magnetic resonance (MR) imaging. They identified three structures: the main body—EAS-M, the subcutaneous sphincter—EAS-SQ, and the wing-shaped end—EAS-W, which has fibers with lateral origins near the ischiopubic ramus. The external sphincter receives blood supply from the inferior rectal artery. Somatic motor fibers from the inferior rectal branch of the pudendal nerve supply innervation.

Internal Anal Sphincter (IAS). This sphincter contributes the bulk of anal canal resting pressure for fecal continence, and it relaxes prior to defecation. The sphincter is formed by distal continuation of the inner circular smooth muscle layer of the rectum and colon. The IAS measures 3 to 4 cm in length, and at its distal margin, it overlaps the external sphincter for 1 to 2 cm (DeLancey and co-workers, 1997; Rociu and associates, 2000). Thus, the IAS may be involved in fourth-degree lacerations, and reunion of this ring is incorporated in their repair (see Chap. 17, p. 400).

Anal Cushions

Within the anal canal, there are highly vascularized cushions, which when apposed aid complete closure of the anal canal and fecal continence. Increasing uterine size, excessive straining, and hard stools can increase venous engorgement within these cushions to form *hemorrhoids* (Fig. 2-7). External hemorrhoids are those that arise distal to the dentate line. They are covered by stratified squamous epithelium and receive sensory innervation from the inferior rectal nerve. Accordingly, pain and a palpable mass are typical complaints. Following resolution, a *hemorrhoidal tag* may remain and is composed of redundant anal skin and fibrotic tissue. In contrast, *internal hemorrhoids* are those that form above the dentate line and are covered by insensate anorectal mucosa. These may prolapse or bleed but rarely become painful unless they develop thrombosis and necrosis.

Hemorrhoids form commonly in pregnancy (see Chap. 8, p. 211). Abramowitz and colleagues (2002) evaluated 165 consecutive pregnant women proctoscopically and found thrombosed hemorrhoids in 9 percent during their last 3 months of pregnancy and an even greater percentage postpartum.

FIGURE 2-7 Veins within the anal cushions engorge to form hemorrhoids. Those above the dentate line are termed internal, whereas those below it are called external hemorrhoids.

TABLE 2-1. Perineal Body

Function
Anchors the anorectum
Anchors the vagina
Helps maintains urinary and fecal continence
Maintains the orgasmic platform
Prevents expansion of the urogenital hiatus
Provides a physical barrier between the vagina and rectum
Potential Morbidity
Episiotomy may injure the perineal body
Pudendal nerve injury may be associated with concurrent perineal body injury

Adapted from Woodman and Graney (2002).

Perineal Body

The median raphe of the levator ani, between the anus and the vagina, is reinforced by the central tendon of the perineum. The bulbocavernosus, superficial transverse perineal, and external anal sphincter muscles also converge on the central tendon. Thus, these structures contribute to the perineal body, which provides significant perineal support as shown in Table 2-1. The perineal body is incised by an episiotomy incision and is torn with second-, third-, and fourth-degree lacerations.

INTERNAL GENERATIVE ORGANS

Uterus

The nonpregnant uterus is situated in the pelvic cavity between the bladder anteriorly and the rectum posteriorly. Almost the entire posterior wall of the uterus is covered by serosa, that is, visceral peritoneum. The lower portion of this peritoneum forms the anterior boundary of the *recto-uterine cul-de-sac,* or *pouch of Douglas.* Only the upper portion of the anterior wall of the uterus is so covered (Fig. 2-8). The peritoneum in this area reflects forward onto the bladder dome to create the *vesicouterine pouch.* The lower portion of the anterior uterine wall is united to the posterior wall of the bladder by a well-defined loose layer of connective tissue. This is the *vesicouterine space.* During cesarean delivery, the peritoneum of the vesicouterine pouch is sharply incised and the vesicouterine space is entered. Dissection caudally within this space lifts the bladder off the lower uterine segment for hysterotomy and delivery (see Chap. 25, p. 550).

Size and Shape

The uterus is described as being *pyriform* or pear-shaped, and as shown in Figure 2-9, it resembles a flattened pear. It consists of two major but unequal parts: an upper triangular portion—the

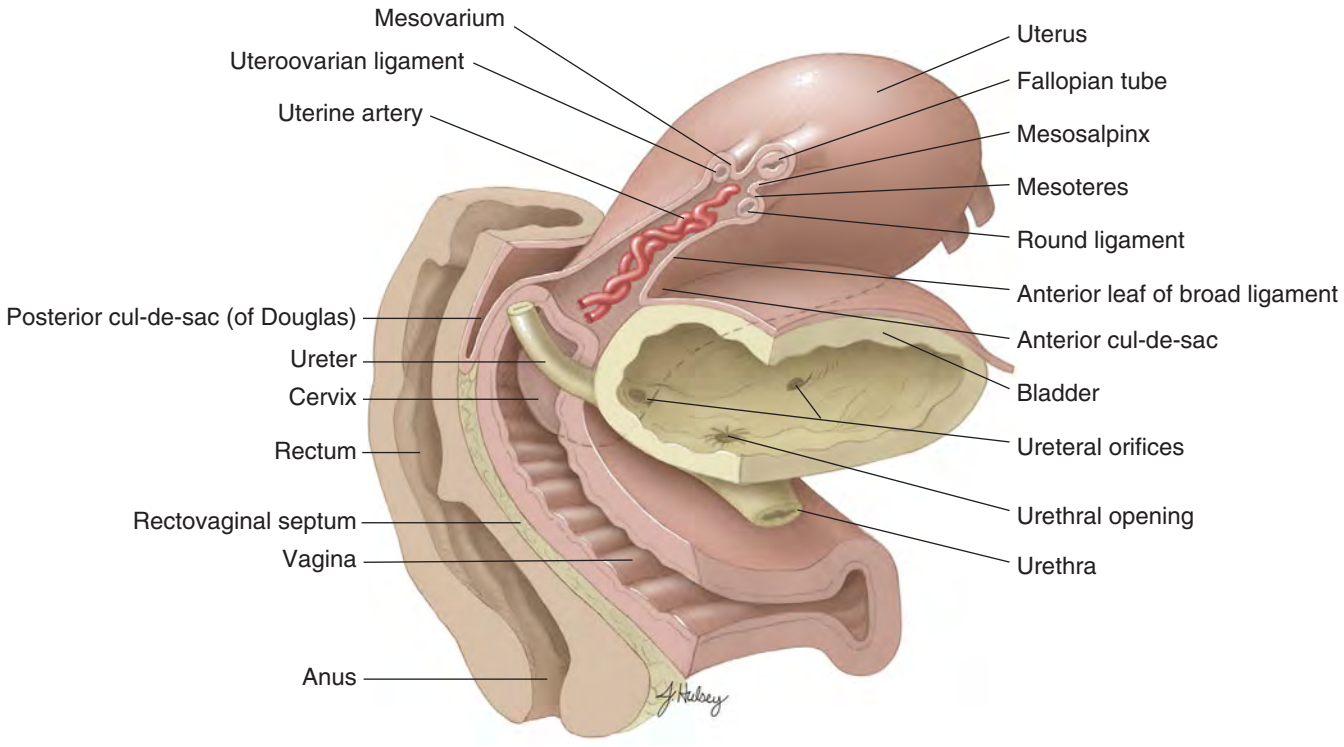

FIGURE 2-8 Vertical section through the uterine end of the right broad ligament. (Used with permission from Jennifer Hulsey.)

body or *corpus,* and a lower, cylindrical portion—the *cervix,* which projects into the vagina. The *isthmus* is that portion of the uterus between the internal cervical os and the endometrial cavity (Fig. 2-10). It is of special obstetrical significance because it forms the lower uterine segment during pregnancy (see Chap. 6, p. 142). The fallopian tubes, also called oviducts, emerge from the *cornua* of the uterus at the junction of the superior and lateral margins. The fundus is the convex upper segment between the points of insertion of the fallopian tubes.

The bulk of the body of the uterus, but not the cervix, is composed of muscle. The inner surfaces of the anterior and posterior walls lie almost in contact, and the cavity between these

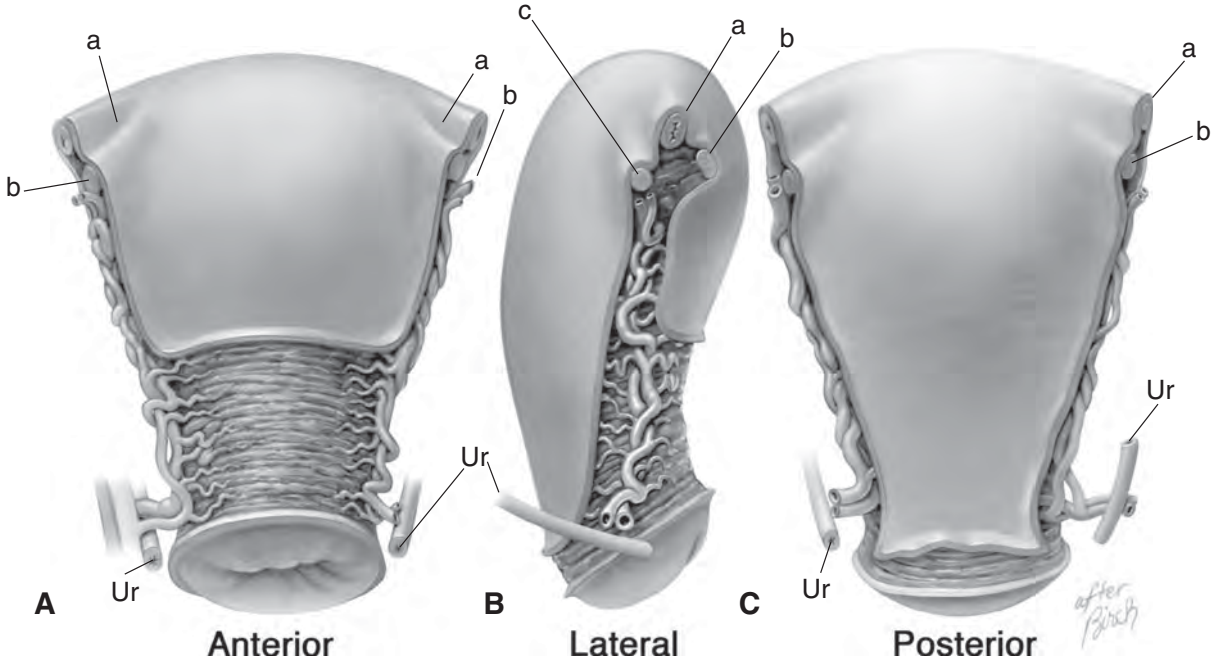

FIGURE 2-9 Anterior **(A)**, right lateral **(B)**, and posterior **(C)** views of the uterus of an adult woman. (a = oviduct; b = round ligament; c = ovarian ligament; Ur = ureter.)

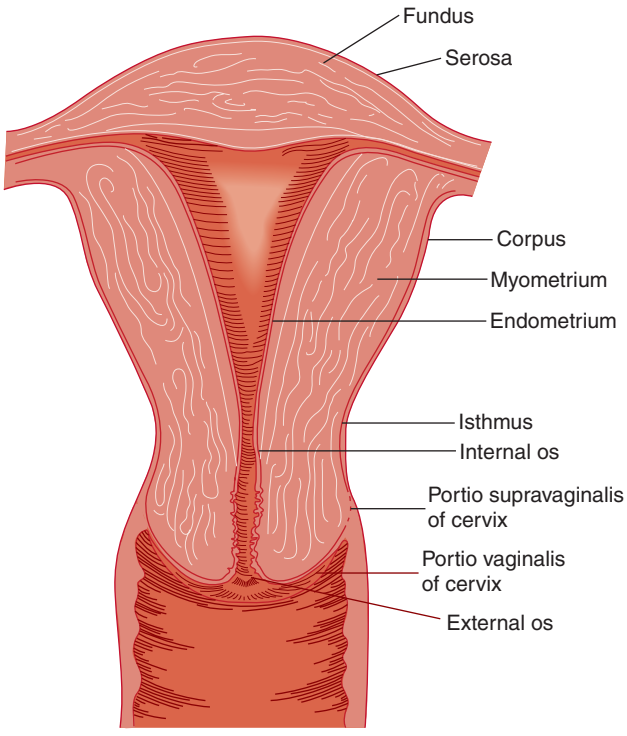

FIGURE 2-10 Uterine and cervical anatomy. Reprinted from Schorge J, Schaffer J, Halvorson L, et al: *Williams Gynecology*, p. 782. Copyright © 2008 The McGraw-Hill Companies, Inc.

walls forms a mere slit. The uterus of adult nulliparous women measures 6 to 8 cm in length as compared with 9 to 10 cm in multiparous women. In nonparous women, the uterus averages 50 to 70 g, whereas in parous women it averages 80 g or more (Langlois, 1970). In nulliparous women, the fundus and cervix are approximately equal length, but in multiparous women, the cervix is only a little more than a third of the total length.

Pregnancy-Induced Uterine Changes

Pregnancy stimulates remarkable uterine growth due to hypertrophy of muscle fibers. Uterine weight increases from 70 g to approximately 1100 g at term. Its total volume averages about 5 L. The uterine fundus, a previously flattened convexity between tubal insertions, now becomes dome shaped (**Fig. 2-11**). The round ligaments now appear to insert at the junction of the middle and upper thirds of the organ. The fallopian tubes elongate, but the ovaries grossly appear unchanged.

Congenital Anomalies

Abnormal müllerian fusion may give rise to a number of uterine anomalies that are discussed in Chapter 40 (p. 891).

Cervix

The cervical portion of the uterus is fusiform and open at each end by small apertures—the *internal* and *external os* (see Fig. 2-10). Anteriorly, the upper boundary of the cervix is the internal os, which corresponds to the level at which the peritoneum is reflected up onto the bladder. The upper segment of the cervix—the *portio supravaginalis*, lies above the vaginal attachment to the cervix. It is covered by peritoneum on its posterior surface, the cardinal ligaments attach laterally, and it is separated from the overlying bladder by loose connective tissue. The lower vaginal portion of the cervix is called the *portio vaginalis.*

Before childbirth, the external cervical os is a small, regular, oval opening (**Fig. 2-12**). After labor, and especially vaginal childbirth, the orifice is converted into a transverse slit that is divided such that there are the so-called *anterior* and *posterior lips* of the cervix. If torn deeply during delivery, the cervix may heal in such a manner that it appears to be irregular, nodular, or stellate. These changes are sufficiently characteristic to permit an examiner to ascertain with some certainty whether a woman

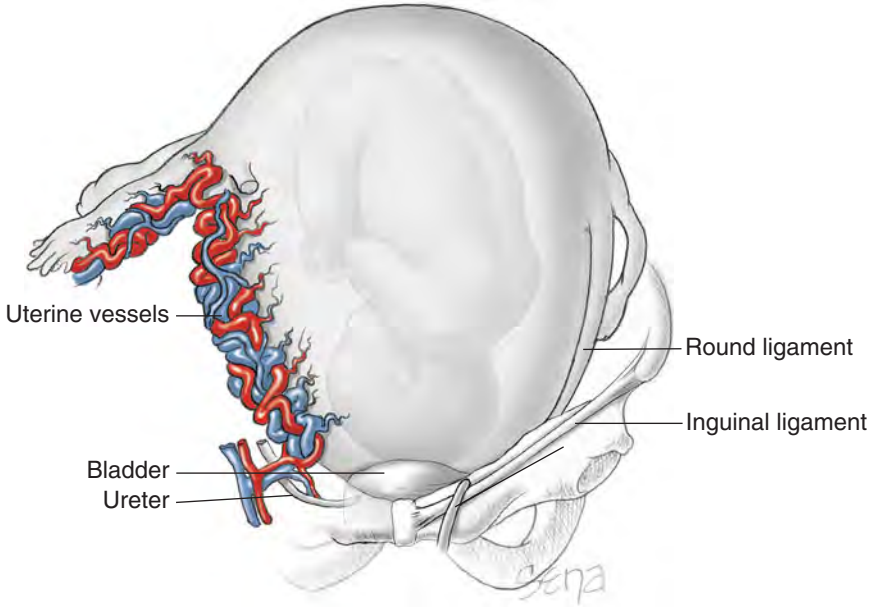

FIGURE 2-11 Uterus of near-term pregnancy. The fundus is now dome shaped, and the tubes and round ligaments appear to insert in the upper middle portion of the uterine body. Note the markedly hypertrophied vascular supply.

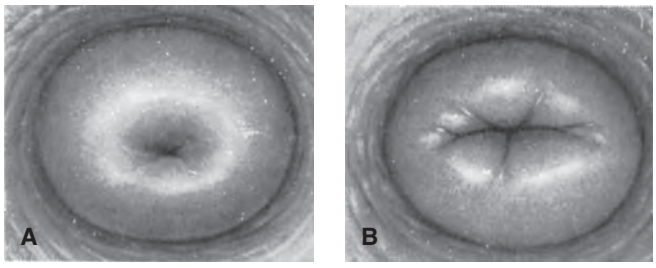

FIGURE 2-12 Differences in cervical os apperance due to labor and delivery. **A.** Nulliparous cervix. **B.** Parous cervix.

has borne children by vaginal delivery. If a woman undergoes cesarean delivery, however, then the postoperative cervical appearance reflects the degree of dilatation prior to surgery. Cervices without labor may appear nulliparous, whereas as those with intrapartum dilation may appear parous.

The portion of the cervix exterior to the external os is called the *ectocervix* and is lined predominantly by nonkeratinized stratified squamous epithelium. In contrast, the endocervical canal is covered by a single layer of mucin-secreting columnar epithelium, which creates deep cleftlike infoldings or "glands." Mucus produced by the endocervical epithelia changes during pregnancy. It becomes thick and forms a mucus plug within the endocervical canal.

Commonly during pregnancy, the endocervical epithelia moves out and onto the ectocervix during enlargement of the cervix in a process termed *eversion* (see Chap. 5, p. 109). As a result, a band of columnar epithelium may ring the external os. With time, this everted columnar epithelium, under the influence of vaginal acidity or during reparative healing, may be replaced by squamous epithelium in a process termed *squamous metaplasia*. This replacement with squamous epithelium may block endocervical clefts. If so, accumulated mucus from the underlying clefts forms *nabothian cysts,* which are benign, firm, smooth, rounded, opaque-yellow or ground-glass gray elevations on the ectocervix.

The cervical stroma is composed mainly of collagen, elastin, and proteoglycans, but very little smooth muscle. Changes in the amount, composition, and orientation of these components lead to cervical ripening prior to labor onset (see Chap. 6, p. 138). In early pregnancy, increased vascularity and edema within the cervix stroma leads to the blue tint and softening characteristics of Chadwick and Hegar signs, respectively.

Endometrium

This mucosal layer lines the uterine cavity in nonpregnant women. It is a thin, pink, velvet-like membrane, which on close examination, is perforated by many minute ostia of the uterine glands. The endometrium normally varies greatly in thickness. It is composed of surface epithelium, glands, and interglandular mesenchymal tissue in which there are numerous blood vessels (**Fig. 2-13**).

The epithelium is comprised of a single layer of closely packed, high columnar cells that rests on a thin basement membrane (see Fig. 3-2 p. 38). The tubular *uterine glands* are invaginations of the epithelium. The glands extend through the entire thickness of the endometrium to the myometrium, which is occasionally penetrated for a short distance. The connective tissue between the surface epithelium and the myometrium is a mesenchymal stroma. Histologically, the stroma varies remarkably throughout the ovarian cycle. Specifically, following ovulation, *decidualization* of the stromal compartment develops in the mid-luteal phase. As discussed further in Chapter 3 (p. 42), this process of endometrial remodeling prepares for pregnancy and includes secretory transformation of the uterine glands and vascular remodeling (Gellersen and colleagues, 2003, 2007).

The vascular architecture of the uterus and endometrium is of signal importance in pregnancy. The uterine and ovarian arteries branch and penetrate the uterine wall obliquely inward

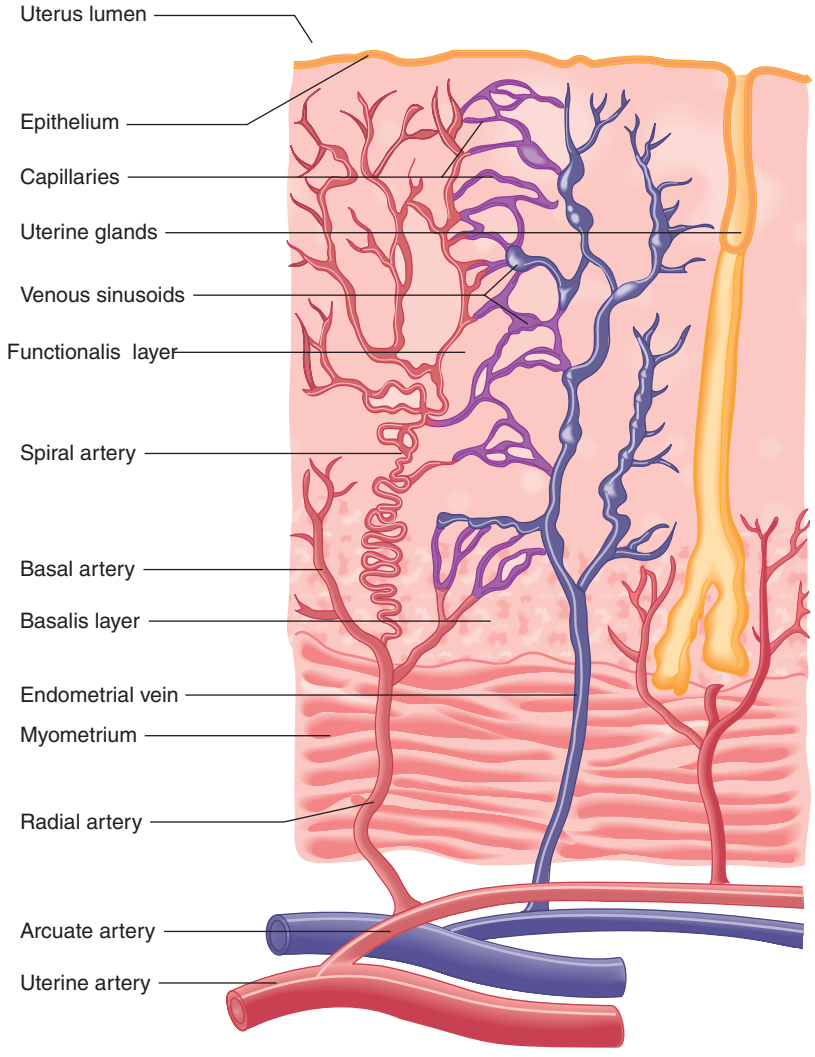

FIGURE 2-13 Vascular supply to the endometrium. (Reprinted from Schorge J, Schaffer J, Halvorson L, et al: *Williams Gynecology*, p. 177. Copyright © 2008 The McGraw-Hill Companies, Inc.)

and reach its middle third. They then ramify in a plane that is parallel to the surface and are therefore named the *arcuate arteries* (DuBose and colleagues, 1985). Radial branches extend from the arcuate arteries at right angles and enter the endometrium to become *coiled* or *spiral arteries.* Also from the radial arteries, *basal* or *straight arteries* branch at a sharp angle. The spiral arteries supply most of the midportion and all of the superficial third of the endometrium. These vessels respond—especially by vasoconstriction, to a number of hormones and thus probably serve an important role in the mechanism(s) of menstruation. The basal arteries extend only into the basal layer of the endometrium and are not responsive to hormonal influences.

Myometrium

This layer comprises most of the uterus. It is composed of bundles of smooth muscle united by connective tissue in which there are many elastic fibers. The interlacing myometrial fibers that surround the myometrial vessels are integral to control of bleeding from the placental site during the third stage of labor. As shown in **Fig. 2-14**, vessels are compressed by smooth muscle contraction. According to Schwalm and Dubrauszky (1966), the number of muscle fibers of the uterus progressively diminishes caudally such that, in the cervix, muscle comprises only 10 percent of the tissue mass. In the inner wall of the body of the uterus, there is relatively more muscle than in the outer layers; and in the anterior and posterior walls, there is more muscle than in the lateral walls. During pregnancy, the upper myometrium undergoes marked hypertrophy, but there is no significant change in cervical muscle content.

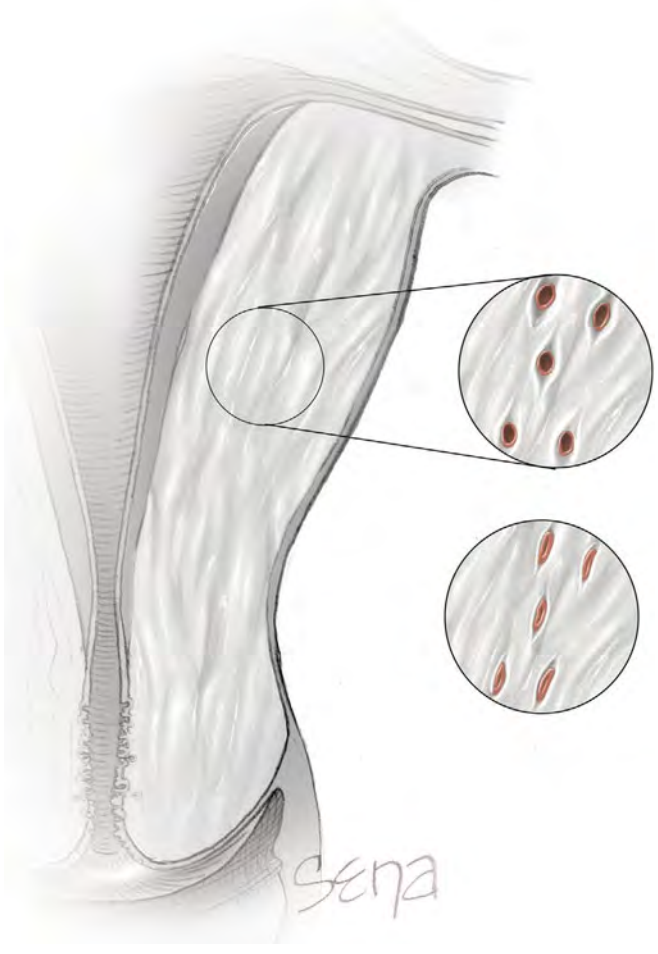

FIGURE 2-14 The smooth muscle fibers compress traversing blood vessels when contracted.

Ligaments

Several ligaments extend from the lateral surface of the uterus toward the pelvic sidewalls and include the round, broad, and cardinal ligaments. The *round ligaments* originate somewhat below and anterior to the origin of the fallopian tubes (see Fig. 2-8). Each round ligament extends laterally and downward to the inguinal canal, through which it passes to terminate in the upper portion of the labium majus. *Sampson artery*, a branch of the uterine artery, runs within this ligament. The location of the round ligament anterior to the fallopian tube can help distinguish surgical anatomy such as with puerperal tubal sterilization (see Chap. 33, p. 698). This may be especially true if pelvic adhesions limit tubal mobility and thus, limit identification of fimbria prior to tubal ligation.

The round ligament corresponds embryologically to the gubernaculum testis of men. In nonpregnant women, it varies from 3 to 5 mm in diameter and is composed of smooth muscle (Ozdegirmenci and colleagues, 2005). During pregnancy, the round ligaments undergo considerable hypertrophy and increase appreciably in both length and diameter.

The *broad ligaments* are composed of two winglike structures that extend from the lateral uterine margins of the uterus to the pelvic sidewalls. They divide the pelvic cavity into anterior and posterior compartments. Each broad ligament consists of a fold of peritoneum termed the *anterior* and *posterior leaves.* This peritoneum drapes over structures extending from the cornua. Peritoneum that overlies the fallopian tube is termed the *mesosalpinx*, that around the round ligament is the *mesoteres*, and that over the uterovarian ligament is the *mesovarium* (see Fig. 2-8). Peritoneum that extends beneath the fimbriated end of the fallopian tube to the pelvic wall forms the *infundibulopelvic ligament* or *suspensory ligament of the ovary,* through which the ovarian vessels traverse. During pregnancy, these vessels, especially the venous plexuses, are dramatically hypertrophied.

The thick base of the broad ligament is continuous with the connective tissue of the pelvic floor. The densest portion is usually referred to as the *cardinal ligament*—also called the *transverse cervical ligament* or *Mackenrodt ligament.* It is composed of connective tissue that medially is united firmly to the supravaginal portion of the cervix. A vertical section through the uterine end of the broad ligament is triangular, and the uterine vessels and ureter are found within its broad base (see Fig. 2-8). In its lower part, it is widely attached to the connective tissues that are adjacent to the cervix, that is, the *parametrium.*

Each *uterosacral ligament* extends from an attachment posterolaterally to the supravaginal portion of the cervix and inserts into the fascia over the sacrum. Umek and colleagues (2004) used magnetic resonance imaging to describe anatomical variations of these ligaments. The ligaments are composed of connective tissue, small bundles of vessels and nerves, and some smooth muscle. They are covered by peritoneum and form the lateral boundaries of the pouch of Douglas.

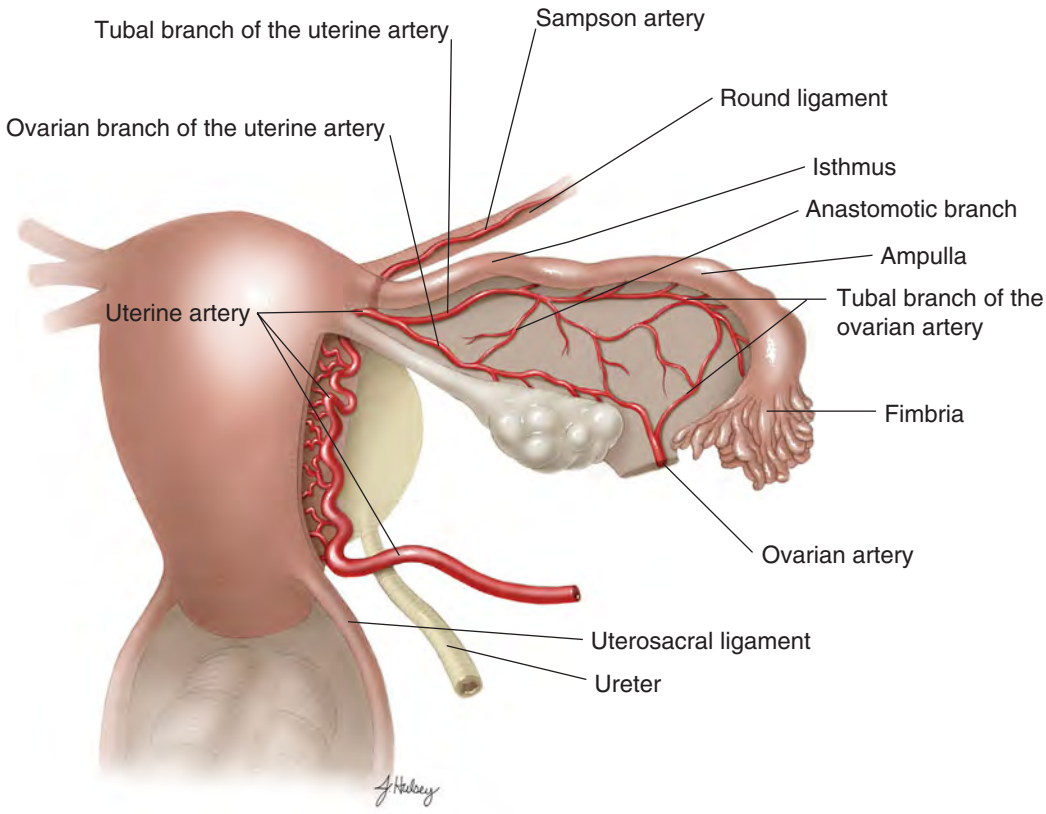

FIGURE 2-15 Blood supply to the left ovary, left fallopian tube, and left side of the uterus. The ovarian and uterine vessels anastomose freely. Note the uterine artery and vein crossing over the ureter that lies immediately adjacent to the cervix. (Used with permission from Jennifer Hulsey.)

Blood Vessels

The vascular supply of the uterus is derived principally from the uterine and ovarian arteries. The uterine artery, a main branch of the internal iliac artery—previously called the hypogastric artery—enters the base of the broad ligament and makes its way medially to the side of the uterus. Immediately adjacent to the supravaginal portion of the cervix, the uterine artery divides. The smaller cervicovaginal artery supplies blood to the lower cervix and upper vagina. The main branch turns abruptly upward and extends as a highly convoluted vessel that traverses along the margin of the uterus. A branch of considerable size extends to the upper portion of the cervix, and numerous other branches penetrate the body of the uterus. Just before the main branch of the uterine artery reaches the fallopian tube, it divides into three terminal branches (**Fig. 2-15**). The ovarian branch of the uterine artery anastomoses with the terminal branch of the ovarian artery; the tubal branch makes its way through the mesosalpinx and supplies part of the fallopian tube; and the fundal branch is distributed to the uppermost uterus.

Approximately 2 cm lateral to the cervix, the uterine artery crosses over the ureter. The proximity of the uterine artery and vein to the ureter at this point is of great surgical significance. Because of their close proximity, the ureter may be injured or ligated during a hysterectomy when the vessels are clamped and ligated.

The *ovarian artery* is a direct branch of the aorta. It enters the broad ligament through the infundibulopelvic ligament. At the ovarian hilum, it divides into a number of smaller branches that enter the ovary. Its main stem, however, traverses the entire length of the broad ligament and makes its way to the upper lateral portion of the uterus. Here it anastomoses with the ovarian branch of the uterine artery. There are numerous additional communications among the arteries on both sides of the uterus.

When the uterus is in a contracted state, its numerous venous lumens are collapsed. But in injected specimens, the greater part of the uterine wall appears to be occupied by dilated venous sinuses. On either side, the arcuate veins unite to form the *uterine vein,* which empties into the internal iliac and then the common iliac vein. Some of the blood from the upper uterus, the ovary, and the upper part of the broad ligament is collected by several veins. Within the broad ligament, these veins form the large *pampiniform plexus* that terminates in the ovarian vein. The right ovarian vein empties into the vena cava, whereas the left ovarian vein empties into the left renal vein. During pregnancy, there is marked hypertrophy of the uterine vasculature (see Fig. 2-11).

Blood supply to the pelvis is predominantly supplied from branches of the internal iliac artery (**Fig. 2-16**). These branches are organized into anterior and posterior divisions and subsequent branches are highly variable between individuals. The anterior division provides substantial blood supply to the pelvic organs and perineum, whereas the posterior division branches extend to the buttock and thigh. In some cases, branches of these vessels traverse close to the presacral space (Wieslander and associates, 2006). The surgical anatomy of the internal iliac artery is discussed further in Chapter 35, p. 796.

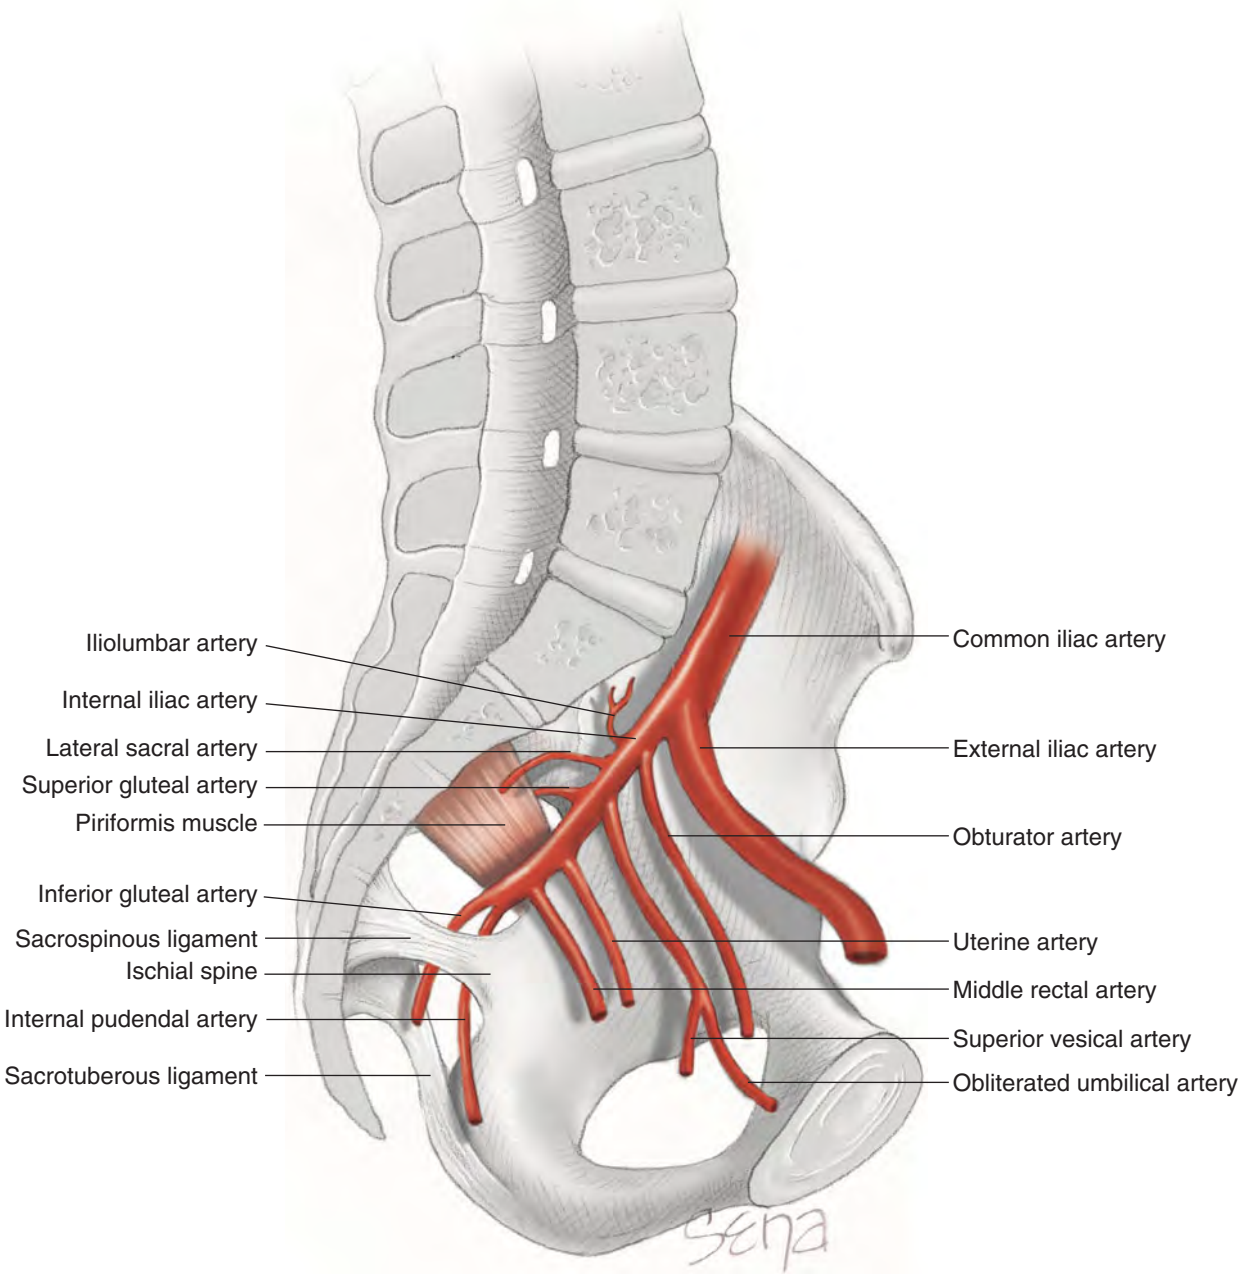

FIGURE 2-16 Pelvic blood supply.

The pelvis has extensive collateral circulation, and the internal iliac artery shares anastomoses with branches of the aorta and external iliac and femoral artery. As a result, ligation of the anterior division of the internal iliac artery can be performed without compromise to pelvic organ viability. For this reason, during internal iliac ligation to control obstetrical hemorrhage, many advocate internal iliac ligation distal to the posterior division to avoid compromised blood flow to the areas supplied by this division (Bleich and colleagues, 2007; Burchell, 1968).

Lymphatics

The endometrium is abundantly supplied with true lymphatic vessels that are confined largely to the basal layer. The lymphatics of the underlying myometrium are increased in number toward the serosal surface and form an abundant lymphatic plexus just beneath it. Lymphatics from the cervix terminate mainly in the internal iliac nodes, which are situated near the bifurcation of the common iliac vessels. The lymphatics from the uterine corpus are distributed to two groups of nodes. One set of vessels drains into the internal iliac nodes. The other set, after joining certain lymphatics from the ovarian region, terminates in the para-aortic lymph nodes.

Innervation

The pelvic nerve supply is derived principally from the sympathetic nervous system, but also partly from the cerebrospinal and parasympathetic systems. The parasympathetic system is represented on either side by the pelvic nerve, which is made up of a few fibers that are derived from the second, third, and fourth sacral nerves. It loses its identity in the *cervical ganglion of Frankenhäuser.* The sympathetic system enters the pelvis by way of the internal

iliac plexus that arises from the aortic plexus just below the promontory of the sacrum (Wieslander and colleagues, 2006). After descending on either side, it also enters the *uterovaginal plexus of Frankenhäuser*, which is made up of ganglia of various sizes, but particularly of a large ganglionic plate that is situated on either side of the cervix, proximate to the uterosacral ligaments and just above the posterior fornix in front of the rectum.

Branches from these plexuses supply the uterus, bladder, and upper vagina. In the 11th and 12th thoracic nerve roots, there are sensory fibers from the uterus that transmit the painful stimuli of contractions to the central nervous system. The sensory nerves from the cervix and upper part of the birth canal pass through the pelvic nerves to the second, third, and fourth sacral nerves. Those from the lower portion of the birth canal pass primarily through the pudendal nerve. Knowledge of the innervation of dermatomes and its clinical application to providing epidural or spinal analgesia for labor and vaginal or cesarean delivery is illustrated in Figures 19-1 and 19-3 (p. 447).

Fallopian Tubes

These tubular extensions from the uterus vary in length from 8 to 14 cm, and each tube is divided into an interstitial portion, isthmus, ampulla, and infundibulum. The *interstitial portion* is embodied within the muscular wall of the uterus. The *isthmus*, or the narrow portion of the tube that adjoins the uterus, passes gradually into the wider, lateral portion, or *ampulla*. The *infundibulum*, or fimbriated extremity, is the funnel-shaped opening of the distal end of the fallopian tube (**Fig. 2-17**). The fallopian tube varies considerably in thickness. The narrowest portion of the isthmus measures from 2 to 3 mm in diameter, and the widest portion of the ampulla measures from 5 to 8 mm. The fimbriated end of the infundibulum opens into the abdominal cavity. One projection, the *fimbria ovarica*, which is considerably longer than the other fimbriae, forms a shallow gutter that approaches or reaches the ovary.

Tubal smooth muscle is arranged in an inner circular and an outer longitudinal layer. In the distal portion, the two layers are

FIGURE 2-17 The fallopian tube of an adult woman with cross-sectioned illustrations of the gross structure in several portions: **(A)** isthmus, **(B)** ampulla, and **(C)** infundibulum. Below these are photographs of corresponding histological sections. (Used with permission from Dr. Kelley S. Carrick.)

less distinct and near the fimbriated extremity, are replaced by an interlacing network of muscular fibers. The tubal musculature undergoes rhythmic contractions constantly, the rate of which varies with ovarian cyclical hormonal changes. The greatest frequency and intensity of contractions is reached during transport of ova.

The fallopian tubes are lined by a single layer of columnar cells, some of them ciliated and others secretory. The ciliated cells are most abundant at the fimbriated extremity, elsewhere, they are found in discrete patches. There are differences in the proportions of these two types of cells in different phases of the ovarian cycle. Because there is no submucosa, the epithelium is in close contact with the underlying muscular layer. In the tubal mucosa, there are cyclical histological changes similar to those of the endometrium, but much less striking. The mucosa is arranged in longitudinal folds that are more complex toward the fimbriated end. On cross-sections through the uterine portion, four simple folds are found that form a figure that resembles a Maltese cross. The isthmus has a more complex pattern. In the ampulla, the lumen is occupied almost completely by the arborescent mucosa, which consists of very complicated folds. The current produced by the tubal cilia is such that the direction of flow is toward the uterine cavity. Tubal peristalsis is believed to be an extraordinarily important factor in ovum transport.

The tubes are supplied richly with elastic tissue, blood vessels, and lymphatics. Sympathetic innervation of the tubes is extensive, in contrast to their parasympathetic innervation.

Diverticula may extend occasionally from the lumen of the tube for a variable distance into the muscular wall and reach almost to the serosa. These diverticula may play a role in the development of ectopic pregnancy (see Chap. 10, p. 240).

Ovaries

Compared with each other, as well as between women, the ovaries vary considerably in size. During childbearing years, they are from 2.5 to 5 cm in length, 1.5 to 3 cm in breadth, and 0.6 to 1.5 cm in thickness. Their position also varies, but they usually lie in the upper part of the pelvic cavity and rest in a slight depression on the lateral wall of the pelvis. This *ovarian fossa of Waldeyer* is between the divergent external and internal iliac vessels.

The ovary is attached to the broad ligament by the *mesovarium.* The *utero-ovarian ligament* extends from the lateral and posterior portion of the uterus, just beneath the tubal insertion, to the uterine pole of the ovary. Usually, it is a few centimeters long and 3 to 4 mm in diameter. It is covered by peritoneum and is made up of muscle and connective tissue fibers. The *infundibulopelvic* or *suspensory ligament of the ovary* extends from the upper or tubal pole to the pelvic wall; through it course the ovarian vessels and nerves.

The ovary consists of the cortex and medulla. In young women, the outermost portion of the cortex is smooth, has a dull white surface, and is designated the *tunica albuginea.* On its surface, there is a single layer of cuboidal epithelium, the *germinal epithelium of Waldeyer.* The cortex contains oocytes and developing follicles. The *medulla* is the central portion, which is composed of loose connective tissue. There are a large number of arteries and veins in the medulla and a small number of smooth muscle fibers.

The ovaries are supplied with both sympathetic and parasympathetic nerves. The sympathetic nerves are derived primarily from the ovarian plexus that accompanies the ovarian vessels. Others are derived from the plexus that surrounds the ovarian branch of the uterine artery. The ovary is richly supplied with nonmyelinated nerve fibers, which for the most part accompany the blood vessels.

MUSCULOSKELETAL PELVIC ANATOMY

Pelvic Bones

The pelvis is composed of four bones: the sacrum, coccyx, and two innominate bones (**Fig. 2-18**). Each innominate bone is formed by the fusion of the *ilium*, *ischium*, and *pubis*. The innominate bones are joined to the sacrum at the sacroiliac synchondroses and to one another at the symphysis pubis.

The *false pelvis* lies above the *linea terminalis* and the true pelvis below this anatomical boundary (**Fig. 2-19**). The *false pelvis* is bounded posteriorly by the lumbar vertebra and laterally by the iliac fossa. In front, the boundary is formed by the lower portion of the anterior abdominal wall.

The *true pelvis* is the portion important in childbearing. It is bounded above by the promontory and alae of the sacrum, the linea terminalis, and the upper margins of the pubic bones, and below by the pelvic outlet. The cavity of the true pelvis can be described as an obliquely truncated, bent cylinder with its greatest height posteriorly.

The walls of the true pelvis are partly bony and partly ligamentous. The posterior boundary is the anterior surface of the sacrum, and the lateral limits are formed by the inner surface of the ischial bones and the sacrosciatic notches and ligaments. In front, the true pelvis is bounded by the pubic bones, the ascending superior rami of the ischial bones, and the obturator foramen.

The sidewalls of the true pelvis of an adult woman converge somewhat. Extending from the middle of the posterior margin of each ischium are the ischial spines. These are of great obstetrical importance because the distance between them usually represents the shortest diameter of the pelvic cavity. They also serve as valuable landmarks in assessing the level to which the presenting part of the fetus has descended into the true pelvis (see Chap. 17, p. 392).

The sacrum forms the posterior wall of the pelvic cavity. Its upper anterior margin corresponds to the promontory that may be felt during bimanual pelvic examination in women with small pelves. It can provide a landmark for clinical pelvimetry. Normally, the sacrum has a marked vertical and a less pronounced horizontal concavity, which in abnormal pelves may undergo important variations. A straight line drawn from the promontory to the tip of the sacrum usually measures 10 cm, whereas the distance along the concavity averages 12 cm.

The descending inferior rami of the pubic bones unite at an angle of 90 to 100 degrees to form a rounded arch under which the fetal head must pass.

Pelvic Joints

Symphysis Pubis

Anteriorly, the pelvic bones are joined together by the symphysis pubis. This structure consists of fibrocartilage and the superior and inferior pubic ligaments. The latter are frequently designated the *arcuate ligament of the pubis.*

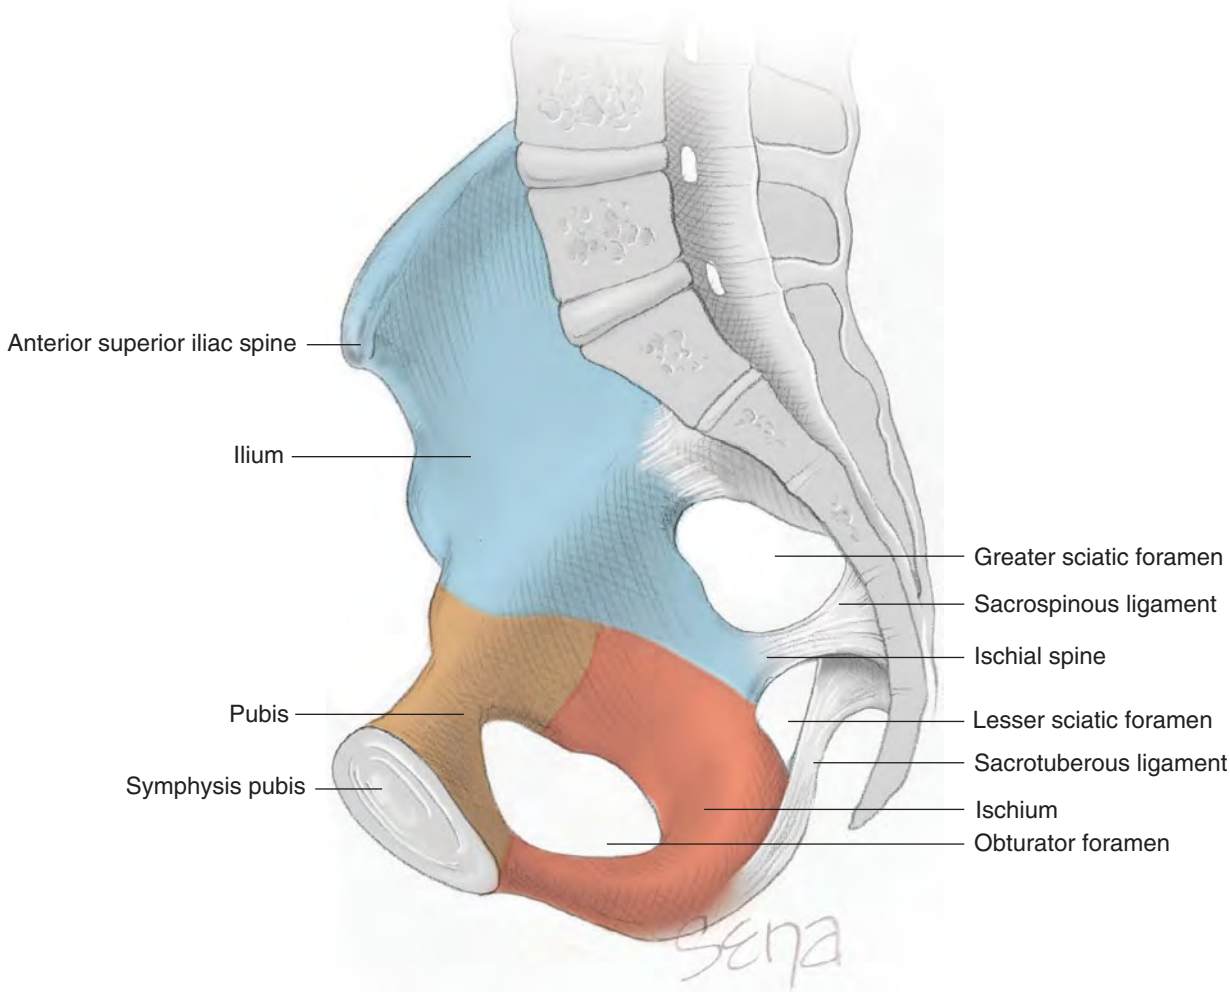

FIGURE 2-18 Sagittal view of pelvic bones.

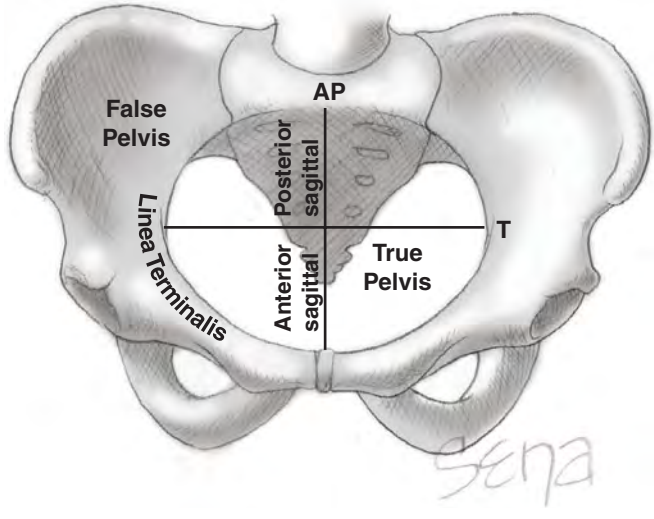

FIGURE 2-19 Anteroposterior view of a normal female pelvis. Anteroposterior (AP) and transverse (T) diameters of the pelvic inlet are illustrated.

Sacroiliac Joints

Posteriorly, the pelvic bones are joined by articulations between the sacrum and the iliac portion of the innominate bones to form the sacroiliac joints. These joints also have a certain degree of mobility.

Relaxation of the Pelvic Joints

During pregnancy, there is remarkable relaxation of these joints, although the cause(s) is unclear. It likely results from hormonal stimulation (see Chap. 5, p. 130). Abramson and co-workers (1934) observed that relaxation of the symphysis pubis commenced in women in the first half of pregnancy and increased during the last 3 months. They also observed that this laxity began to regress immediately after parturition and that regression was completed within 3 to 5 months. The symphysis pubis also increases in width during pregnancy—more so in multiparas than in primigravidas—and returns to normal soon after delivery.

There are important changes in sacroiliac joint mobility. Borell and Fernstrom (1957) demonstrated that the rather marked mobility of the pelvis at term was caused by an upward gliding

movement of the sacroiliac joint. The displacement, which is greatest in the dorsal lithotomy position, may increase the diameter of the outlet by 1.5 to 2.0 cm. **This is the main justification for placing a woman in this position for a vaginal delivery.** But increase in diameter of the pelvic outlet occurs only if the sacrum is allowed to rotate posteriorly. Thus, it will not occur if the sacrum is forced anteriorly by the weight of the maternal pelvis against the delivery table or bed (Russell, 1969, 1982). Sacroiliac joint mobility is also the likely reason that the McRoberts maneuver often is successful in releasing an obstructed shoulder in a case of shoulder dystocia (see Chap. 20, p. 483). These changes have also been attributed to the success of the modified squatting position to hasten second-stage labor (Gardosi and co-workers, 1989). The squatting position may increase the interspinous diameter and the diameter of the pelvic outlet (Russell, 1969, 1982). These latter observations are unconfirmed, but this position is assumed for birth in many primitive societies.

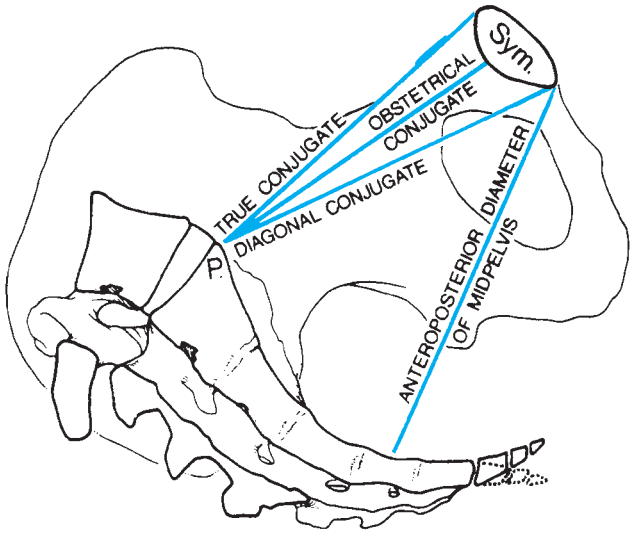

FIGURE 2-20 Three anteroposterior diameters of the pelvic inlet are illustrated: the true conjugate, the more important obstetrical conjugate, and the clinically measurable diagonal conjugate. The anteroposterior diameter of the midpelvis is also shown. (p = sacral promontory; sym = symphysis pubis.)

Planes and Diameters of the Pelvis

The pelvis is described as having four imaginary planes:

1. The plane of the pelvic inlet—the superior strait.
2. The plane of the pelvic outlet—the inferior strait.
3. The plane of the midpelvis—the least pelvic dimensions.
4. The plane of greatest pelvic dimension—of no obstetrical significance.

Pelvic Inlet

The superior strait or pelvic inlet is bounded posteriorly by the promontory and alae of the sacrum, laterally by the linea terminalis, and anteriorly by the horizontal pubic rami and the symphysis pubis. The inlet of the female pelvis—compared with the male pelvis—typically is more nearly round than ovoid. Caldwell (1934) identified radiographically a nearly round or *gynecoid* pelvic inlet in approximately half of white women.

Four diameters of the pelvic inlet are usually described: anteroposterior, transverse, and two oblique diameters. The obstetrically important *anteroposterior diameter* is the shortest distance between the promontory of the sacrum and the symphysis pubis and is designated the *obstetrical conjugate* (Fig. 2-20). Normally, this measures 10 cm or more. This diameter is distinct from the anteroposterior diameter of the pelvic inlet that has been identified as the *true conjugate*. The obstetrical conjugate cannot be measured directly with the examining fingers. For clinical purposes, the obstetrical conjugate is estimated indirectly by subtracting 1.5 to 2 cm from the *diagonal conjugate,* which is determined by measuring the distance from the lower margin of the symphysis to the sacral promontory (Fig. 2-21).

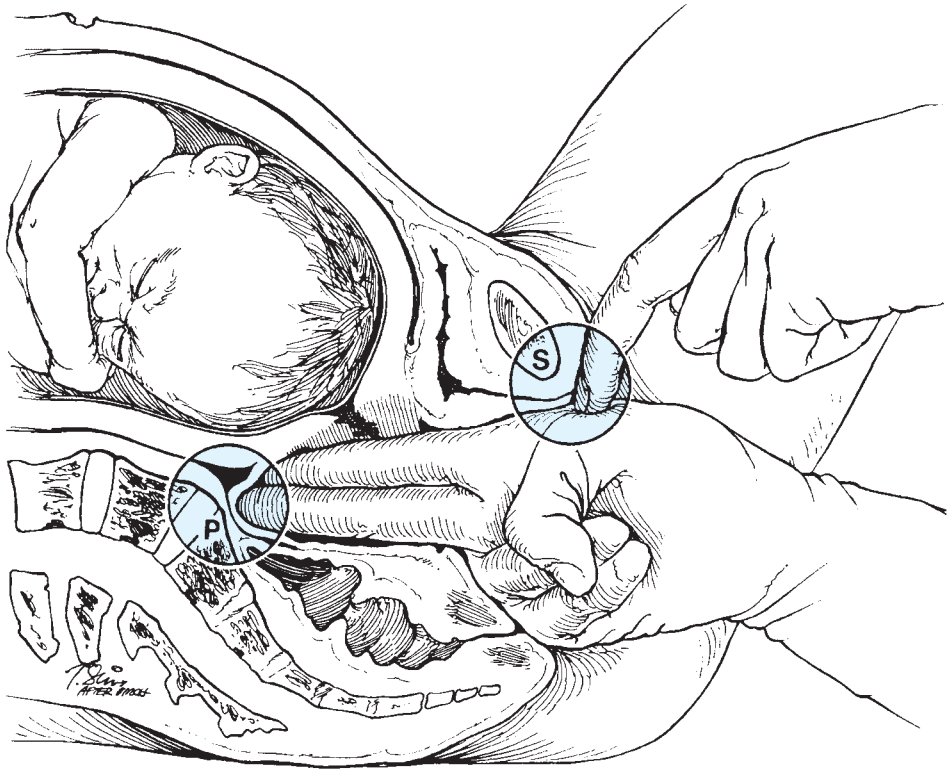

FIGURE 2-21 Vaginal examination to determine the diagonal conjugate. (p = sacral promontory; s = symphysis pubis.)

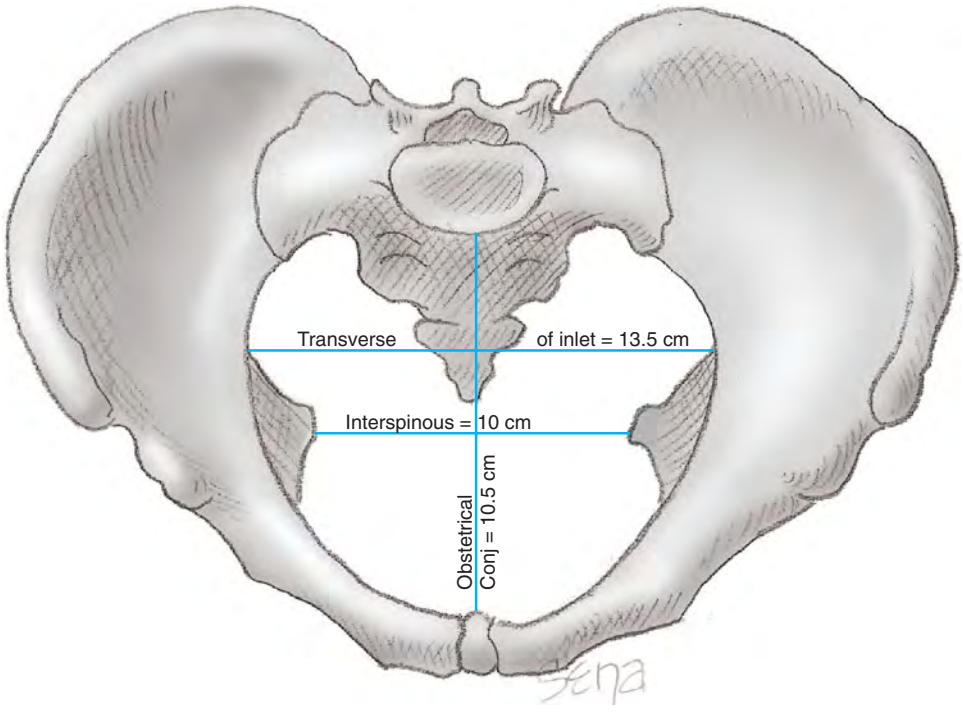

FIGURE 2-22 Adult female pelvis demonstrating the interspinous diameter of the midpelvis. The anteroposterior and transverse diameters of the pelvic inlet are also shown.

The *transverse diameter* is constructed at right angles to the obstetrical conjugate and represents the greatest distance between the linea terminalis on either side (Fig. 2-22). It usually intersects the obstetrical conjugate at a point approximately 4 cm in front of the promontory. Each of the two oblique diameters extends from one of the sacroiliac synchondroses to the iliopectineal eminence on the opposite side. They average less than 13 cm.

Midpelvis

The midpelvis is measured at the level of the ischial spines—the midplane, or plane of least pelvic dimensions (see Fig. 2-22). It is of particular importance following engagement of the fetal head in obstructed labor. The *interspinous diameter*, 10 cm or slightly greater, is usually the smallest pelvic diameter. The anteroposterior diameter through the level of the ischial spines normally measures at least 11.5 cm.

Pelvic Outlet

This consists of two approximately triangular areas that are not in the same plane. They have a common base, which is a line drawn between the two ischial tuberosities (Fig. 2-23). The apex of the posterior triangle is at the tip of the sacrum, and the lateral boundaries are the sacrosciatic ligaments and the ischial tuberosities. The anterior triangle is formed by the area under the pubic arch. Three diameters of the pelvic outlet usually are described: the anteroposterior, transverse, and posterior sagittal.

Pelvic Shapes

Caldwell and Moloy (1933, 1934) developed a classification of the pelvis that is still used. The classification is based on the shape of the pelvis, and its familiarity helps the clinician understand better the mechanisms of labor.

The *Caldwell-Moloy classification* is based on measurement of the greatest transverse diameter of the inlet and its division into anterior and posterior segments. The shapes of these are used to classify the pelvis as gynecoid, anthropoid, android, or platypelloid (Fig. 2-24). The character of the posterior segment determines the type of pelvis, and the character of the anterior segment determines the tendency. These are both determined because many pelves are not pure but are mixed types. For example, a gynecoid pelvis with an android tendency means that the posterior pelvis is gynecoid and the anterior pelvis is android in shape.

From viewing the four basic types in Figure 2-24, the configuration of the gynecoid pelvis would intuitively seem suited for delivery of most fetuses. Indeed, Caldwell and co-workers (1939) reported that the gynecoid pelvis was found in almost half of women.

Muscular Support

The *pelvic diaphragm* forms a broad muscular sling and provides substantial support to the pelvic viscera (Fig. 2-25). This

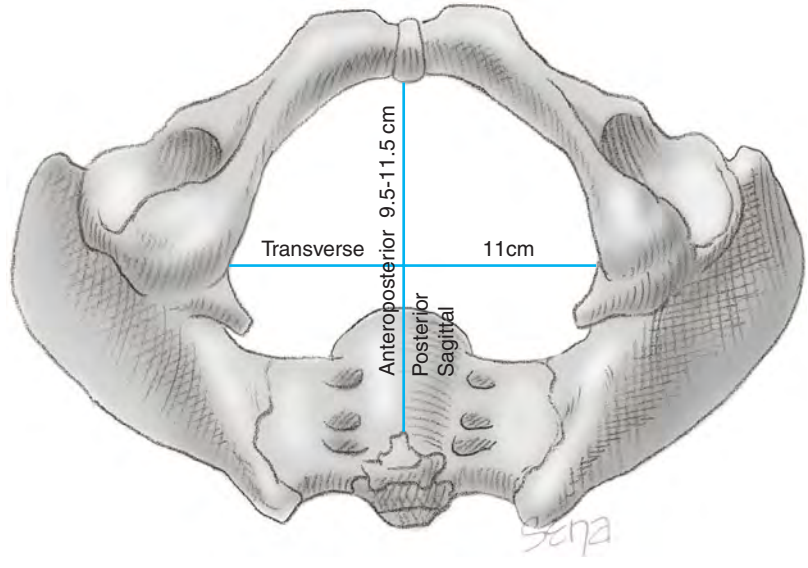

FIGURE 2-23 Pelvic outlet with diameters marked. Note that the anteroposterior diameter may be divided into anterior and posterior sagittal diameters.

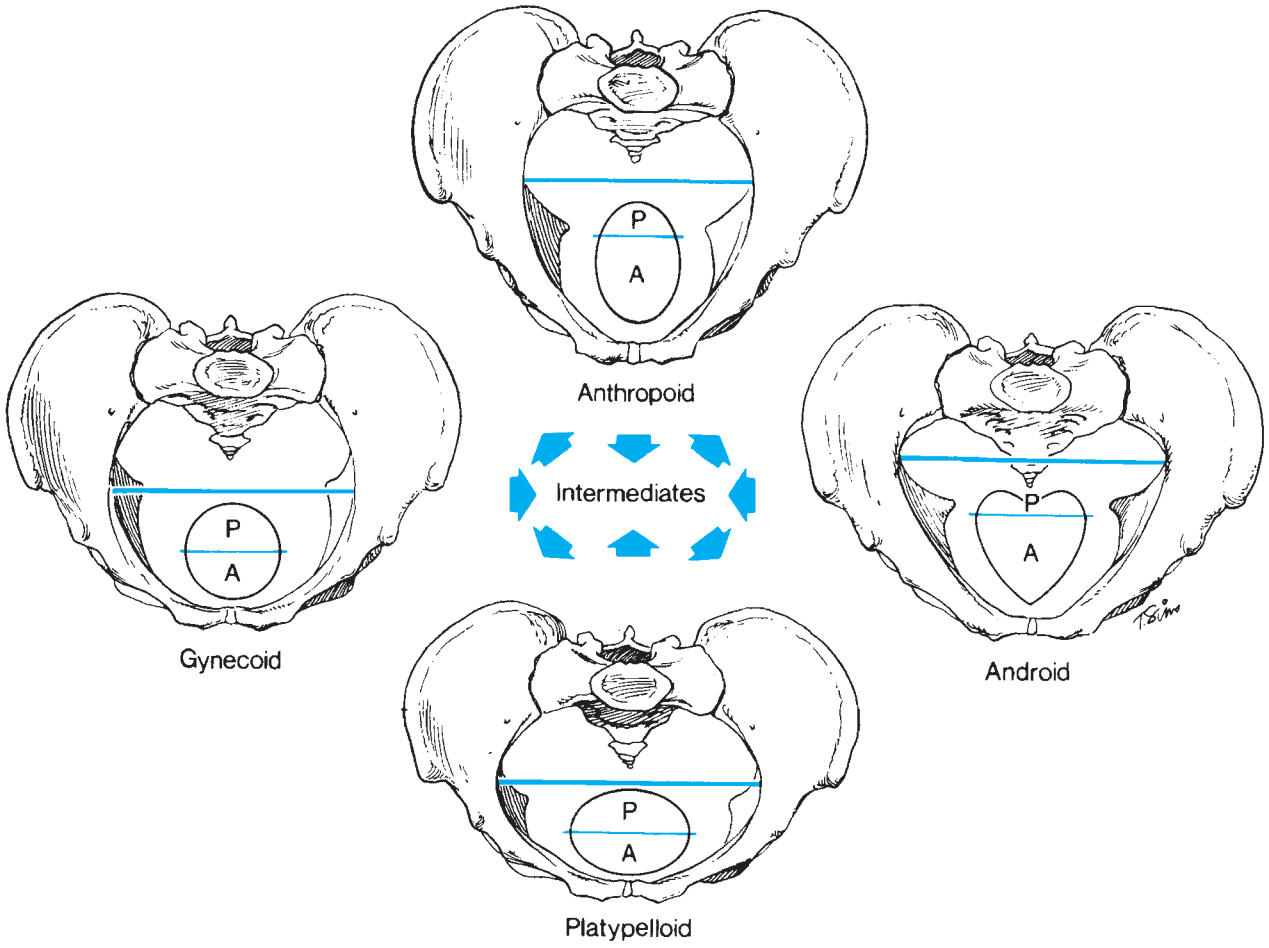

FIGURE 2-24 The four parent pelvic types of the Caldwell–Moloy classification. A line passing through the widest transverse diameter divides the inlets into posterior (P) and anterior (A) segments.

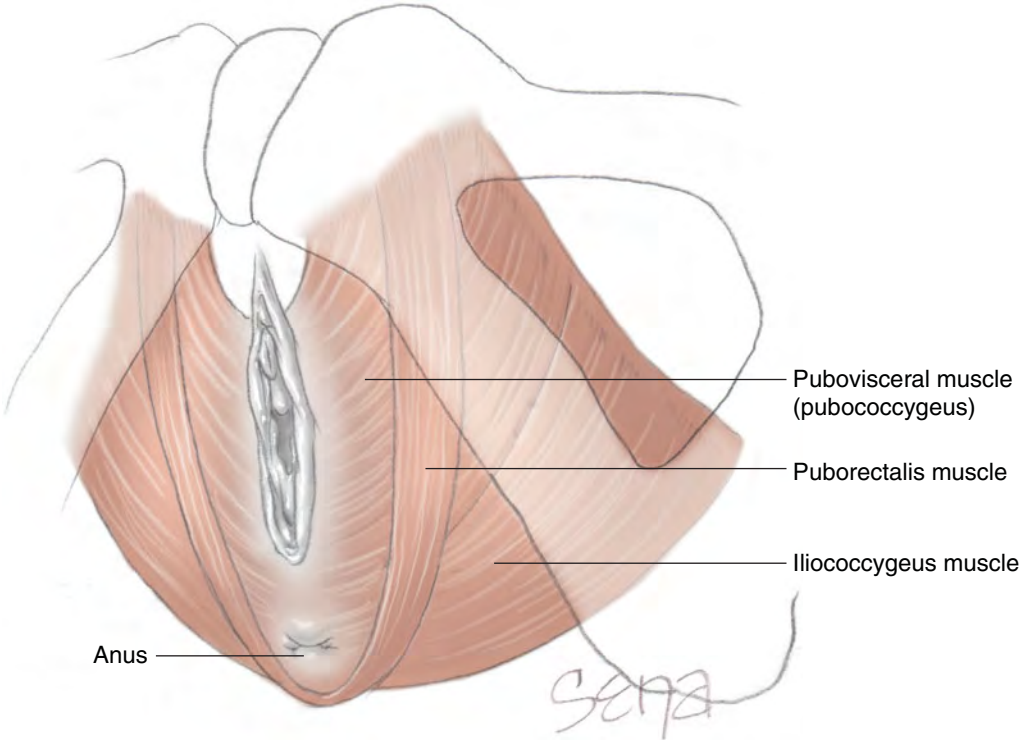

FIGURE 2-25 Pelvic floor muscles.

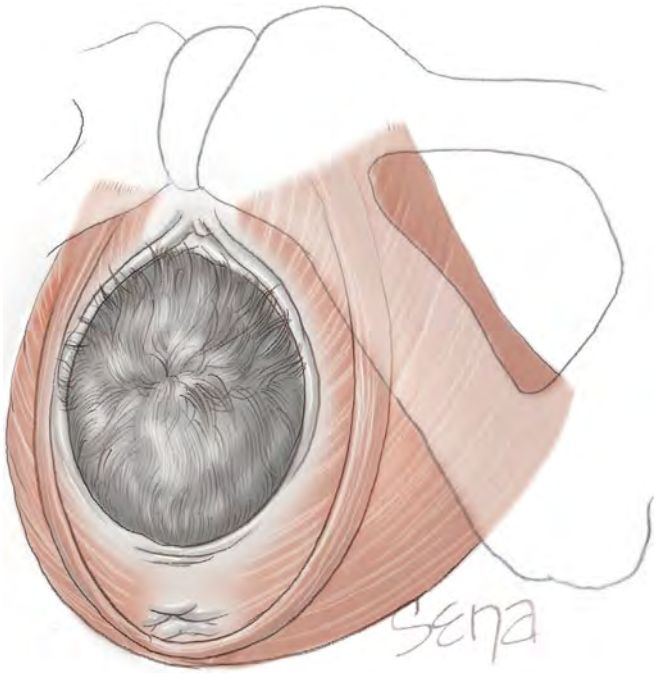

FIGURE 2-26 Illustration of levator ani muscle stretch during delivery.

muscle group is comprised of the *levator ani* and the *coccygeus muscle*. The levator ani is composed of the *pubococcygeus, puborectalis*, and *ileococcygeus muscles*. The pubococcygeus muscle now is preferably termed the *pubovisceral muscle* and is subdivided based on points of insertion and function. These include the *pubovaginalis, puboperinealis, and puboanalis muscles*, which insert into the vaginal, perineal body, and anus, respectively (Kearney and co-workers, 2004).

As shown in **Figure 2-26**, vaginal birth conveys significant risk for damage to the levator ani muscle or to its innervation (DeLancey and associates, 2003; Weidner and colleagues, 2006). Of these muscles, the pubovisceral muscle is more commonly damaged (Lien and associates, 2004; Margulies and colleagues, 2007). Evidence supports that these injuries may predispose women to greater risk of pelvic organ prolapse or urinary incontinence (DeLancey and associates, 2007a, b; Rortveit and co-workers, 2003). For this reason, current research efforts are aimed at minimizing these injuries.

CHAPTER 3

Implantation, Embryogenesis, and Placental Development

THE OVARIAN–ENDOMETRIAL CYCLE 36
THE DECIDUA 44
IMPLANTATION, PLACENTAL FORMATION, AND FETAL MEMBRANE DEVELOPMENT 47
PLACENTAL HORMONES 62
FETAL ADRENAL GLAND HORMONES 69

All obstetricians should be aware of the basic reproductive biological processes required for women to successfully achieve pregnancy. A number of abnormalities can affect each of these processes and lead to infertility or pregnancy loss. In most women, spontaneous, cyclical ovulation at 25- to 35-day intervals continues during almost 40 years between menarche and menopause. Without contraception, there are approximately 400 opportunities for pregnancy, which may occur with intercourse on any of 1200 days—the day of ovulation and its two preceding days. This narrow window for fertilization is controlled by tightly regulated production of ovarian steroids. These hormones promote optimal regeneration of endometrium after menstruation ends in preparation for the next implantation window.

Should fertilization occur, the events that unfold after initial implantation of the blastocyst onto the endometrium and through to parturition result from a unique interaction between fetal trophoblasts and maternal endometrium-decidua. The ability of mother and fetus to coexist as two distinct immunological systems results from endocrine, paracrine, and immunological modification of fetal and maternal tissues in a manner not seen elsewhere. The placenta mediates a unique fetal–maternal communication system, which creates a hormonal environment that helps initially to maintain pregnancy and eventually initiates the events leading to parturition. The following sections address the physiology of the ovarian-endometrial cycle, implantation, placenta, and fetal membranes, and specialized endocrine arrangements between fetus and mother.

THE OVARIAN–ENDOMETRIAL CYCLE

The endometrium-decidua is the anatomical site of blastocyst apposition, implantation, and placental development. From an evolutionary perspective, the human endometrium is highly developed to accommodate endometrial implantation and a hemochorial type of placentation. Endometrial development of a magnitude similar to that observed in women—that is, with special spiral (or coiling) arteries—is restricted to only a few primates, such as humans, great apes, and Old World monkeys. Trophoblasts of the blastocyst invade these endometrial arteries during implantation and placentation to establish uteroplacental vessels.

These primates are the only mammals that menstruate, which is a process of endometrial tissue shedding with hemorrhage and is dependent on sex steroid hormone-directed changes in blood flow in the spiral arteries. With nonfertile, but ovulatory, ovarian cycles, menstruation effects endometrial desquamation. New growth and development must be initiated with each cycle so that endometrial maturation corresponds rather precisely with the next opportunity for implantation and pregnancy. There seems to be a narrow window of endometrial receptivity to blastocyst implantation that corresponds approximately to menstrual cycle days 20 to 24.

The Ovarian Cycle

The development of predictable, regular, cyclical, and spontaneous ovulatory menstrual cycles is regulated by complex interactions of the hypothalamic-pituitary axis, the ovaries, and the genital tract (Fig. 3-1). The average cycle duration is approximately

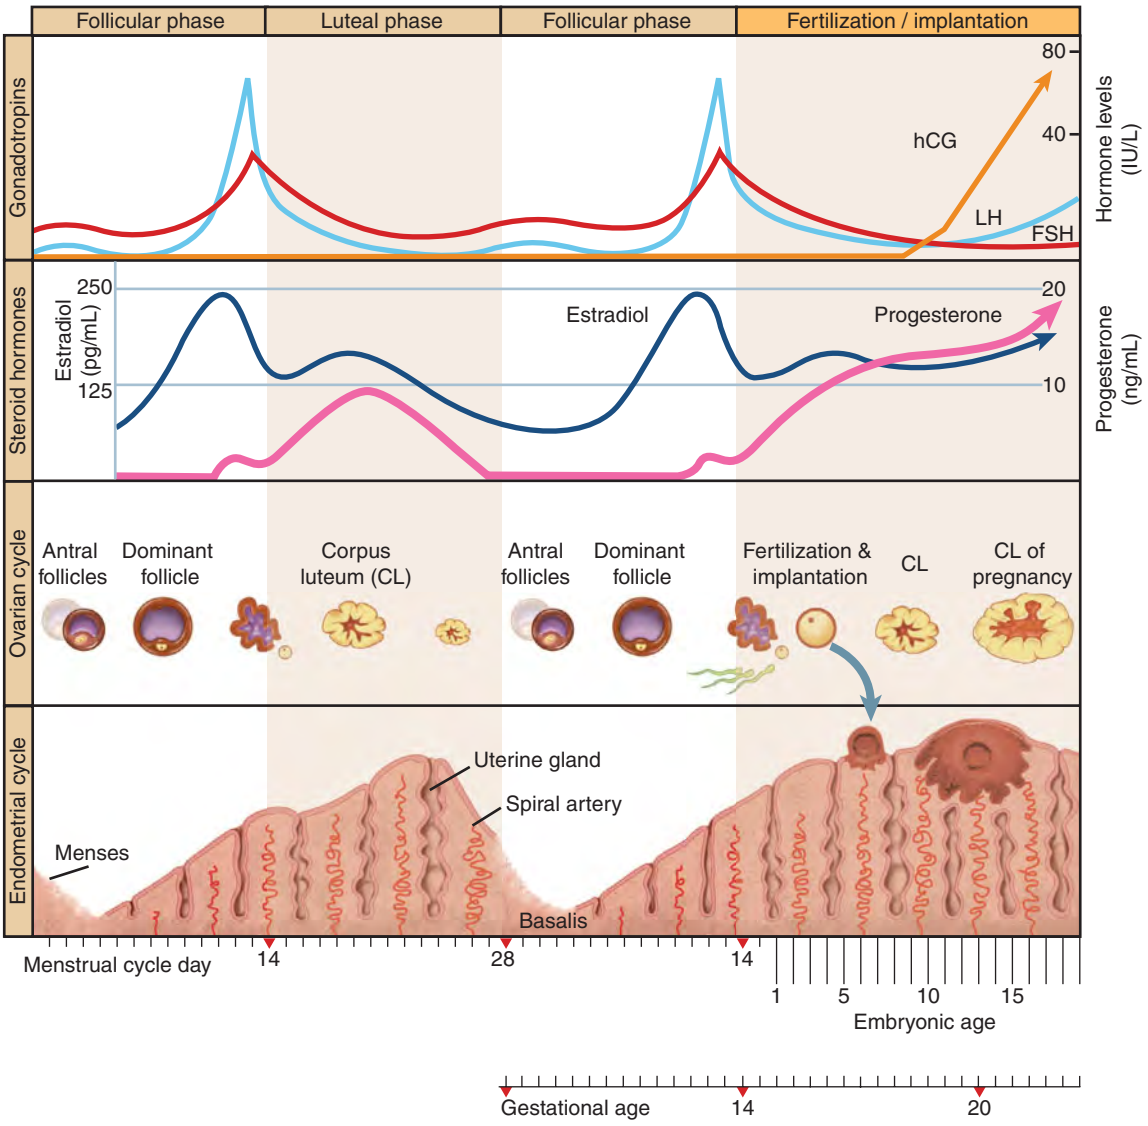

FIGURE 3-1 Gonadotropin control of the ovarian and endometrial cycles. The ovarian-endometrial cycle has been structured as a 28-day cycle. The follicular phase (days 1 to 14) is characterized by rising levels of estrogen, thickening of the endometrium, and selection of the dominant "ovulatory" follicle. During the luteal phase (days 14 to 21), the corpus luteum (CL) produces estrogen and progesterone, which prepare the endometrium for implantation. If implantation occurs, the developing blastocysts will begin to produce human chorionic gonadotropin (hCG) and rescue the corpus luteum, thus maintaining progesterone production. FSH = follicle-stimulating hormone; LH-luteinizing hormone.

28 days, with a range of 25 to 32 days. The sequence of hormonal events leading to ovulation directs the menstrual cycle. The cyclical changes in endometrial histology are faithfully reproduced during each ovulatory cycle.

In 1937, Rock and Bartlett suggested that endometrial histological features were sufficiently characteristic to permit "dating" of the cycle. These changes are illustrated in **Figure 3-2**. The follicular—proliferative—phase and the postovulatory-luteal or secretory—phase of the cycle are customarily divided into early and late stages.

Follicular or Preovulatory Ovarian Phase

There are 2 million oocytes in the human ovary at birth, and about 400,000 follicles are present at the onset of puberty (Baker, 1963). The remaining follicles are depleted at a rate of approximately 1000 follicles per month until age 35, when this rate accelerates (Faddy and colleagues, 1992). Only 400 follicles are normally released during female reproductive life. Therefore, more than 99.9 percent of follicles undergo atresia through a process of cell death termed *apoptosis* (Gougeon, 1996; Kaipia and Hsueh, 1997).

Follicular development consists of several stages, which include the gonadotropin-independent recruitment of primordial follicles from the resting pool and their growth to the antral stage. This appears to be under the control of locally produced growth factors. Two members of the transforming growth factor-β family—*growth differentiation factor 9 (GDF9)* and *bone morphogenetic protein 15 (BMP-15)*—regulate proliferation and differentiation of granulosa cells as primary follicles grow (Trombly and co-workers, 2009; Yan and colleagues, 2001). They

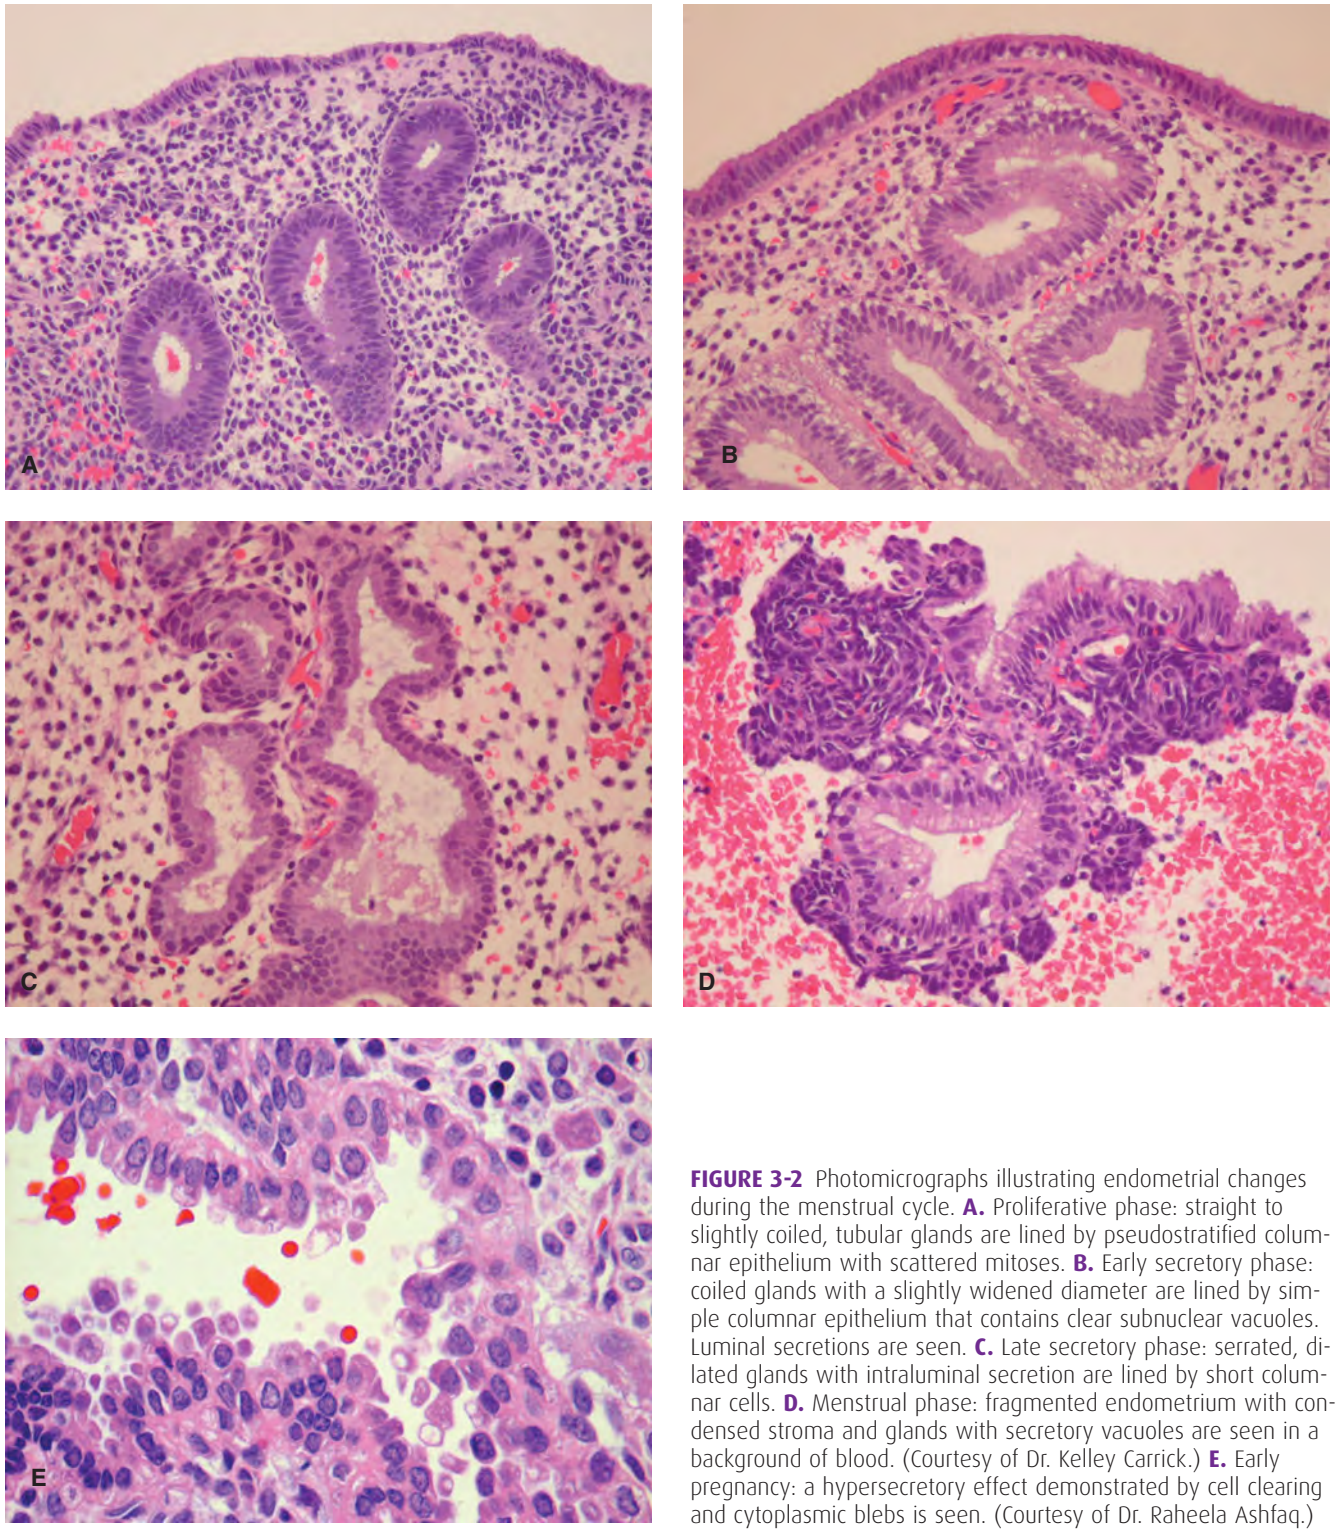

FIGURE 3-2 Photomicrographs illustrating endometrial changes during the menstrual cycle. **A.** Proliferative phase: straight to slightly coiled, tubular glands are lined by pseudostratified columnar epithelium with scattered mitoses. **B.** Early secretory phase: coiled glands with a slightly widened diameter are lined by simple columnar epithelium that contains clear subnuclear vacuoles. Luminal secretions are seen. **C.** Late secretory phase: serrated, dilated glands with intraluminal secretion are lined by short columnar cells. **D.** Menstrual phase: fragmented endometrium with condensed stroma and glands with secretory vacuoles are seen in a background of blood. (Courtesy of Dr. Kelley Carrick.) **E.** Early pregnancy: a hypersecretory effect demonstrated by cell clearing and cytoplasmic blebs is seen. (Courtesy of Dr. Raheela Ashfaq.)

also stabilize and expand the cumulus oocyte complex (COC) in the oviduct (Aaltonen and associates, 1999; Hreinsson and colleagues, 2002). These factors are produced by oocytes, suggesting that the early steps in follicular development are, in part, oocyte controlled. As antral follicles develop, surrounding stromal cells are recruited, by a yet-to-be-defined mechanism, to become thecal cells.

Although not required for early stages of follicular development, follicle-stimulating hormone (FSH) is required for further development of large antral follicles (Hillier, 2001). During each ovarian cycle, a group of antral follicles, known as a *cohort,* begins a phase of semisynchronous growth as a result of their maturation state during the FSH rise of the late luteal phase of the previous cycle. This FSH rise leading to

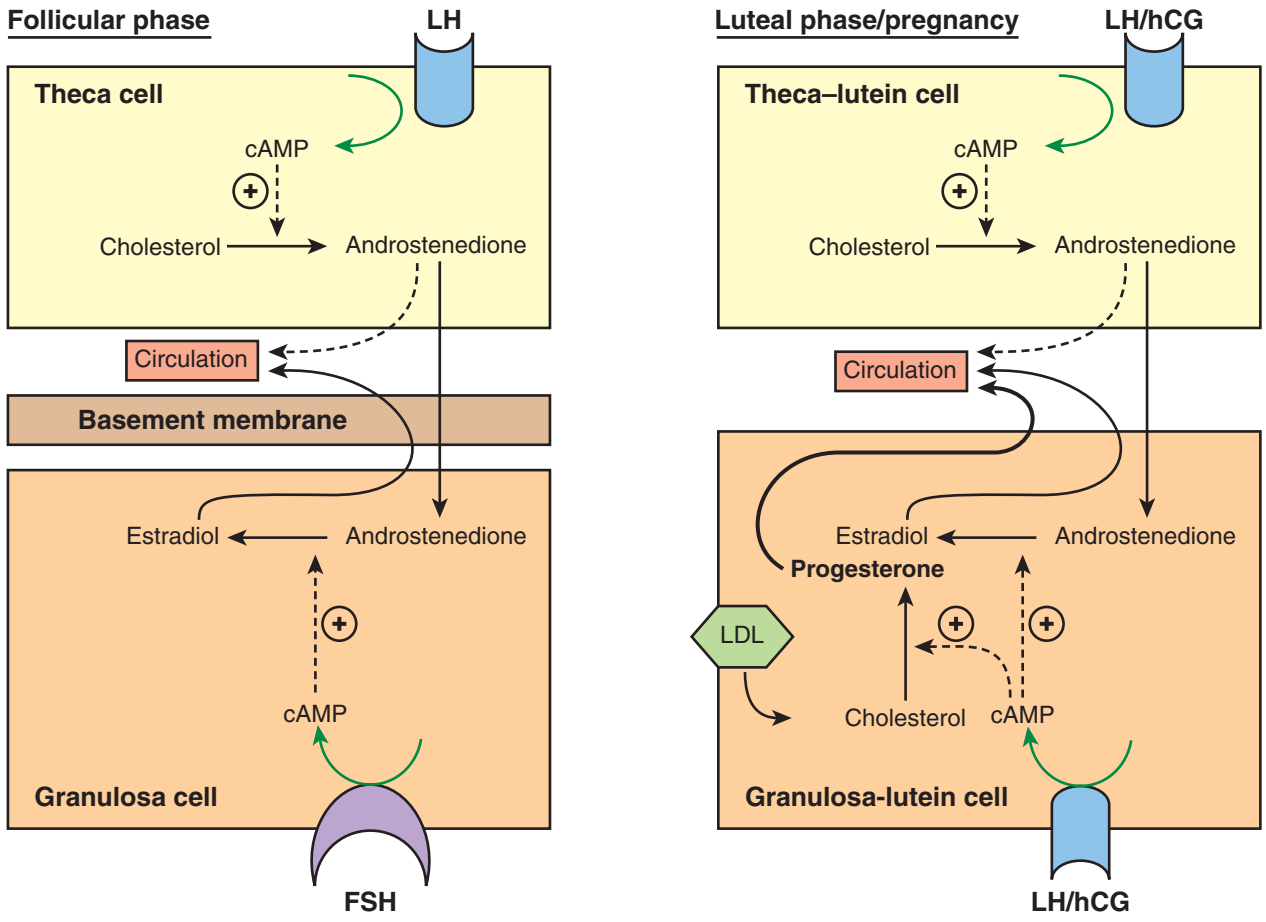

FIGURE 3-3 The two-cell-two-gonadotropin principle of ovarian steroid hormone production. During the follicular phase (*left panel*), luteinizing hormone (LH) controls theca cell production of androstenedione, which diffuses into the adjacent granulosa cells and acts as precursor for estradiol biosynthesis. The capacity for the granulosa cell to convert androstenedione to estradiol is controlled by follicle-stimulating hormone (FSH). After ovulation (*right panel*), the corpus luteum forms and both theca-lutein and granulosa-lutein cells respond to LH. The theca-lutein cells continue to produce androstenedione, whereas granulosa-lutein cells greatly increase their capacity to produce progesterone and to convert androstenedione to estradiol. If pregnancy occurs, the production of human chorionic gonadotropin (hCG) by the placenta rescues the corpus luteum through the LH receptor. Low-density lipoproteins (LDL) are an important source of cholesterol for steroidogenesis. cAMP = cyclic adenosine monophosphate.

follicle development is called the *selection window* of the ovarian cycle (Macklon and Fauser, 2001). Only the follicles progressing to this stage develop the capacity to produce estrogen.

During the follicular phase, estrogen levels rise in parallel to growth of a dominant follicle and the increase in its number of granulosa cells (see Fig. 3-1). These cells are the exclusive site of FSH receptor expression. The increase in circulating FSH during the late luteal phase of the previous cycle stimulates an increase in FSH receptors and subsequently, the ability of cytochrome P_{450} aromatase to convert androstenedione into estradiol. The requirement for thecal cells, which respond to luteinizing hormone (LH), and granulosa cells, which respond to FSH, represents the *two-gonadotropin, two-cell hypothesis* for estrogen biosynthesis (Short, 1962). As shown in **Figure 3-3**, FSH induces aromatase and expansion of the antrum of growing follicles. The follicle within the cohort that is most responsive to FSH is likely to be the first to produce estradiol and initiate expression of LH receptors.

After the appearance of LH receptors, the preovulatory granulosa cells begin to secrete small quantities of progesterone. The preovulatory progesterone secretion, although somewhat limited, is believed to exert positive feedback on the estrogen-primed pituitary to either cause or augment LH release. In addition, during the late follicular phase, LH stimulates thecal cell production of androgens, particularly androstenedione, which are then transferred to the adjacent follicles where they are aromatized to estradiol (see Fig. 3-3). During the early follicular phase, granulosa cells also produce inhibin B, which can feed back on the pituitary to inhibit FSH release (Groome and colleagues, 1996). As the dominant follicle begins to grow, the production of estradiol and the inhibins increases, resulting in a decline of follicular-phase FSH. This drop in FSH is responsible for the failure of other follicles to reach preovulatory status—*the Graafian follicle stage*—during any one cycle. Thus, 95 percent of plasma estradiol produced at this time is secreted by the dominant follicle—the follicle destined to ovulate. During this time, the contralateral ovary is relatively inactive.

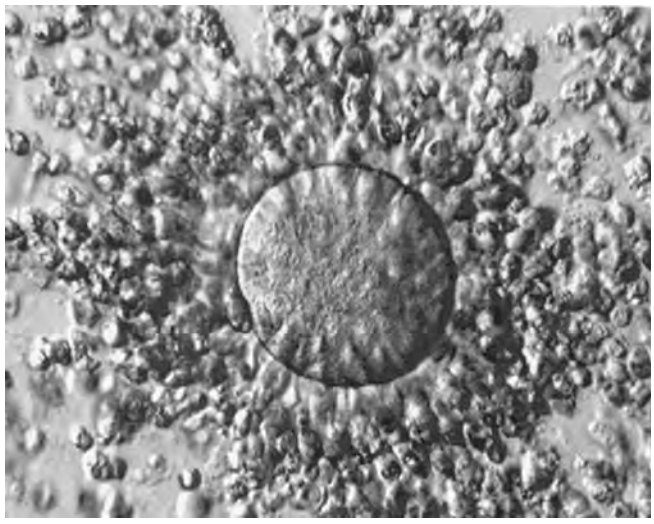

FIGURE 3-4 An ovulated cumulus-oocyte complex (COC). An oocyte is at the center of the complex. Cumulus cells are widely separated from each other in the cumulus layer by the hyaluronan-rich extracellular matrix. (Courtesy of Dr. Kevin J. Doody.)

Ovulation

The onset of the gonadotropin surge resulting from increasing estrogen secretion by preovulatory follicles is a relatively precise predictor of ovulation. It occurs 34 to 36 hours before release of the ovum from the follicle (see Fig. 3-1). LH secretion peaks 10 to 12 hours before ovulation and stimulates the resumption of meiosis in the ovum with the release of the first polar body. Current studies suggest that in response to LH, increased progesterone and prostaglandin production by the cumulus cells, as well as GDF9 and BMP-15 by the oocyte, activates expression of genes critical to formation of a hyaluronan-rich extracellular matrix by the COC (Richards, 2007). As seen in **Figure 3-4**, during synthesis of this matrix, cumulus cells lose contact with one another and move outward from the oocyte along the hyaluronan polymer—this process is called *expansion*. This results in a 20-fold increase in the volume of the complex. Studies in mice indicate that COC expansion is critical for maintenance of fertility. In addition, LH induces remodeling of the ovarian extracellular matrix to allow release of the mature oocyte with surrounding cumulus cells through the surface epithelium. Activation of proteases likely plays a pivotal role in weakening of the follicular basement membrane and ovulation (Curry and Smith, 2006; Ny and colleagues, 2002).

Luteal or Postovulatory Ovarian Phase

Following ovulation, the corpus luteum develops from the remains of the dominant or *Graafian follicle* in a process referred to as *luteinization.* Rupture of the follicle initiates a series of morphological and chemical changes leading to transformation into the corpus luteum (Browning, 1973). The basement membrane separating the granulosa-lutein and theca-lutein cells breaks down, and by day 2 postovulation, blood vessels and capillaries invade the granulosa cell layer. The rapid neovascularization of the once avascular granulosa may be due to angiogenic factors that include vascular endothelial growth factor (VEGF) and others produced in response to LH by theca-lutein and granulosa-lutein cells (Albrecht and Pepe, 2003; Fraser and Wulff, 2001). During luteinization, these cells undergo hypertrophy and increase their capacity to synthesize hormones (see Fig. 3-1).

It has been well established in studies of hypophysectomized women that LH is the primary luteotropic factor (Vande Wiele and colleagues, 1970). The life span of the corpus luteum in these women is dependent on repeated injections of LH or human chorionic gonadotropin (hCG). In addition, LH injections can extend the life span of the corpus luteum in normal women by 2 weeks (Segaloff and colleagues, 1951). In normal cycling women, the corpus luteum is maintained by low-frequency, high-amplitude pulses of LH secreted by gonadotropes in the anterior pituitary (Filicori and colleagues, 1986).

The pattern of hormone secretion by the corpus luteum is different from that of the follicle (see Fig. 3-1). The increased capacity of granulosa-lutein cells to produce progesterone is the result of increased access to considerably more steroidogenic precursors through blood-borne low-density lipoprotein (LDL)-derived cholesterol (see Fig. 3-3)(Carr and colleagues, 1981b). It is also due to increases in the level of steroidogenic acute regulatory protein. This protein transports cholesterol from the outer to the inner mitochondria, where the enzyme that metabolizes cholesterol to progesterone is found (Devoto and colleagues, 2002). The important role for LDL in progesterone biosynthesis is supported by the observation that women with extremely low levels of LDL cholesterol exhibit low progesterone secretion during the luteal phase (Illingworth and colleagues, 1982). In addition, high-density lipoprotein (HDL) may contribute to progesterone production in granulosa-lutein cells (Ragoobir and colleagues, 2002).

Estrogen levels follow a more complex pattern of secretion. Specifically, just after ovulation, estrogen levels decrease followed by a secondary rise that reaches a peak production of 0.25 mg/day of 17β-estradiol at the midluteal phase. Toward the end of the luteal phase, there is a secondary decrease in estradiol production.

Ovarian progesterone production peaks at 25 to 50 mg/day during the midluteal phase. With pregnancy, the corpus luteum continues progesterone production in response to embryonic hCG, which will bind and activate luteal cell LH receptors (see Fig. 3-3).

The human corpus luteum is a transient endocrine organ that, in the absence of pregnancy, will rapidly regress 9 to 11 days after ovulation. The mechanisms that control luteolysis remain unclear. However, in part, it results from decreased levels of circulating LH in the late luteal phase and decreased LH sensitivity of luteal cells (Duncan and colleagues, 1996; Filicori and colleagues, 1986). The role of other luteotropic factors is less clear, however, prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) appears to be luteolytic in nonhuman primates (Auletta, 1987; Wentz and Jones, 1973). Within the corpus luteum, luteolysis is characterized by a loss of luteal cells by apoptotic cell death (Vaskivuo and colleagues, 2002). The endocrine effects, consisting of a dramatic drop in circulating estradiol and progesterone levels, are critical to allow the follicular development and ovulation during the next ovarian cycle. In addition, corpus luteum regression and decrease in circulating steroids signal the endometrium to initiate molecular events that lead to menstruation.

Estrogen and Progesterone Action

Estrogen Effects

The fluctuating levels of ovarian steroids are the direct cause of the endometrial cycle. Recent advances in the molecular biology of estrogen and progesterone receptors have greatly improved our understanding of their function. The most biologically potent naturally occurring estrogen—17β-estradiol—is secreted by granulosa cells of the dominant follicle and luteinized granulosa cells of the corpus luteum (see Fig. 3-3). Estrogen is the essential hormonal signal on which most events in the normal menstrual cycle depend. Estradiol action is complex and appears to involve two classic nuclear hormone receptors designated estrogen receptor α (ERα) and β (ERβ) (Katzenellenbogen and colleagues, 2001). These isoforms are the product of separate genes and can exhibit distinct tissue expression. Both estradiol-receptor complexes act as transcriptional factors that become associated with the estrogen response element of specific genes. They share a robust activation by estradiol. However, differences in their binding affinities of other estrogens and their cell-specific expression patterns suggest that ERα and ERβ receptors may have both distinct and overlapping function (Saunders, 2005). Both receptors are expressed in the uterine endometrium (Bombail and co-workers, 2008; Lecce and colleagues, 2001).

The interaction with steroid ligands brings about estrogen receptor–specific initiation of gene transcription. This in turn promotes synthesis of specific messenger RNAs, and thereafter, the synthesis of specific proteins. Among the many proteins upregulated in most estrogen-responsive cells are estrogen and progesterone receptors themselves. In addition, estradiol has been proposed to act at the endothelial cell surface to stimulate nitric oxide production, leading to its rapid vasoactive properties (Shaul, 2002). The ability of estradiol to work in the cell nucleus through classic ligand-regulated nuclear hormone receptors and at the cell surface to cause rapid changes in cell signaling molecules is one explanation for the complex responses seen with estrogen therapies.

Progesterone Effects

Most progesterone actions on the female reproductive tract are mediated through nuclear hormone receptors. Progesterone enters cells by diffusion and in responsive tissues becomes associated with progesterone receptors (Conneely and colleagues, 2002). There are multiple isoforms of the human progesterone receptor. The best understood isoforms are the progesterone receptor type A (PR-A) and B (PR-B). Both arise from a single gene, are members of the steroid receptor superfamily of transcription factors, and regulate transcription of target genes. These receptors have unique actions. When PR-A and PR-B receptors are co-expressed, it appears that PR-A can inhibit PR-B gene regulation. The inhibitory effect of PR-A may extend to actions on other steroid receptors, including estrogen receptors. In addition, progesterone can evoke rapid responses such as changes in intracellular free calcium levels that cannot be explained by genomic mechanisms. G-protein-coupled membrane receptors for progesterone have been identified recently, but their role in the ovarian-endometrium cycle remains to be elucidated (Peluso, 2007).

Expression patterns of PR-A and PR-B endometrial receptors have been examined using immunohistochemistry (Mote and colleagues, 1999). The endometrial glands and stroma appear to have different expression patterns for these receptors that vary over the menstrual cycle. The glands express both receptors in the proliferative phase, suggesting that both receptors are involved with subnuclear vacuole formation. After ovulation, the glands continue to express PR-B through the midluteal phase, suggesting that glandular secretion seen during the luteal phase is PR-B regulated. In contrast, the stroma and predecidual cells express only PR-A throughout the menstrual cycle, suggesting that progesterone-stimulated events within the stroma are mediated by this receptor.

Progesterone receptor expression has not been found in inflammatory cells or in endothelial cells of endometrial vessels. The role of these two receptor isoforms in the regulation of human menstruation is unclear, but they likely play distinct roles. Animal models suggest that PR-A regulates the antiproliferative effects of progesterone during the secretory phase.

The Endometrial Cycle

Proliferative or Preovulatory Endometrial Phase

Fluctuations in estrogen and progesterone levels produce striking effects on the reproductive tract, particularly the endometrium (Fig. 3-2). The growth and functional characteristics of the human endometrium are unique. Epithelial—glandular cells; stromal—mesenchymal cells; and blood vessels of the endometrium replicate cyclically in reproductive-aged women at a rapid rate. The endometrium is regenerated during each ovarian–endometrial cycle. The superficial endometrium, termed *functionalis layer*, is shed and regenerated from the deeper *basalis layer* almost 400 times during the reproductive lifetime of most women (**Fig. 3-5**). There is no other example in humans of such cyclical shedding and regrowth of an entire tissue.

Follicular-phase production of estradiol is the most important factor in endometrial recovery following menstruation. Although up to two thirds of the functionalis endometrium is fragmented and shed during menstruation, re-epithelialization begins even before menstrual bleeding has ceased. By the fifth day of the endometrial cycle—fifth day of menses, the epithelial surface of the endometrium has been restored, and revascularization is in progress. The preovulatory endometrium is characterized by proliferation of vascular endothelial, stromal, and glandular cells (see Fig. 3-2). During the early part of the proliferative phase, the endometrium is thin, usually less than 2 mm thick. The glands at this stage are narrow, tubular structures that pursue almost a straight and parallel course from the basalis layer toward the surface of the endometrial cavity. Mitotic figures, especially in the glandular epithelium, are identified by the fifth cycle day, and mitotic activity in both epithelium and stroma persists until day 16 to 17, or 2 to 3 days after ovulation. Although blood vessels are numerous and prominent,

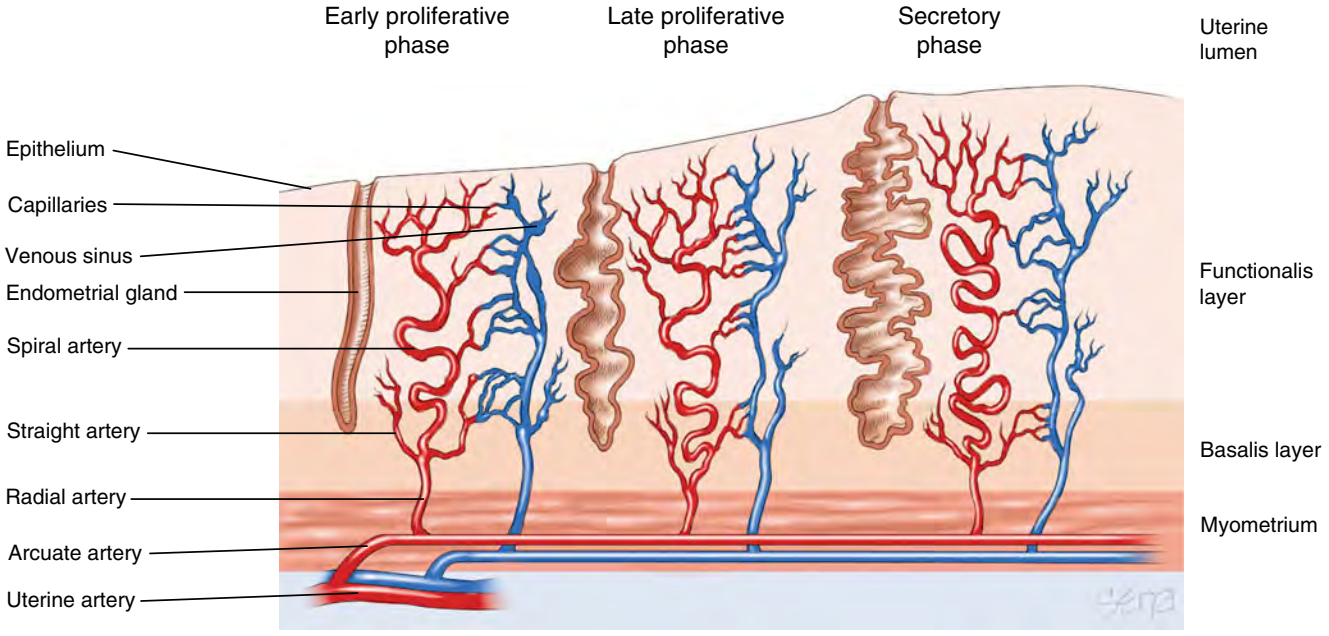

FIGURE 3-5 The endometrium consists of two layers, the functionalis layer and basalis layer. These layers are supplied by the spiral and straight arteries, respectively. Numerous glands also span these layers. As the menstrual cycle progresses, greater coiling of the spiral arteries and increased folds in the glands can be seen. Near the end of the menstrual cycle (day 27), the coiled arteries constrict, deprive blood supply to the functionalis layer, and lead to necrosis and sloughing of this layer.

there is no extravascular blood or leukocyte infiltration in the endometrium at this stage.

Clearly, re-epithelialization and angiogenesis are important to cessation of endometrial bleeding (Chennazhi and Nayak, 2009; Rogers and associates, 2009). These are dependent on tissue regrowth, which is estrogen regulated. Epithelial cell growth also is regulated in part by epidermal growth factor (EGF) and transforming growth factor α (TGFα). Stromal cell proliferation appears to increase through paracrine and autocrine action of estrogen and increased local levels of fibroblast growth factor-9 (Tsai and colleagues, 2002). Estrogens also increase local production of VEGF, which causes angiogenesis through vessel elongation in the basalis (Bausero and colleagues, 1998; Gargett and Rogers, 2001; Sugino and coworkers, 2002).

By the late proliferative phase, the endometrium thickens from both glandular hyperplasia and increased stromal ground substance, which is edema and proteinaceous material. The loose stroma is especially prominent, and the glands in the functionalis layer are widely separated. This is compared with those of the basalis layer, in which the glands are more crowded and the stroma is denser. At midcycle, as ovulation nears, glandular epithelium becomes taller and pseudostratified. The surface epithelial cells acquire numerous microvilli, which increase epithelial surface area, and cilia, which aid in the movement of endometrial secretions during the secretory phase (Ferenczy, 1976).

Determining the menstrual cycle day by endometrial histological criteria, termed *dating*, is difficult during the proliferative phase because of the considerable variation of phase length among women. Specifically, the follicular phase normally may be as short as 5 to 7 days or as long as 21 to 30 days. In contrast, the luteal or secretory postovulatory phase of the cycle is remarkably constant at 12 to 14 days.

Secretory or Postovulatory Endometrial Phase

During the early secretory phase, endometrial dating is based on glandular epithelium histology. After ovulation, the estrogen-primed endometrium responds to rising progesterone levels in a highly predictable manner (see Fig. 3-1). By day 17, glycogen accumulates in the basal portion of glandular epithelium, creating subnuclear vacuoles and pseudostratification. This is the first sign of ovulation that is histologically evident. It is likely the result of direct progesterone action through receptors expressed in glandular cells (Mote and colleagues, 2000). On day 18, vacuoles move to the apical portion of the secretory nonciliated cells. By day 19, these cells begin to secrete glycoprotein and mucopolysaccharide contents into the lumen (Hafez and colleagues, 1975). Glandular cell mitosis ceases with secretory activity on day 19 due to rising progesterone levels, which antagonize the mitotic effects of estrogen. Estradiol action is also decreased because of glandular expression of the type 2 isoform of 17β-hydroxysteroid dehydrogenase. This converts estradiol to the less active estrone (Casey and MacDonald, 1996).

Dating in the mid- to late-secretory phase relies on changes in the endometrial stroma (see Fig. 3-2). On days 21 to 24, the stroma becomes edematous. On days 22 to 25, stromal cells surrounding the spiral arterioles begin to enlarge, and stromal mitosis becomes apparent. Days 23 to 28 are characterized by predecidual cells, which surround spiral arterioles.

An important feature of secretory-phase endometrium between days 22 and 25 is striking changes associated with predecidual transformation of the upper two thirds of the functionalis layer. The glands exhibit extensive coiling and luminal secretions

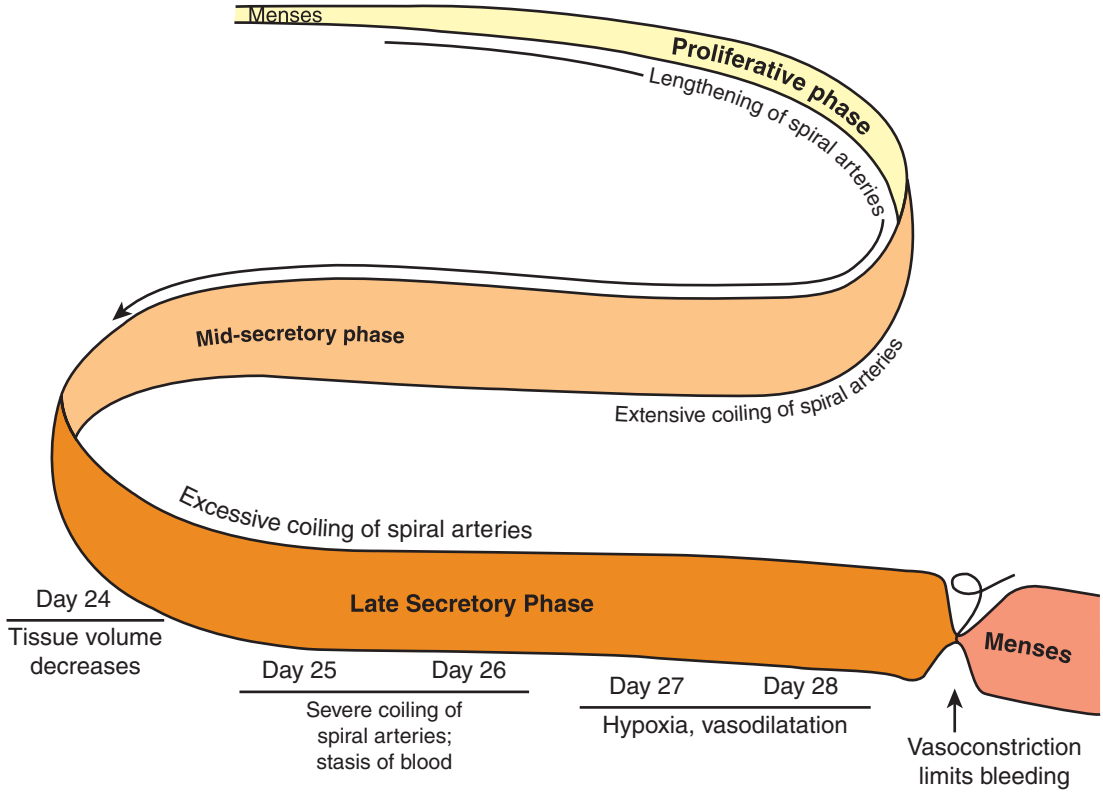

FIGURE 3-6 The spiral arteries of human endometrium are modified during the ovulatory cycle. Initially, changes in blood flow through these vessels aid endometrial growth. Excessive coiling and stasis in blood flow coincide with regression of corpus luteum function and lead to a decline in endometrial tissue volume. Finally, spiral artery coiling leads to endometrial hypoxia and necrosis. Prior to endometrial bleeding, intense spiral artery vasospasm serves to limit blood loss with menstruation.

become visible. Changes within the endometrium also can mark the so-called *window of implantation* seen on days 20 to 24. Epithelial surface cells show decreased microvilli and cilia but appearance of luminal protrusions on the apical cell surface (Nikas, 2003). These *pinopodes* are important in preparation for blastocyst implantation. They also coincide with changes in the surface glycocalyx that allow acceptance of a blastocyst (Aplin, 2003).

The secretory phase is also highlighted by the continuing growth and development of the spiral arteries. Boyd and Hamilton (1970) emphasized the extraordinary importance of the endometrial spiraling or coiled arteries. They arise from arcuate arteries, which are myometrial branches of the uterine vessels (see Fig. 3-5). The morphological and functional properties of spiral arteries are unique and essential for establishing changes in blood flow to permit either menstruation or implantation. During endometrial growth, spiral arteries lengthen at a rate appreciably greater than the rate of increase in endometrial tissue height or thickness (Fig. 3-6). This growth discordance obliges even greater coiling of the already spiraling vessels. Spiral artery development reflects a marked induction of angiogenesis, consisting of widespread vessel sprouting and extension. Perrot-Applanat and associates (1988) described progesterone and estrogen receptors in the smooth muscle cells of the uterus and spiral arteries. They further demonstrated that such rapid angiogenesis is regulated, in part, through estrogen- and progesterone-regulated synthesis of VEGF (Ancelin and colleagues, 2002; Chennazhi and Nayak, 2009). This protein is secreted by stromal cells and glandular epithelium and stimulates endothelial cell proliferation and increases vascular permeability. Thus, steroid hormone influences on growth and vasculature are directed to a large degree through the local production of growth factors.

Menstruation

The midluteal–secretory phase of the endometrial cycle is a critical branch point in endometrial development and differentiation. With corpus luteum rescue and continued progesterone secretion, the process of decidualization continues. If luteal progesterone production decreases with *luteolysis,* events leading to menstruation are initiated. Many molecular mechanisms involving endometrial progesterone withdrawal, as well as the subsequent inflammatory response that causes endometrial sloughing, have been defined (Critchley and colleagues, 2006).

A notable histological characteristic of late premenstrual-phase endometrium is stromal infiltration by neutrophils, giving a pseudoinflammatory appearance to the tissue. These cells infiltrate primarily on the day or two immediately preceding menses onset. The endometrial stromal and epithelial cells produce interleukin-8 (IL-8), which is a chemotactic–activating factor for neutrophils (Arici and colleagues, 1993). IL-8 may be one agent that serves to recruit neutrophils just prior to menstruation. Similarly, monocyte chemotactic protein-1 (MCP-1) is synthesized by endometrium (Arici and colleagues, 1995).

Leukocyte infiltration is considered key to extracellular matrix breakdown of the functionalis layer. Invading leukocytes secrete enzymes that are members of the matrix metalloproteinase (MMP) family. These add to the proteases already produced by endometrial stromal cells. The rising level of MMPs tips the balance between proteases and protease inhibitors, effectively initiating matrix degradation. This phenomenon has been proposed to initiate the events leading to menstruation (Dong and colleagues, 2002).

Anatomical Events During Menstruation

The classic study by Markee (1940) described tissue and vascular changes in endometrium before menstruation. First, there were marked changes in endometrial blood flow essential for menstruation. With endometrial regression, coiling of spiral arteries becomes sufficiently severe that resistance to blood flow increases strikingly, causing hypoxia of the endometrium. Resultant stasis is the primary cause of endometrial ischemia and tissue degeneration (Fig. 3-6). A period of vasoconstriction precedes menstruation and is the most striking and constant event observed in the cycle. Intense vasoconstriction of the spiral arteries also serves to limit menstrual blood loss. Blood flow appears to be regulated in an endocrine manner by sex steroid hormone–induced modifications of a paracrine-mediated vasoactive peptide system as described subsequently.

Prostaglandins and Menstruation

Progesterone withdrawal increases expression of inducible cyclooxygenase 2 (COX-2) enzyme to synthesize prostaglandins and decreases expression of 15-hydroxyprostaglandin dehydrogenase (PGDH), which degrades prostaglandins (Casey and colleagues, 1980, 1989). The net result is increased prostaglandin production by stromal cells along with increased prostaglandin receptor density on blood vessels and surrounding cells.

A role for prostaglandins—especially vasoconstricting prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$)—in initiation of menstruation has been suggested (Abel, 2002). Large amounts of prostaglandins are present in menstrual blood. $PGF_{2\alpha}$ administration prompts symptoms that mimic dysmenorrhea, which is commonly associated with normal menses and likely caused by myometrial contractions and uterine ischemia. $PGF_{2\alpha}$ administration to nonpregnant women also will cause menstruation. This response is believed to be mediated by $PGF_{2\alpha}$-induced vasoconstriction of spiral arteries, causing the uppermost endometrial zones to become hypoxic. This is a potent inducer of angiogenesis and vascular permeability factors such as VEGF. Prostaglandins play an important role in the cascade of events leading to menstruation that include vasoconstriction, myometrial contractions, and upregulation of proinflammatory responses.

Vasoactive Peptides and Menstruation

A number of peptides may comprise a hormone-responsive paracrine system in the endometrium to regulate spiral artery blood flow. One is the endothelin–enkephalinase system (Casey and MacDonald, 1996). The endothelins—ET-1, ET-2, and ET-3—are small, 21-amino-acid peptides. Endothelin-1 (ET-1) is a potent vasoconstrictor first identified as a product of vascular endothelial cells (Yanagisawa and colleagues, 1988). Endothelins are degraded by enkephalinase, which is localized in endometrial stromal cells. Its specific activity in these cells increases strikingly and in parallel with the increase in progesterone blood levels after ovulation. The specific activity of enkephalinase is highest during the midluteal phase and declines steadily thereafter as progesterone plasma levels decrease (Casey and colleagues, 1991).

Activation of Lytic Mechanisms

Following vasoconstriction and endometrial cytokine changes, activation of proteases within stromal cells and leukocyte invasion is required to degrade the endometrial interstitial matrix. And matrix metalloproteases—MMP-1 and MMP-3—are released from stromal cells and may activate other neutrophilic proteases such as MMP-8 and MMP-9.

Origin of Menstrual Blood

Menstrual bleeding is from both systems, but arterial bleeding is appreciably greater than venous. Endometrial bleeding appears to follow rupture of an arteriole of a coiled artery, with consequent hematoma formation. With a hematoma, the superficial endometrium is distended and ruptures. Subsequently, fissures develop in the adjacent functionalis layer, and blood, as well as tissue fragments of various sizes, are sloughed. Hemorrhage stops with arteriolar constriction. Changes that accompany partial tissue necrosis also serve to seal vessel tips.

The endometrial surface is restored by growth of flanges, or collars, that form the everted free ends of the endometrial glands (Markee, 1940). These flanges increase in diameter very rapidly, and epithelial continuity is reestablished by fusion of the edges of these sheets of migrating thin cells.

Interval between Menses

The modal interval of menstruation is considered to be 28 days, but there is considerable variation among women, as well as in the cycle lengths of a given woman. Marked differences in the intervals between menstrual cycles are not necessarily indicative of infertility. Arey (1939) analyzed 12 studies comprising about 20,000 calendar records from 1500 women. He concluded that there is no evidence of perfect menstrual cycle regularity. Among average adult women, a third of cycles departed by more than 2 days from the mean of all cycle lengths. In his analysis of 5322 cycles in 485 normal women, an average interval of 28.4 days was estimated. Average cycle length in pubertal girls was 33.9 days. Haman (1942) surveyed 2460 cycles in 150 women, and the distribution curve for cycle length is shown in **Figure 3-7**.

THE DECIDUA

The decidua is a specialized, highly modified endometrium of pregnancy and is a function of hemochorial placentation. The latter has in common the process of trophoblast invasion, and considerable research has focused on the interaction between decidual cells and invading trophoblasts. *Decidualization*—transformation of secretory endometrium to decidua—is dependent on estrogen and progesterone and factors secreted by the implanting blastocyst. The special relationship that exists between the decidua and the invading trophoblast seemingly defies the laws of transplantation immunology (Beer and

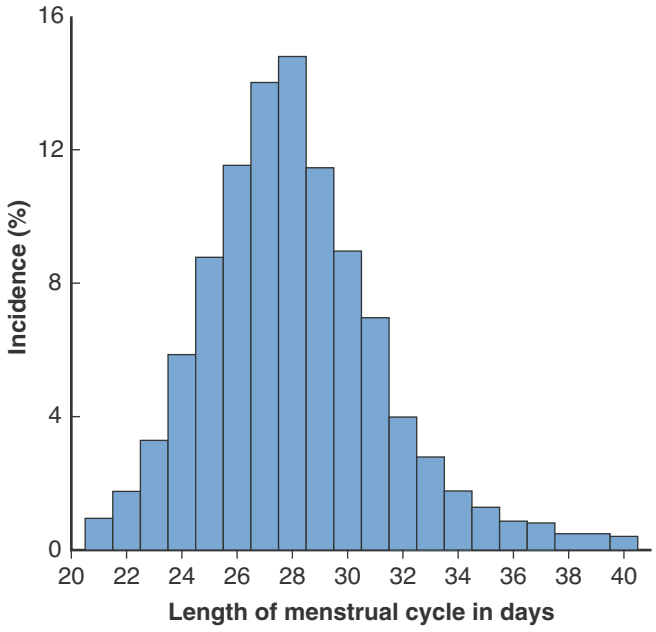

FIGURE 3–7. Duration of menstrual cycle. (Based on distribution data of Arey, 1939, and Haman, 1942.)

Billingham, 1971). The success of this unique semiallograft not only is of great scientific interest but may involve processes that harbor insights leading to more successful transplantation surgery and perhaps even immunological treatment of neoplasia (Billingham and Head, 1986; Lala and colleagues, 2002).

Decidual Structure

The first scientific description of the *membrana decidua* was in the 18th century by William Hunter. According to Damjanov (1985), *membrana* denoted its gross anatomical appearance, whereas *decidua* was an analogy to deciduous leaves to indicate that it is shed after childbirth. The decidua is classified into three parts based on anatomical location. Decidua directly beneath blastocyst implantation is modified by trophoblast invasion and becomes the *decidua basalis*. The *decidua capsularis* overlies the enlarging blastocyst, and initially separates it from the rest of the uterine cavity (**Fig. 3-8**). This portion is most prominent during the second month of pregnancy, consisting of decidual cells covered by a single layer of flattened epithelial cells. Internally, it contacts the avascular, extraembryonic fetal membrane—the *chorion laeve*. The remainder of the uterus is lined by *decidua parietalis*—sometimes called *decidua vera* when decidua capsularis and parietalis are joined.

During early pregnancy, there is a space between the decidua capsularis and parietalis because the gestational sac does not fill the entire uterine cavity. By 14 to 16 weeks, the expanding sac has enlarged to completely fill the uterine cavity. With fusion of the decidua capsularis and parietalis, the uterine cavity is functionally obliterated. In early pregnancy, the decidua begins to thicken, eventually attaining a depth of 5 to 10 mm. With magnification, furrows and numerous small openings, representing the mouths of uterine glands, can be detected. Later in pregnancy, the decidua becomes thinner, presumably because of pressure exerted by the expanding uterine contents.

The decidua parietalis and basalis, like the secretory endometrium, are composed of three layers. There is a surface, or compact zone—*zona compacta*; a middle portion, or spongy zone—*zona spongiosa*—with remnants of glands and numerous small blood vessels; and a basal zone—*zona basalis*. The zona compacta and spongiosa together form the *zona functionalis*. The basal zone remains after delivery and gives rise to new endometrium.

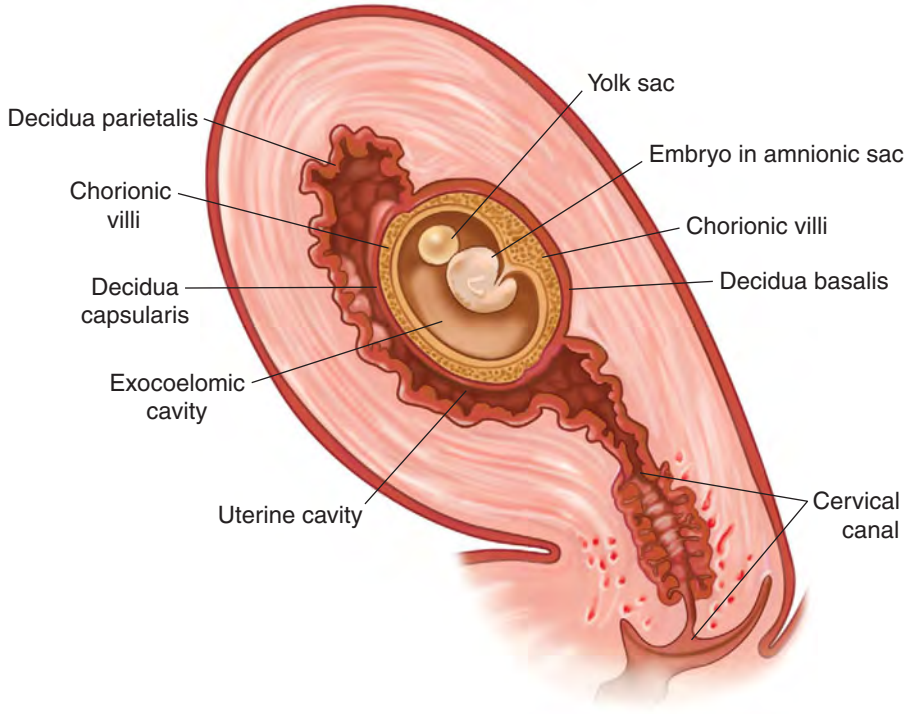

FIGURE 3-8 Decidualized endometrium covers the early embryo. Three portions of the decidua (basalis, capsularis, and parietalis) also are illustrated.

Decidual Reaction

In human pregnancy, the decidual reaction is completed only with blastocyst implantation. Predecidual changes, however, commence first during the midluteal phase in endometrial stromal cells adjacent to the spiral arteries and arterioles. Thereafter, they spread in waves throughout the uterine endometrium and then from the site of implantation. The endometrial stromal cells enlarge to form polygonal or round decidual cells. The nuclei become round and vesicular, and the cytoplasm becomes clear, slightly basophilic, and surrounded by a translucent membrane. Each mature decidual cell becomes surrounded by a pericellular membrane. Thus, the human decidual cells clearly build walls around themselves and possibly around the fetus. The pericellular matrix surrounding the decidual cells may allow attachment of cytotrophoblasts through

cellular adhesion molecules. The cell membrane also may provide decidual cell protection against selected cytotrophoblastic proteases.

Decidual Blood Supply

As a consequence of implantation, the blood supply to the decidua capsularis is lost as the embryo-fetus grows. Blood supply to the decidua parietalis through spiral arteries persists, as in the endometrium during the luteal phase of the cycle. The spiral arteries in the decidua parietalis retain a smooth muscle wall and endothelium and thereby remain responsive to vasoactive agents that act on their smooth muscle or endothelial cells.

The spiral arterial system supplying the decidua basalis directly beneath the implanting blastocyst, and ultimately the intervillous space, is altered remarkably. These spiral arterioles and arteries are invaded by cytotrophoblasts. During this process, the walls of vessels in the basalis are destroyed. Only a shell without smooth muscle or endothelial cells remains. Importantly, as a consequence, these vascular conduits of maternal blood—which become the uteroplacental vessels—are not responsive to vasoactive agents. By contrast, the fetal chorionic vessels, which transport blood between the placenta and the fetus, contain smooth muscle and thus do respond to vasoactive agents.

Decidual Histology

The decidua contains numerous cell types, whose composition varies with the stage of gestation (Loke and King, 1995). The primary cellular components are the true decidual cells, which differentiated from the endometrial stromal cells, and numerous maternal bone marrow–derived cells. The zona compacta consists of large, closely packed, epithelioid, polygonal, light-staining cells with round nuclei. Many stromal cells appear stellate, with long protoplasmic processes that anastomose with those of adjacent cells. This is particularly so when the decidua is edematous.

A striking abundance of large, granular lymphocytes termed decidual natural killer cells (NK) are present in the decidua early in pregnancy. In peripheral blood, there are two subsets of NK cells. About 90 percent are highly cytolytic and 10 percent show less cytolytic ability but increased secretion of cytokines. In contrast to peripheral blood, 95 percent of NK cells in decidua secrete cytokines. About half of these unique cells also express angiogenic factors. These decidua NK cells likely play an important role in trophoblast invasion and vasculogenesis.

Early in pregnancy, zona spongiosa of the decidua consists of large distended glands, often exhibiting marked hyperplasia and separated by minimal stroma. At first, the glands are lined by typical cylindrical uterine epithelium with abundant secretory activity that contributes to nourishment of the blastocyst. As pregnancy progresses, the epithelium gradually becomes cuboidal or even flattened, later degenerating and sloughing to a greater extent into the gland lumens. Later in pregnancy, the glandular elements largely disappear. In comparing the decidua parietalis at 16 weeks with the early proliferative endometrium of a nonpregnant woman, it is clear that there is marked hypertrophy but only slight hyperplasia of the endometrial stroma during decidual transformation.

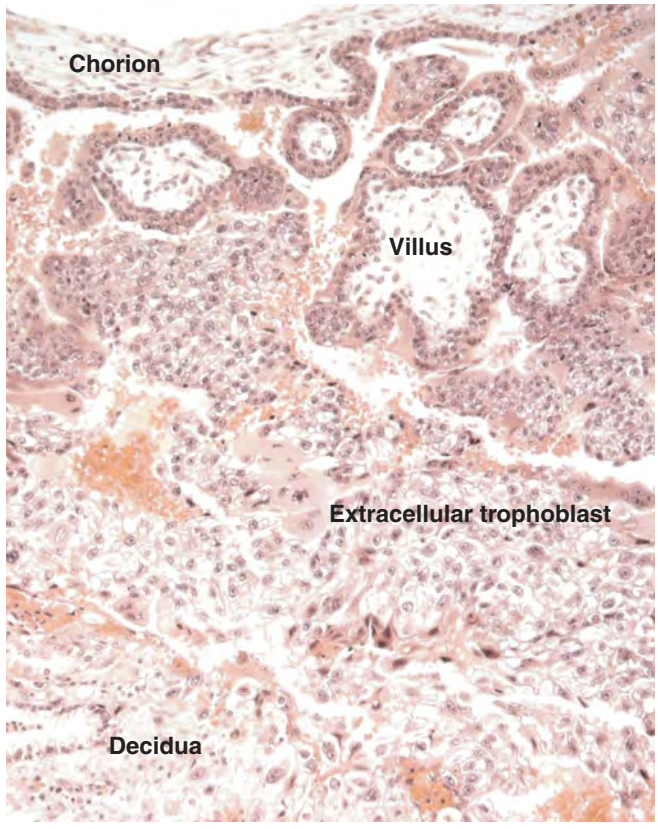

FIGURE 3-9 Section through junction of chorion, villi, and decidua basalis in early first-trimester pregnancy. (Used with permission from Dr. Kurt Benirschke.)

The decidua basalis contributes to the formation of the basal plate of the placenta (Fig. 3-9). It differs histologically from the decidua parietalis in two important respects. First, the spongy zone of the basalis consists mainly of arteries and widely dilated veins, and by term, the glands have virtually disappeared. Second, the decidua basalis is invaded by large numbers of interstitial trophoblast cells and trophoblastic giant cells. Although most abundant in the decidua, the giant cells commonly penetrate the upper myometrium. Their number and invasiveness may be so extensive as to resemble choriocarcinoma.

The *Nitabuch layer* is a zone of fibrinoid degeneration in which invading trophoblasts meet the decidua. If the decidua is defective, as in placenta accreta, the Nitabuch layer is usually absent (see Chap. 35, p. 776). There is also a more superficial, but inconsistent, deposition of fibrin—*Rohr stria*—at the bottom of the intervillous space and surrounding the anchoring villi. McCombs and Craig (1964) found that decidual necrosis is a normal phenomenon in the first and probably second trimesters. Thus, necrotic decidua obtained through curettage after spontaneous abortion in the first trimester should not necessarily be interpreted as either a cause or an effect of the pregnancy loss.

Decidual Prolactin

Convincing evidence has been presented that the decidua is the source of prolactin that is present in enormous amounts in amnionic fluid (Golander and colleagues, 1978; Riddick

and co-workers, 1979). Decidual prolactin is not to be confused with placental lactogen (hPL), which is produced only by the syncytiotrophoblast. Rather, decidual prolactin is a product of the same gene that encodes for anterior pituitary prolactin. And although the amino acid sequence of prolactin in both tissues is identical, an alternative promoter is used within the prolactin gene to initiate transcription in decidua (Telgmann and Gellersen, 1998). The latter is thought to explain the different mechanisms that regulate expression in the decidua versus pituitary (Christian and colleagues, 2002a, 2000b).

The protein preferentially enters amnionic fluid, and little enters maternal blood. Consequently, prolactin levels in amnionic fluid are extraordinarily high and may reach 10,000 ng/mL during weeks 20 to 24 (Tyson and colleagues, 1972). This compares with fetal serum levels of 350 ng/mL and maternal serum levels of 150 to 200 ng/mL. As a result, decidual prolactin is a classic example of paracrine function between maternal and fetal tissues.

Role(s) of Decidual Prolactin

The exact physiological roles of decidual prolactin are still unknown. Its action is mediated by relative expression of two unique prolactin receptors as well as the amount of intact or full-length prolactin protein compared with the truncated 16-kDa form (Jabbour and Critchley, 2001). Receptor expression has been demonstrated in decidua, chorionic cytotrophoblasts, amnionic epithelium, and placental syncytiotrophoblast (Maaskant and colleagues, 1996). There are a number of possible roles for decidual prolactin. First, because most or all decidual prolactin enters amnionic fluid, there may be a role for this hormone in transmembrane solute and water transport, and thus, in maintenance of amnionic fluid volume. Second, there are prolactin receptors in a number of bone marrow-derived immune cells, and prolactin may stimulate T cells in an autocrine or paracrine manner (Pellegrini and colleagues, 1992). This raises the possibility that decidual prolactin may act in regulating immunological functions during pregnancy. Prolactin may play a role in regulation of angiogenesis during implantation. In this regard, intact prolactin protein enhances angiogenesis, whereas the proteolytic fragment can inhibit new vessel growth. Lastly, decidual prolactin has been shown in the mouse to have a protective function by repressing expression of genes detrimental to pregnancy maintenance (Bao and colleagues, 2007).

Regulation of Decidual Prolactin

Factors that regulate decidual prolactin production are not clearly defined. Most agents known to inhibit or stimulate pituitary prolactin secretion—including dopamine, dopamine agonists, and thyrotropin-releasing hormone—do not alter decidual prolactin secretion either in vivo or in vitro. Brosens and colleagues (2000) demonstrated that progestins act synergistically with cyclic adenosine monophosphate on endometrial stromal cells in culture to increase prolactin expression. This suggests that the level of progesterone receptor expression may determine the decidualization process, at least as marked by prolactin production. And arachidonic acid, but not $PGF_{2\alpha}$ or PGE_2, attenuates the rate of decidual prolactin secretion (Handwerger and colleagues, 1981). Conversely, a variety of cytokines and growth factors—ET-1, IL-1, IL-2, and epidermal growth factor—decrease decidual prolactin secretion (Chao and colleagues, 1994; Frank and associates, 1995).

IMPLANTATION, PLACENTAL FORMATION, AND FETAL MEMBRANE DEVELOPMENT

Human placental development is as uniquely intriguing as fetal embryology. During its brief intrauterine passage, the fetus is dependent on the placenta for pulmonary, hepatic, and renal functions. These are accomplished through the unique placental anatomical association with the maternal interface. The placenta links mother and fetus by indirect interaction with maternal blood that spurts into the intervillous space from uteroplacental vessels. Maternal blood bathes the outer syncytiotrophoblast to allow exchange of gases and nutrients with fetal capillary blood within connective tissue at the villous core. Fetal and maternal blood are not normally mixed in this hemochorial placenta. There is also a paracrine system that links mother and fetus through the anatomical and biochemical juxtaposition of extraembryonic chorion laeve of fetal origin and maternal decidua parietalis. This is an extraordinarily important arrangement for communication between fetus and mother and for maternal immunological acceptance of the conceptus (Guzeloglu-Kayisli and associate, 2009).

Fertilization and Implantation

Ovum Fertilization and Zygote Cleavage

The union of egg and sperm at fertilization represents one of the most important and fascinating processes in biology. Ovulation frees the secondary oocyte and adherent cells of the cumulus-oocyte complex from the ovary. Although technically this mass of cells is released into the peritoneal cavity, the oocyte is quickly engulfed by the infundibulum of the fallopian tube. Further transport through the oviduct is accomplished by directional movement of cilia and tubal peristalsis. Fertilization normally occurs in the oviduct, and it is generally agreed that it must take place within a few hours, and no more than a day after ovulation.

Because of this narrow window of opportunity, spermatozoa must be present in the tube at the time of oocyte arrival. Almost all pregnancies result when intercourse occurs during the 2 days preceding or on the day of ovulation. Thus, the postovulatory and postfertilization developmental ages are similar.

Steps involved with fertilization are highly complex. Molecular mechanisms allow passage of spermatozoa between follicular cells, through the zona pellucida, and into the oocyte cytoplasm leading to the formation of the zygote. These are reviewed by Primakoff and Myles (2002).

The timing of events in early human development is described as days or weeks postfertilization, that is, postconceptional. By contrast, in most chapters of this book, clinical pregnancy dating is calculated from the start of the last menstrual period. As discussed earlier, the length of the follicular phase of the cycle is subject to more variability than the luteal phase. Thus, 1 week postfertilization corresponds to approximately 3 weeks from the last menstrual period in women with regular 28-day cycles.

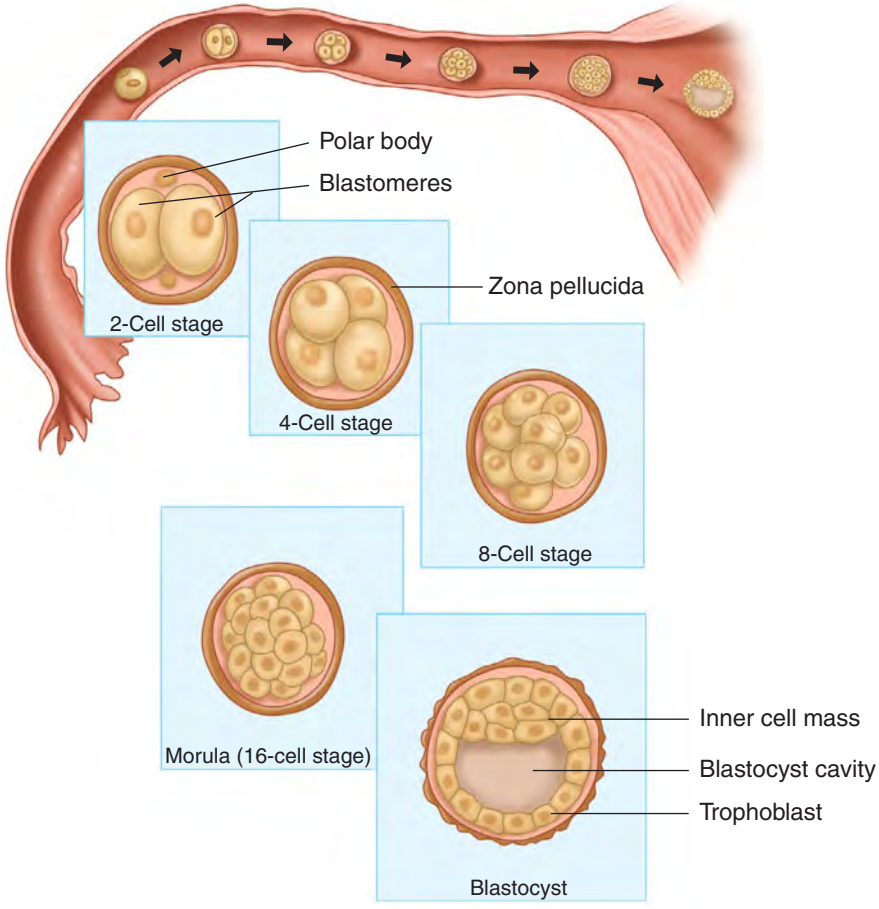

FIGURE 3-10 Zygote cleavage and formation of the blastocyst. The period of the morula begins at the 12- to 16-cell stage and ends when the blastocyst forms, which occurs when there are 50 to 60 blastomeres present. The zona pellucida has disappeared by the late blastocyst stage (5 days). The polar bodies, shown in the 2-cell stage, are small nonfunctional cells that soon degenerate.

After fertilization in the fallopian tube, the mature ovum becomes a *zygote*—a diploid cell with 46 chromosomes—that then undergoes cleavage into blastomeres (Fig. 3-10). In the two-cell zygote, the blastomeres and polar body are free in the perivitelline fluid and are surrounded by a thick *zona pellucida*. The zygote undergoes slow cleavage for 3 days while still within the fallopian tube. As the blastomeres continue to divide, a solid mulberry-like ball of cells—the *morula*—is produced. The morula enters the uterine cavity about 3 days after fertilization. Gradual accumulation of fluid between the cells of the morula results in the formation of the early *blastocyst*.

The Blastocyst

In the earliest stages of the human blastocyst, the wall of the primitive blastodermic vesicle consists of a single layer of ectoderm. As early as 4 to 5 days after fertilization, the 58-cell blastula differentiates into five embryo-producing cells—the *inner cell mass,* and 53 cells destined to form trophoblasts (Hertig, 1962). In a 58-cell blastocyst, the outer cells, called the *trophectoderm,* can be distinguished from the inner cell mass that forms the embryo (see Fig. 3-10).

Interestingly, the 107-cell blastocyst is found to be no larger than the earlier cleavage stages, despite the accumulated fluid. It measures about 0.155 mm in diameter, which is similar to the size of the initial postfertilization zygote. At this stage, the eight formative, or embryo-producing cell, are surrounded by 99 trophoblastic cells. It is at this stage that the blastocyst is released from the zona pellucida as a result of secretion of specific proteases from the secretory-phase endometrial glands (O'Sullivan and colleagues, 2002).

Release from the zona pellucida allows blastocyst-produced cytokines and hormones to directly influence endometrial receptivity (Lindhard and colleagues, 2002). Evidence has accumulated that IL-1α and IL-1β are secreted by the blastocyst and that these cytokines can directly influence the endometrium. Embryos also have been shown to secrete human chorionic gonadotropin (hCG), which may influence endometrial receptivity (Licht and coworkers, 2001; Lobo and colleagues, 2001). The receptive endometrium is thought to respond by producing leukemia inhibitory factor (LIF) and colony-stimulating factor-1 (CSF-1). These serve to increase trophoblast protease production that degrades selected endometrial extracellular matrix proteins and allows trophoblast invasion. Thus, embryo "hatching" is a critical step toward successful pregnancy as it allows association of trophoblasts with endometrial epithelial cells and permits release of trophoblast-produced hormones into the uterine cavity.

Blastocyst Implantation

Implantation of the embryo into the uterine wall is a common feature of all mammals. In women, it takes place 6 or 7 days after fertilization. This process can be divided into three phases: (1) apposition—initial adhesion of the blastocyst to the uterine wall; (2) adhesion—increased physical contact between the blastocyst and uterine epithelium; and (3) invasion—penetration and invasion of syncytiotrophoblast and cytotrophoblast into the endometrium, inner third of the myometrium, and uterine vasculature.

Successful implantation requires receptive endometrium appropriately primed with estrogen and progesterone. As shown in Figure 3-1, uterine receptivity is limited to days 20 to 24 of the cycle (Bergh and Navot, 1992). Adherence to epithelium is mediated by cell-surface receptors at the implantation site that interact with receptors on the blastocyst (Carson, 2002; Lessey and Castelbaum, 2002; Lindhard and associates, 2002; Paria and colleagues, 2002). Development of a receptive epithelium results from the postovulatory production of estrogen and progesterone by the corpus luteum. If the blastocyst approaches the endometrium after cycle day 24, the potential for adhesion is diminished because synthesis of antiadhesive glycoproteins prevents receptor interactions (Navot and Bergh, 1991).

At the time of its interaction with the endometrium, the blastocyst is composed of 100 to 250 cells. The blastocyst loosely adheres to the endometrial epithelium by *apposition.* This most commonly occurs on the upper posterior uterine wall. In women, syncytiotrophoblast has not been distinguished prior to implantation. Attachment of the trophectoderm of the blastocyst to the endometrial surface by apposition and adherence appears to be closely regulated by paracrine interactions between these two tissues.

Successful endometrial blastocyst adhesion involves modification in expression of cellular adhesion molecules (CAMs). The *integrins*—one of four families of CAMs—are cell-surface receptors that mediate adhesion of cells to extracellular matrix proteins (Lessey and Castelbaum, 2002). Great diversity of cell binding to a host of different extracellular matrix proteins is possible by differential regulation of the integrin receptors. Endometrial integrins are hormonally regulated, and a specific set of integrins expressed at implantation (Lessey and colleagues, 1996). Specifically, αVβ3 and α4β1 integrins expressed on endometrial epithelium are considered a marker of receptivity for blastocyst attachment. Aberrant expression of αVβ3 has been associated with infertility (Lessey and coworkers, 1995).

Biology of the Trophoblast

The formation of the human placenta begins with the trophectoderm, which is first to differentiate at the morula stage. It gives rise to the layer of trophoblast cells encircling the blastocyst. And then until term, the trophoblast plays critical roles at the fetal-maternal interface. Trophoblast exhibits the most variable structure, function, and developmental pattern of all placental components. Its invasiveness provides for implantation, its role in nutrition of the conceptus is reflected in its name, and its function as an endocrine organ is essential to maternal physiological adaptations and to maintenance of pregnancy.

Trophoblast Differentiation

By the eighth day postfertilization, after initial implantation, the trophoblast has differentiated into an outer multinucleated syncytium—primitive *syncytiotrophoblast,* and an inner layer of primitive mononuclear cells—*cytotrophoblast* (**Fig. 3-11**). The latter are germinal cells for the syncytium and are the primary secretory component within the placenta. Although the ability to undergo DNA synthesis and mitosis, a well-demarcated cell border, and a single nucleus characterize each cytotrophoblast, these characteristics are lacking in the syncytiotrophoblast (Arnholdt and colleagues, 1991). It is so named because it has no individual cells. Instead, it has an amorphous cytoplasm without cell borders, nuclei that are multiple and diverse in size and shape, and a continuous syncytial lining. This configuration aids transport across the syncytiotrophoblast, because control of transport is not dependent on the participation of individual cells.

After implantation is complete, the trophoblast further differentiates along two main pathways, giving rise to villous and extravillous trophoblast. As shown in **Figure 3-12**, both pathways give rise to populations of trophoblast cells that have distinct functions when in contact with maternal tissues (Loke and King, 1995). The *villous trophoblast* gives rise to the chorionic villi, which primarily transport oxygen and nutrients between the fetus and mother. The *extravillous trophoblast* migrates into the decidua and myometrium and also penetrates maternal vasculature, thus coming into contact with a variety of maternal cell types (Pijnenborg, 1994). The extravillous trophoblast is thus further classified as *interstitial trophoblast* and *endovascular trophoblast.* The interstitial trophoblast invades the decidua and eventually penetrates the myometrium to form placental bed

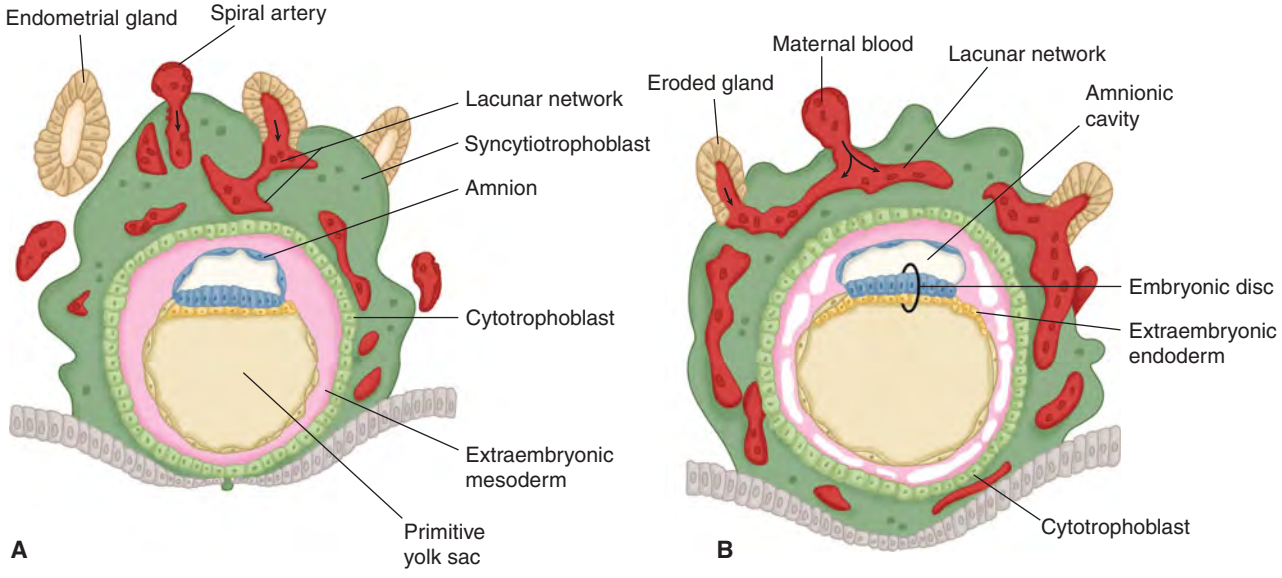

FIGURE 3-11 Drawing of sections through implanted blastocysts. **A.** At 10 days. **B.** At 12 days after fertilization. The stage of development is characterized by the intercommunication of the lacunae filled with maternal blood. Note in **(B)** that large cavities have appeared in the extraembryonic mesoderm, forming the beginning of the extraembryonic coelom. Also note that extraembryonic endodermal cells have begun to form on the inside of the primitive yolk sac. (Adapted from Moore, 1988.)

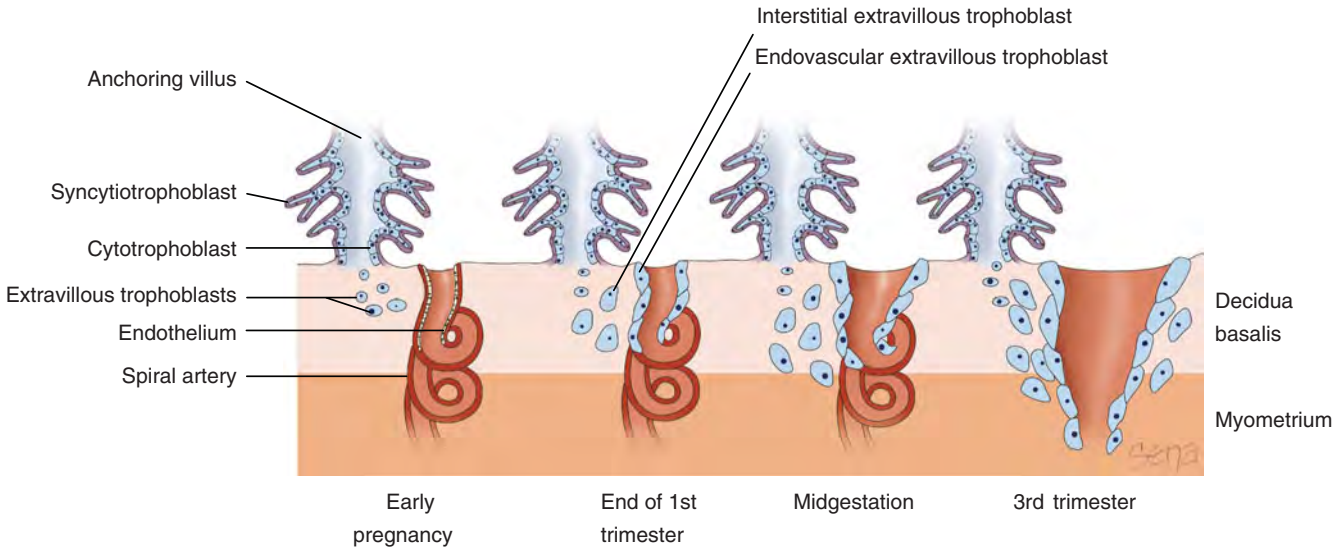

FIGURE 3-12 Extravillous trophoblasts are found outside the villus and can be subdivided in endovascular and interstitial categories. Endovascular trophoblasts invade and transform spiral arteries during pregnancy to create low-resistance blood flow that is characteristic of the placenta. Interstitial trophoblasts invade the decidua and surround spiral arteries.

giant cells. These trophoblasts also surround spiral arteries. The endovascular trophoblast penetrates the lumen of the spiral arteries (Pijnenborg and colleagues, 1983). These are both discussed in greater detail in sections that follow.

Embryonic Development after Implantation

Early Trophoblast Invasion

After gentle erosion between epithelial cells of the surface endometrium, invading trophoblasts burrow deeper, and by the 10th day, the blastocyst becomes totally encased within endometrium (Fig. 3-13). The mechanisms leading to trophoblast invasion into the endometrium are similar to the characteristics of metastasizing malignant cells. They are discussed further on page 53.

At 9 days of development, the blastocyst wall facing the uterine lumen is a single layer of flattened cells (Figs. 3-11 and 3–14). The opposite, thicker wall comprises two zones—the trophoblasts and the embryo-forming inner cell mass. As early as 7½ days after fertilization, the inner cell mass or embryonic disc is differentiated into a thick plate of

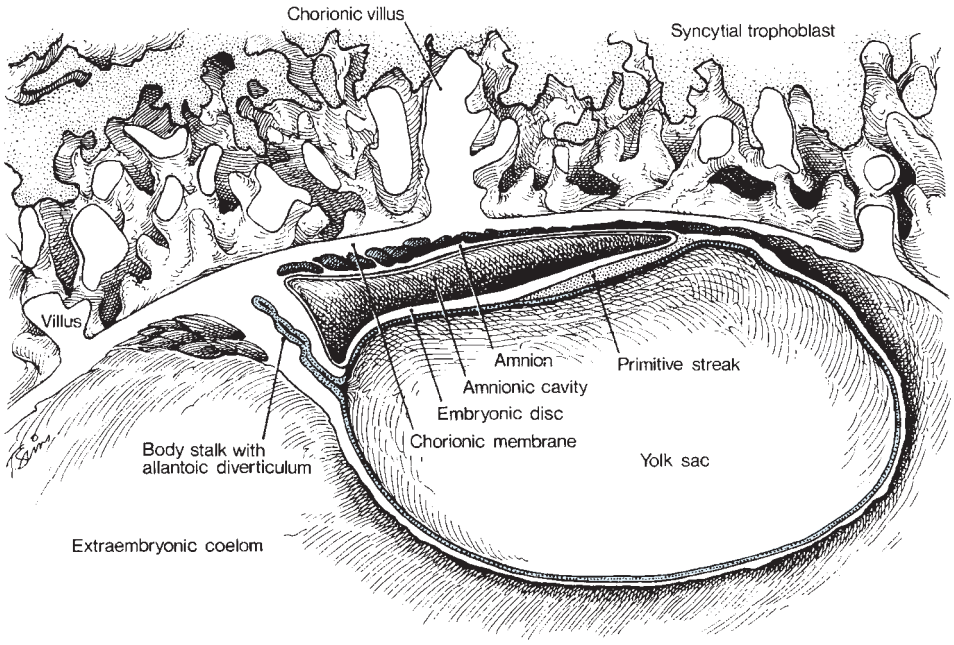

FIGURE 3-15 Median view of a drawing of a wax reconstruction of an 18-day-old Mateer-Streeter embryo shows the amnionic cavity and its relations to chorionic membrane and yolk sac (×500). (After Streeter, 1920.)

primitive ectoderm and an underlying layer of endoderm. Some small cells appear between the embryonic disc and the trophoblast and enclose a space that will become the amnionic cavity.

Embryonic mesenchyme first appears as isolated cells within blastocyst cavity. When the cavity is completely lined with mesoderm, it is termed the *chorionic vesicle,* and its membrane, now called the *chorion,* is composed of trophoblasts and mesenchyme. The amnion and yolk sac are illustrated in Figure 3-15. Mesenchymal cells within the cavity are the most numerous and eventually will condense to form the body stalk. This stalk joins the embryo to the nutrient chorion and later develops into the umbilical cord. The body stalk can be recognized at an early stage at the caudal end of the embryonic disc.

Lacunae Formation within the Syncytiotrophoblast

Beginning about 12 days after conception, the syncytiotrophoblast of the trophoblast shell is permeated by a system of intercommunicating channels called trophoblastic lacunae. As the embryo enlarges, more maternal decidua basalis is invaded by basal syncytiotrophoblast. After invasion of superficial decidual capillary walls, lacunae become filled with maternal blood (see Fig. 3-11). At the same time, the decidual reaction intensifies in the surrounding stroma, which is characterized by enlargement of the decidual stromal cells and glycogen storage.

Development of Primary Villous Stalks

With deeper blastocyst invasion into the decidua, the extravillous cytotrophoblasts give rise to solid primary villi composed of a cytotrophoblast core covered by syncytium. These arise from buds of cytotrophoblast that begin to protrude into the primitive syncytium before 12 days postfertilization. As the lacunae join, a complicated labyrinth is formed that is partitioned by these solid cytotrophoblastic columns. The trophoblast-lined labyrinthine channels form the intervillous space, and the solid cellular columns form the primary villous stalks. The villi initially are located over the entire blastocyst surface. They later disappear except over the most deeply implanted portion, which is destined to form the placenta.

Placental Organization

The term *hemochorial* is used to describe human placentation. It derives from *hemo* referring to maternal blood, which directly bathes the syncytiotrophoblast, and *chorio* for chorion (placenta). The older term *hemochorioendothelial* takes into consideration that chorionic tissue is separated from fetal blood by the *endothelial* wall of the fetal capillaries that traverse the villous core.

Chorionic Villi

Beginning on approximately the 12th day after fertilization, chorionic villi can first be distinguished. Mesenchymal cords derived from extraembryonic mesoderm invade the solid trophoblast columns. These form *secondary villi.* After angiogenesis begins in the mesenchymal cores, the resulting villi are termed *tertiary.* Although maternal venous sinuses are tapped early in implantation, maternal arterial blood does not enter the intervillous space until around day 15. By approximately the 17th day, however, fetal blood vessels are functional, and a placental circulation is established. The fetal–placental circulation is completed when embryonic blood vessels are connected with chorionic vessels. In some villi, there is failure of angiogenesis from lack of circulation. They can be seen normally, but the

most striking exaggeration of this process is seen with hydatidiform mole (see Chap. 11, p. 257).

Villi are covered by the outer layer of syncytium and inner layer of cytotrophoblasts, which are also known as *Langhans cells* (see Fig. 3-12). Cytotrophoblast proliferation at the villous tips produce the trophoblastic cell columns that form *anchoring villi*. They are not invaded by fetal mesenchyme, and they are anchored to the decidua at the basal plate. Thus, the base of the intervillous space faces the maternal side and consists of cytotrophoblasts from cell columns, the covering shell of syncytiotrophoblast, and maternal decidua of the basal plate. The base of the chorionic plate forms the roof of the intervillous space and consists of two layers of trophoblasts externally and fibrous mesoderm internally. The "definitive" chorionic plate is formed by 8 to 10 weeks as the amnionic and primary chorionic plate mesenchyme fuse together. This formation is accomplished by expansion of the amnionic sac, which also surrounds the connective stalk and the allantois and joins these structures to form the umbilical cord (Kaufmann and Scheffen, 1992).

Villus Ultrastructure

Interpretation of the fine structure of the placenta came from electron microscopic studies of Wislocki and Dempsey (1955). There are prominent microvilli on the syncytial surface that correspond to the so-called brush border described by light microscopy (**Fig. 3-16**). Associated pinocytotic vacuoles and vesicles are related to absorptive and secretory placental functions. Microvilli act to increase surface area in direct contact with maternal blood. This contact between the trophoblastic surface and maternal blood is the defining characteristic of the hemochorial placenta.

The human hemochorial placenta can be subdivided into hemodichorial or hemomonochorial (Enders, 1965). The dichorial type is more prominent during the first trimester of gestation. It consists of the inner layer of the cytotrophoblasts with the associated basal lamina, covered by a layer of syncytiotrophoblasts (see Fig. 3-16). Later in gestation the inner layer of cytotrophoblasts is no longer continuous, and by term there are only scattered cells present (**Fig. 3-17**). These create a narrower hemomonochorial barrier that aids nutrient and oxygen transport to the fetus.

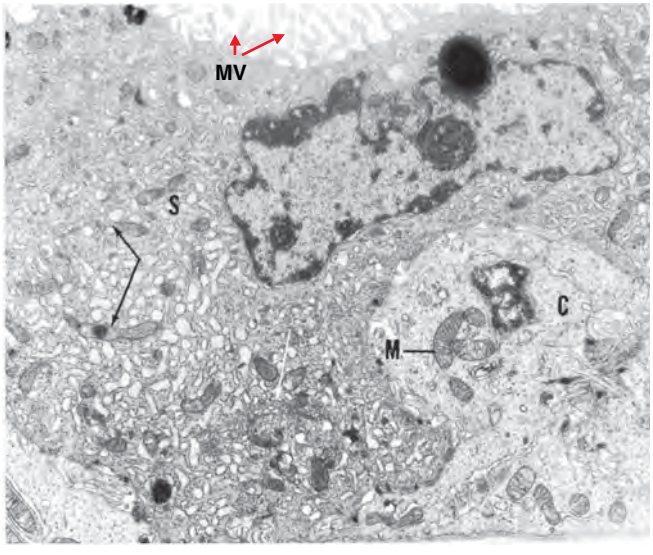

FIGURE 3-16 Electron micrograph of first-trimester human placenta showing well-differentiated syncytiotrophoblast (S) with numerous mitochondria (*black arrows*). Cytotrophoblast (C) has large mitochondria (M) but few other organelles. At the top, there is a prominent border of microvilli (*red arrows*) arising from the syncytium.

Placental Development

Development of the Chorion and Decidua

In early pregnancy, the villi are distributed over the entire periphery of the chorionic membrane. A blastocyst dislodged from the endometrium at this stage of development appears shaggy (**Fig. 3-18**). As the blastocyst with its surrounding trophoblasts grows and expands into the decidua, one pole extends outward toward the endometrial cavity. The opposite pole will form the placenta from villous trophoblasts and anchoring cytotrophoblasts. Chorionic villi in contact with the decidua basalis proliferate to form the *chorion frondosum*—or leafy chorion—which is the fetal component of the placenta. As growth of embryonic and extraembryonic tissues continues, the blood supply of the chorion facing the endometrial cavity is restricted. Because of this, villi in contact with the decidua capsularis cease to grow and degenerate. This portion of the chorion becomes the avascular fetal membrane that abuts the decidua parietalis, that is, the chorion laeve—or

FIGURE 3-18 Photograph of an opened chorionic sac. An early embryo and yolk sac are seen. Note the prominent fringe of chorionic villi. (From *The Human Placenta*, JD Boyd and WJ Hamilton (eds), p. 84. Copyright © 1970 Heffer & Sons, Ltd. Reproduced with permission of Blackwell Publishing Ltd.)

smooth chorion. The chorion laeve is generally more translucent than the amnion and rarely exceeds 1-mm thickness. The chorion is composed of cytotrophoblasts and fetal mesodermal mesenchyme that survives in a relatively low-oxygen atmosphere.

Until near the end of the third month, the chorion laeve is separated from the amnion by the exocoelomic cavity. Thereafter, they are in intimate contact to form an avascular amniochorion. These two structures are important sites of molecular transfer and metabolic activity. Moreover, they constitute an important paracrine arm of the fetal–maternal communication system.

With continued expansion of the embryo–fetus, the uterine lumen is obliterated, and the chorion laeve becomes contiguous with the entire maternal decidua parietalis that is not occupied by the placenta. As the fetus grows, the decidua capsularis merges with the parietalis. The capsularis then is largely lost by pressure and the attendant loss of blood supply. The area of decidua where decidua capsularis and decidua parietalis merge is referred to as the *decidua vera*.

Maternal Regulation of Trophoblast Invasion and Vascular Growth. Decidual natural killer cells (dNK) accumulate in the decidua during the first half of pregnancy and are found in direct contact with trophoblasts. As described on page 46, these cells lack cytotoxic functions as well as other unique properties that distinguish them from circulating natural killer cells and from natural killer cells in the endometrium prior to pregnancy (Manaster and co-workers, 2008). This is important because it prevents them from recognizing and destroying fetal cells as "foreign." Hanna and associates (2006) have elucidated the ability of dNK cells to attract and promote invasion of trophoblast into the decidua and promote vascular growth. Decidual NK cells express both interleukin-8 and interferon-inducible protein-10, which bind to receptors on invasive trophoblast cells to promote their invasion into the decidua toward the spiral arteries. Decidual NK cells also produce proangiogenic factors, including VEGF and placental growth factor (PlGF), which promote vascular growth in the decidua. In addition, trophoblasts secrete specific chemokines that attract the dNK cells to the maternal-fetal interface. Thus, both cell types simultaneously attract each other to promote decidual population.

Trophoblast Invasion of the Endometrium.

The extravillous trophoblast of the first-trimester placenta are highly invasive. They form columns of cells that extend from the endometrium to the inner third of the myometrium. Recall that hemochorial placental development requires invasion of endometrium and spiral arteries. The invasive ability of trophoblasts results from their ability to secrete numerous proteolytic enzymes capable of digesting the extracellular matrix as well as activating proteinases already present in the endometrium. Trophoblasts produce urokinase-type plasminogen activator, which converts plasminogen into the broadly acting serine protease *plasmin*. This in turn both degrades matrix proteins and activates matrix metalloproteinases (MMPs), which are a family of structurally similar enzymes. One member of the family, matrix metalloproteinase-9 (MMP-9), appears to be critical for human trophoblast invasion. MMP-9 production is increased by trophoblast factors such as IL-1 and hCG as well as paracrine uterine factors such as leukemia inhibiting factor and colony-stimulating factor-1 (Bischof, 2002; Fitzgerald, 2008; Librach, 1991, and all their colleagues).

The relative ability to invade maternal tissue in early pregnancy compared with limited invasiveness in late pregnancy is controlled by autocrine and paracrine trophoblastic and endometrial factors. Trophoblasts secrete insulin-like growth factor II, which acts in an autocrine manner. It promotes invasion into the endometrium, whereas decidual cells secrete insulin-like growth factor binding protein type 4, which blocks this autocrine loop. Thus, the degree of trophoblast invasion is controlled by regulation of matrix degradation as well as by factors that cause trophoblast migration.

Integrin subunit expression also appears important to control trophoblast invasion and adhesive interactions between trophoblast cells during column formation. Recall that the decidual cell becomes completely encased by a pericellular extracellular matrix membrane. This "wall" around the decidual cell provides a scaffolding for attachment of the cytotrophoblasts of the anchoring villi. The cytotrophoblast first elaborate selected proteinases that degrade decidual extracellular matrix. Thereafter, expression of a specific group of integrins enables the docking of these cells. There are also integrin-mediated adhesive interactions of trophoblast cells with each other. In particular, the interaction of L-selectin with its carbohydrate ligands in the cytotrophoblast is important in formation and maintenance of cell columns (Prakobphol and colleagues, 2006). Trophoblasts are further secured by fetal fibronectin (Feinberg and colleagues, 1991). Fetal-specific fibronectin (fFN) is a unique glycopeptide of the

fibronectin molecule. It is also called *trophoblast glue* to describe a critical role in the migration and attachment of trophoblasts to maternal decidua. And related, presence of fFN in cervical or vaginal fluid is used as a prognostic indicator for preterm labor (see Chap. 36, p. 816).

Invasion of Spiral Arteries

One of the most remarkable features of human placental development is the extensive modification of maternal vasculature by trophoblasts, which are by definition of fetal origin. These events occur in the first half of pregnancy and are considered in detail because of their importance to uteroplacental blood flow. They are also integral to some pathological conditions such as preeclampsia and fetal-growth restriction (see Chap. 34, p. 710). Modifications of spiral arteries are carried out by two populations of extravillous trophoblast—interstitial trophoblast, which surrounds the arteries, and endovascular trophoblast, which penetrates the spiral artery lumen (see Fig. 3-12). Although earlier work has focused on the role of the endovascular trophoblast, function of the interstitial trophoblast has more recently been investigated (Benirschke and Kaufmann, 2000; Pijnenborg and colleagues, 1983). These interstitial cells are now recognized to constitute a major portion of the placental bed, penetrating the decidua and adjacent myometrium. They aggregate around spiral arteries, and their functions may include vessel preparation for endovascular trophoblast invasion.

Endovascular trophoblast enters the lumen of the spiral arteries and initially forms cellular plugs. It then destroys vascular endothelium via an apoptosis mechanism and invades and modifies vascular media. Thus, fibrinoid material replaces smooth muscle and connective tissue of the vessel media. Spiral arteries later regenerate endothelium. Hamilton and Boyd (1966) report that Friedlander in 1870 first described structural changes in spiral arteries. Invading endovascular trophoblast can extend several centimeters along the vessel lumen, and they must migrate against arterial flow. These vascular changes are not observed in the decidua parietalis, that is, in decidual sites removed from the invading cytotrophoblasts. Of note, invasion by trophoblasts involves only the decidual spiral arteries and not decidual veins.

In their summary of anatomical studies of the uteroplacental vasculature, Ramsey and Donner (1980) described that development of these uteroplacental vessels proceeds in two waves or stages. The first wave occurs before 12 weeks postfertilization and consists of invasion and modification of spiral arteries up to the border between deciduas and myometrium. The second wave is between 12 and 16 weeks and involves some invasion of the intramyometrial segments of spiral arteries. The remodeling by this two-phase invasion converts narrow-lumen, muscular spiral arteries into dilated, low-resistance uteroplacental vessels. Molecular mechanisms of these crucial events, and their significance in the pathogenesis of preeclampsia and fetal-growth restriction, have been reviewed by Kaufmann (2003) and Red-Horse (2006) and their associates.

Establishment of Maternal Blood Flow

About 1 month after conception, maternal blood enters the intervillous space in fountain-like bursts from the spiral arteries. Blood is propelled outside of the maternal vessels and sweeps over and directly bathes the syncytiotrophoblast. The apical surface of the syncytiotrophoblast consists of a complex microvillous structure that undergoes continual shedding and reformation during pregnancy.

Villus Branching

Although certain villi of the chorion frondosum extend from the chorionic plate to the decidua to serve as anchoring villi, most arborize and end freely in the intervillous space. As gestation proceeds, the short, thick, early stem villi branch to form progressively finer subdivisions and greater numbers of increasingly smaller villi (**Fig. 3-19**). Each of the truncal or main stem villi and their ramifications (rami) constitute a placental *lobule,* or *cotyledon.* Each lobule is supplied with a single truncal branch of the chorionic artery. And each lobule has a single vein so that lobules constitute functional units of placental architecture.

Placental Growth and Maturation

Placental Growth

In the first trimester, placental growth is more rapid than that of the fetus. But by approximately 17 postmenstrual weeks, placental and fetal weights are approximately equal. By term, placental weight is approximately one sixth of fetal weight. According to Boyd and Hamilton (1970), the average placenta at term is 185 mm in diameter and 23 mm in thickness, with a volume of 497 mL and a weight of 508 g. These measurements vary widely, and there are multiple variant placental forms and several types of umbilical cord insertions. These are discussed in detail in Chapter 27 (p. 577).

Viewed from the maternal surface, the number of slightly elevated convex areas, called *lobes,* varies from 10 to 38. Lobes are incompletely separated by grooves of variable depth that overlie *placental septa,* which arise from folding of the basal plate. Although grossly visible lobes are commonly referred to as cotyledons, this is not accurate. Correctly used, lobules or cotyledons are the functional units supplied by each primary villus.

The total number of placental lobes remains the same throughout gestation, and individual lobes continue to grow—although less actively in the final weeks (Crawford, 1959).

Placental Maturation

As villi continue to branch and the terminal ramifications become more numerous and smaller, the volume and prominence of cytotrophoblasts decrease. As the syncytium thins, the fetal vessels become more prominent and lie closer to the surface. The villous stroma also exhibits changes as gestation progresses. In early pregnancy, the branching connective-tissue cells are separated by an abundant loose intercellular matrix. Later, the stroma becomes denser and the cells more spindly and more closely packed.

Another change in the stroma involves the infiltration of *Hofbauer cells,* which are fetal macrophages. These are nearly round with vesicular, often eccentric nuclei and very granular or vacuolated cytoplasm. Hofbauer cells are characterized histochemically by intracytoplasmic lipid and by phenotypic markers specific for macrophages. They increase in numbers and

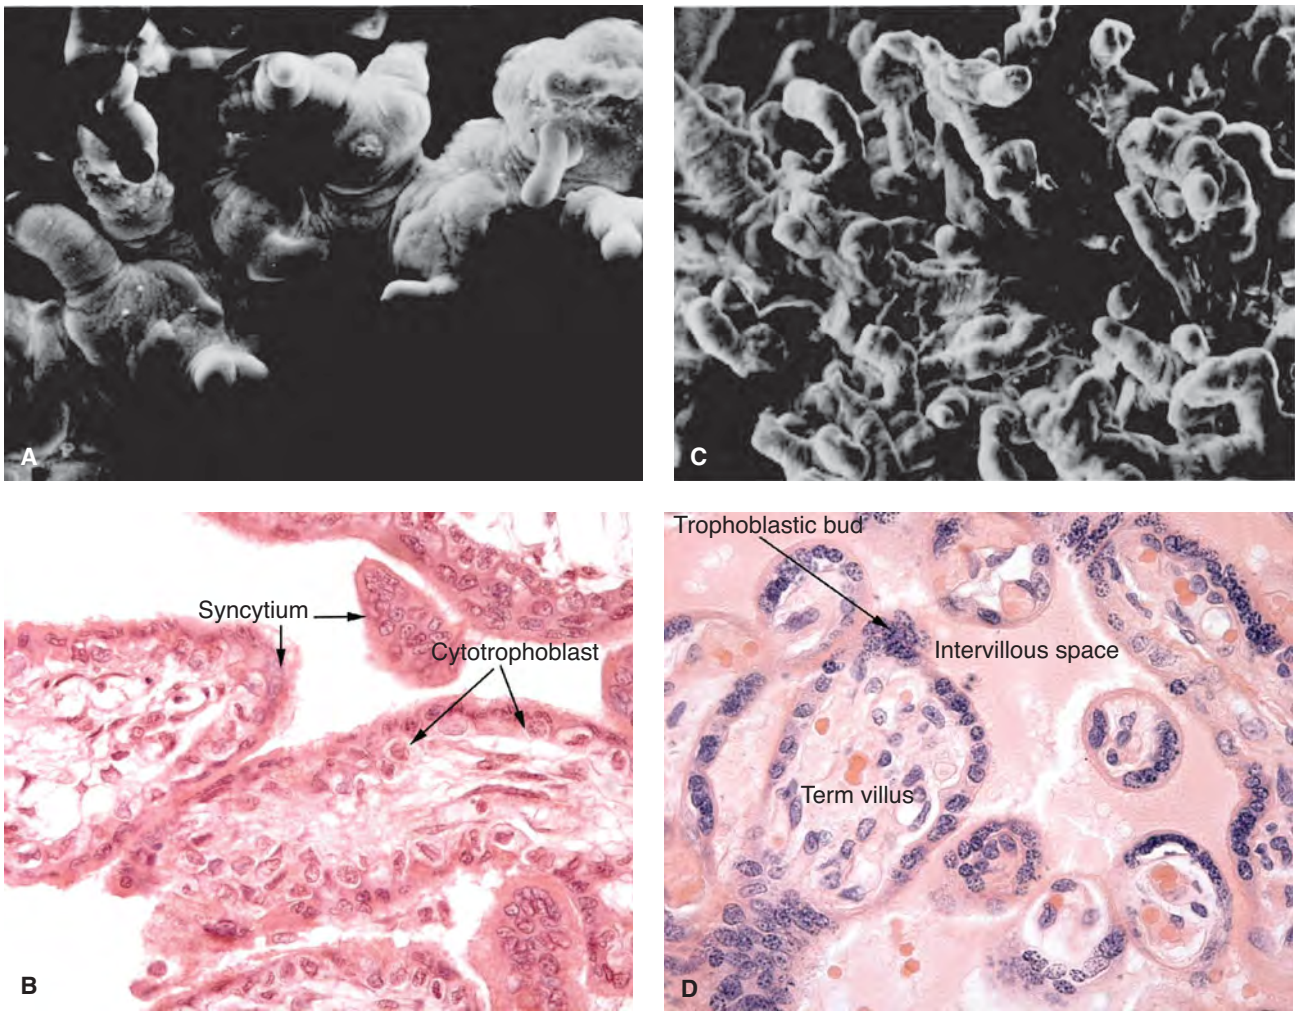

FIGURE 3-19 Electron micrographs **(A, C)** and photomicrographs **(B, D)** of early and late human placentas. **A** and **B.** Limited branching of villi is seen in this early placenta. **C** and **D.** With placenta maturation, increasing villous arborization is seen, and villous capillaries lie closer to the surface of the villus. (The electron micrographs were published in *American Journal of Obstetrics & Gynecology,* Vol. 122, No. 7, BF King and DN Menton, Scanning electron microscopy of human placental villi from early and late in gestation, pp. 824–828, Copyright Elsevier 1975. Photomicrographs used with permission from Dr. Kurt Benirschke.)

maturation state throughout pregnancy. These macrophages are phagocytic, have an immunosuppressive phenotype, can produce a variety of cytokines, and are capable of paracrine regulation of trophoblast functions (Cervar and colleagues, 1999; Vince and Johnson, 1996).

Some of the histological changes that accompany placental growth and maturation provide an increased efficiency of transport and exchange to meet increasing fetal metabolic requirements. Among these changes are decreased syncytiotrophoblastic thickness, significant cytotrophoblast reduction, decreased stroma, and increased number of capillaries with their approximation to the syncytial surface. By 16 weeks the apparent continuity of the cytotrophoblasts is lost. At term, the covering of the villi may be focally reduced to a thin layer of syncytium with minimal connective tissue in which thin-walled fetal capillaries abut the trophoblast and dominate the villi.

There are some changes in placental architecture that can cause decreased efficiency of placental exchange if they are substantive. These include thickening of basal lamina of trophoblast or capillaries, obliteration of certain fetal vessels, and fibrin deposition on the villi surface.

Fetal and Maternal Blood Circulation in the Mature Placenta

Because the placenta is functionally an intimate approximation of the fetal capillary bed to maternal blood, its gross anatomy primarily concerns vascular relations. The fetal surface is covered by the transparent amnion, beneath which chorionic vessels course. A section through the placenta includes amnion, chorion, chorionic villi and intervillous space, decidual (basal) plate, and myometrium (**Figs. 3-20, 3-21, 3-22**). The maternal surface is divided into irregular lobes by furrows produced by septa, which consist of fibrous tissue with sparse vessels. The broad-based septa ordinarily do not reach the chorionic plate, thus providing only incomplete partitions (**Fig. 3-23**).

Fetal Circulation

Deoxygenated venous-like fetal blood flows to the placenta through the two umbilical arteries. As the cord joins the placenta, these umbilical vessels branch repeatedly beneath the amnion and again within the dividing villi, finally forming capillary networks in the terminal divisions. Blood with significantly higher oxygen content returns from the placenta via a single umbilical vein to the fetus.

The branches of the umbilical vessels that traverse along the fetal surface of the placenta in the chorionic plate are referred to as the *placental surface* or *chorionic vessels.* These vessels are responsive to vasoactive substances, but anatomically, morphologically, histologically, and functionally, they are unique. *Chorionic arteries always cross over chorionic veins.* Vessels are most readily recognized by this interesting relationship, but they are difficult to distinguish by histological criteria. In 65 percent of placentas, chorionic arteries form a fine network supplying the cotyledons—a pattern of disperse-type branching. The remaining 35 percent radiate to the edge of the placenta without narrowing. Both types are end arteries that supply one cotyledon as each branch turns downward to pierce the chorionic plate.

Truncal arteries are perforating branches of the surface arteries that pass through the chorionic plate. Each truncal artery supplies one cotyledon. There is a decrease in smooth muscle of the vessel wall and an increase in the caliber of the vessel as it penetrates through the chorionic plate. The loss in muscle continues as the truncal arteries and veins branch into their rami.

Before 10 weeks, there is no end-diastolic flow pattern within the umbilical artery at the end of the fetal cardiac cycle (Cole, 1991; Fisk, 1988; Loquet, 1988, and all their colleagues). After 10 weeks, end-diastolic flow appears and is maintained throughout normal pregnancy (Maulik, 1997). Clinically, these are studied with Doppler sonography to assess fetal well-being (see Chap. 16, p. 363).

Maternal Circulation

Because an efficient maternal–placental circulation is requisite, many investigators have sought to define factors that regulate blood flow into and from the intervillous space. An adequate mechanism must explain how blood can: (1) leave maternal circulation; (2) flow into an amorphous space lined by syncytiotrophoblast, rather than capillary endothelium; and (3) return through maternal veins without producing arteriovenous-like shunts that would prevent maternal blood from remaining in contact with villi long enough for adequate exchange. Early studies of Ramsey and Davis (1963) and Ramsey and Harris (1966) help to provide a physiological explanation of placental circulation. These investigators demonstrated, by careful, low-pressure injections of radiocontrast material, that arterial entrances as well as venous exits are scattered randomly over the entire base of the placenta.

The physiology of maternal-placental circulation is depicted in Figure 3-24. Maternal blood enters through the basal plate and is driven high up toward the chorionic plate by arterial

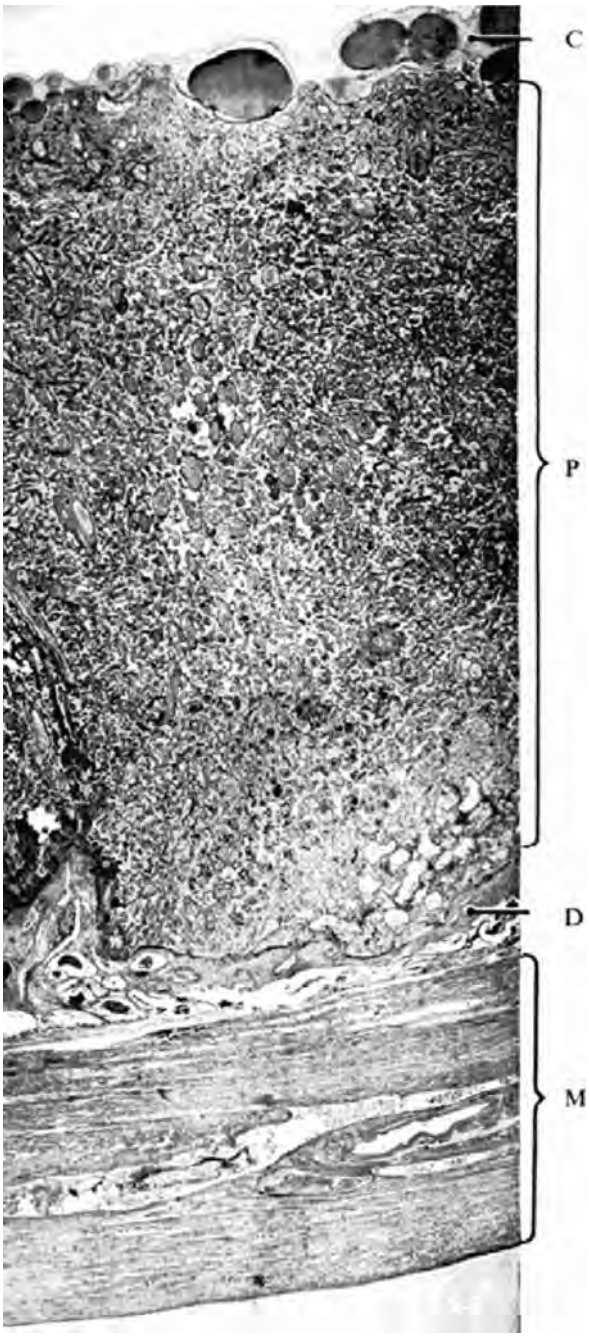

FIGURE 3-21 Photomicrograph of a histological section through amnion, chorion, and decidua basalis depicted in Figure 3-20A (*blue slice*). C = chorionic plate with fetal blood vessels; P = placental villi; D = decidua basalis; M = myometrium.

pressure before laterally dispersing. After bathing the external microvillous surface of chorionic villi, maternal blood drains back through venous orifices in the basal plate and enters uterine veins. Thus, maternal blood traverses the placenta randomly without preformed channels. The previously described trophoblast invasion of the spiral arteries creates low-resistance vessels that can accommodate massive increase in uterine perfusion over gestation. Generally, spiral arteries are perpendicular to, but veins are parallel to, the uterine wall. This

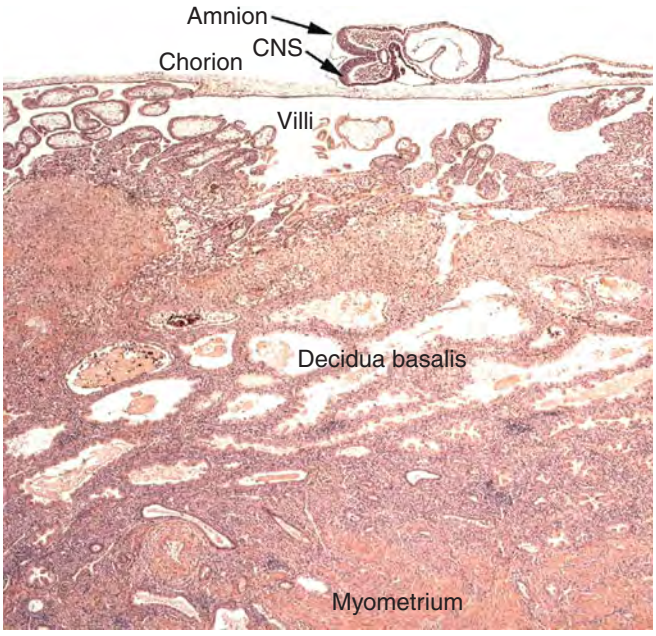

FIGURE 3-22 Photomicrograph of early implanted blastocyst. Trophoblasts are seen invading the decidua basalis. (Used with permission from Dr. Kurt Benirschke.)

arrangement aids closure of veins during a uterine contraction and prevents entry of maternal blood from the intervillous space. The number of arterial openings into the intervillous space becomes gradually reduced by cytotrophoblast invasion. According to Brosens and Dixon (1963), there are about 120 spiral arterial entries into the intervillous space at term. These discharge blood in spurts that bathes the adjacent villi (Borell and co-workers, 1958). After the 30th week, a prominent venous plexus separates the decidua basalis from the myometrium, thus participating in providing a plane of cleavage for placental separation.

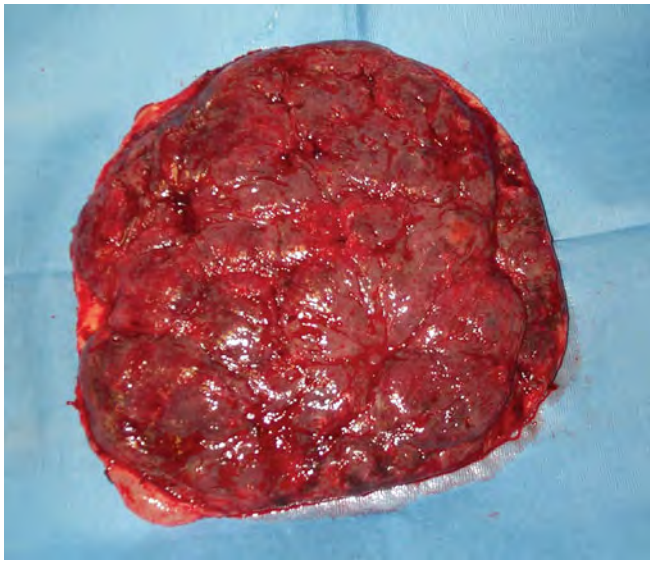

FIGURE 3–23 Photograph of the maternal surface of the placenta. Placenta lobes are formed by clefts on the surface that originate from placental septa. (Used with permission from Dr. Judith J. Head.)

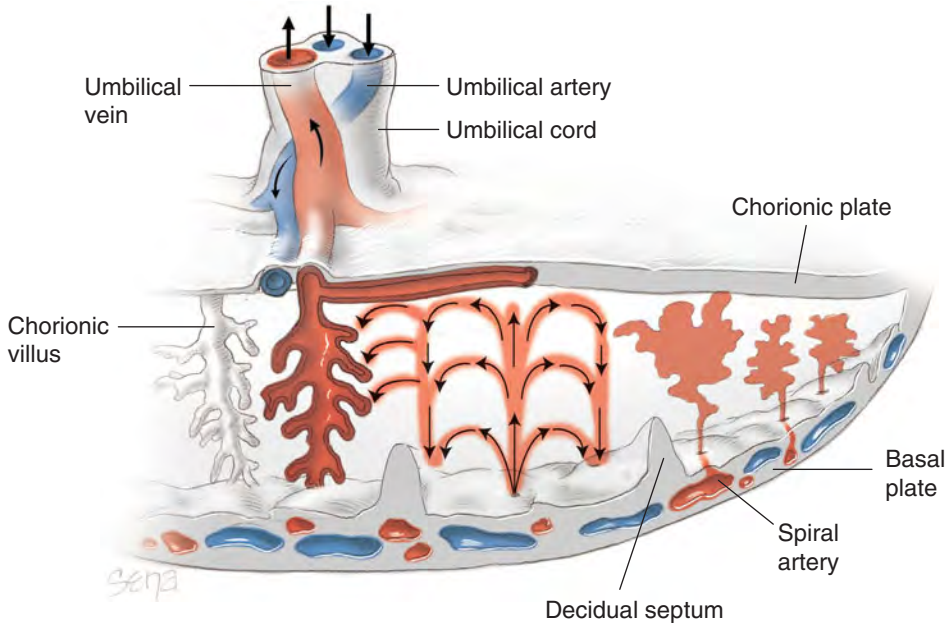

FIGURE 3–24 Schematic drawing of a section through a full-term placenta. Maternal blood flows into the intervillous spaces in funnel-shaped spurts. Exchanges occur with fetal blood as maternal blood flows around the villi. In-flowing arterial blood pushes venous blood into the endometrial veins, which are scattered over the entire surface of the decidua basalis. Note also that the umbilical arteries carry deoxygenated fetal blood to the placenta and that the umbilical vein carries oxygenated blood to the fetus. Placental lobes are separated from each other by placental (decidual) septa.

As discussed, both inflow and outflow are curtailed during uterine contractions. Bleker and associates (1975) used serial sonography during normal labor and found that placental length, thickness, and surface area increased during contractions. They attributed this to distension of the intervillous space as the consequence of relatively greater impairment of venous outflow compared with arterial inflow. During contractions, therefore, a somewhat larger volume of blood is available for exchange even though the rate of flow is decreased. Subsequently, by use of Doppler velocimetry, it was shown that diastolic flow velocity in spiral arteries is diminished during uterine contractions.

From these observations, it can be seen that principal factors regulating blood flow in the intervillous space are arterial blood pressure, intrauterine pressure, the pattern of uterine contractions, and factors that act specifically on arterial walls.

Breaks in the Placental "Barrier"

The placenta does not maintain absolute integrity of the fetal and maternal circulations. There are numerous examples of *trafficking* cells between mother and fetus in both directions. This situation is best exemplified clinically by erythrocyte D-antigen isoimmunization and *erythroblastosis fetalis* (see Chap. 29, p. 618). Desai and Creger (1963) found that, even under normal conditions, labeled maternal leukocytes and platelets crossed the placenta from mother to fetus. Although this likely is a small amount in most cases, occasionally the fetus exsanguinates into the maternal circulation. Indeed, in their recent review, Silver and colleagues (2007) found that fetomaternal hemorrhage accounted for 3 to 14 percent of stillbirths.

It is indisputable that fetal cells can become engrafted in the mother during pregnancy and can be identified decades later. Fetal lymphocytes and CD34+ mesenchymal stem cells reside in maternal blood or bone marrow (Nguyen and coworkers, 2006; Piper and colleagues, 2007). Termed *microchimerism*, such residual stem cells may participate in maternal tissue regeneration and have been implicated to explain the disparate female:male ratio of autoimmune disorders (Gleicher and Barad, 2007; Stevens, 2006). As discussed in Chapter 53 (p. 1127), they are associated with lymphocytic thyroiditis, scleroderma, and systemic lupus erythematosus.

Immunological Considerations of the Fetal–Maternal Interface

For more than 50 years, there have been many attempts to explain survival of the semiallogenic fetal graft. One of the earliest explanations was based on the theory of antigenic immaturity of the embryo-fetus. This was disproved by Billingham (1964), who showed that transplantation (HLA) antigens are demonstrable very early in embryonic life. Another theory posited diminished immunological responsiveness of the pregnant woman, but there is little evidence for this to be other than ancillary. In another explanation, the uterus (decidua) is proposed to be an immunologically privileged tissue site. However, this theory is challenged by cases of advanced ectopic pregnancies (see Chap. 10, p. 240). Thus, the enigma continues.

Clearly, there is no doubt that the lack of uterine transplantation immunity is unique compared with that of other tissues. Survival of the conceptus in the uterus can be attributed to an immunological peculiarity of cells involved in implantation and fetal-placental development. These include decidual natural killer cells with their inefficient cytotoxic abilities, decidual stromal cells, and invasive trophoblasts that populate the decidua (Hanna, 2006; Santoni, 2007; Staun-Ram, 2005, and all their co-workers). The trophoblasts are the only fetal-derived cells in direct contact with maternal tissues. Previous studies have suggested that maternal natural killer cells act to control the invasion of trophoblast cells, which have adapted to survive in an immunologically hostile environment (Thellin and associates, 2000). More recently Hanna and colleagues (2006) have reported a "peaceful" model of trophoblast invasion and maternal vascular remodeling. In this scheme, decidual natural killer cells work in concert with stromal cells. They mediate angiogenesis through production of proangiogenic factors such as VEGF and control trophoblast chemoattraction toward spiral arteries by production of interleukin-8 and interferon inducible protein-10.

Immunogenicity of the Trophoblasts

More than 50 years ago, Sir Peter Medawar (1953) suggested that survival of the fetal semiallograft might be explained by *immunological neutrality.* The placenta was considered immunologically inert and therefore unable to create a maternal immune response. Subsequently, research was focused on defining expression of the *major histocompatibility complex (MHC)* antigens on trophoblasts. *Human leukocyte antigens* (*HLAs*) are the human analogue of the MHC. And indeed, MHC class I and II antigens are absent from villous trophoblasts, which appear to be immunologically inert at all stages of gestation (Weetman, 1999). But invasive extravillous cytotrophoblasts do express MHC class I molecules, which have been the focus of considerable study.

Trophoblast HLA (MHC) Class I Expression

The HLA genes are the products of multiple genetic loci of the MHC located within the short arm of chromosome 6 (Hunt and Orr, 1992). There are 17 HLA class I genes, including three classic genes, *HLA-A*, *-B*, and *-C*, that encode the major class I (class Ia) transplantation antigens. Three other class I genes, designated *HLA-E, -F*, and *-G*, encode class Ib HLA antigens. The remaining DNA sequences appear to be pseudogenes or partial gene fragments.

Moffett-King (2002) reasoned that normal implantation depends on controlled trophoblastic invasion of maternal endometrium–decidua and spiral arteries. Such invasion must proceed far enough to provide for normal fetal growth and development, but there must be a mechanism for regulating its depth. She suggested that uterine decidual natural killer cells (uNK cells) combined with unique expression of three specific HLA class I genes in extravillous cytotrophoblasts act in concert to permit and subsequently limit trophoblast invasion.

Class I antigens in extravillous cytotrophoblasts are accounted for by the expression of classic HLA-C and nonclassical class Ib molecules of HLA-E and HLA-G. To elucidate the importance of HLA-C, HLA-E, and HLA-G expression, it is important to understand the unusual lymphocyte population of the decidua.

Uterine Natural Killer Cells (uNK)

These distinctive lymphocytes are believed to originate in bone marrow and belong to the natural killer cell lineage. They are by far the predominant population of leukocytes present in midluteal phase endometrium at the expected time of implantation (Johnson and colleagues, 1999). These uNKs have a distinct phenotype characterized by a high surface density of CD56 or neural cell adhesion molecule (Loke and King, 1995; Manaster and associates, 2008; Moffett-King, 2002). Their infiltration is increased by progesterone and by stromal cell production of IL-15 and decidual prolactin (Dunn and co-workers, 2002; Gubbay and colleagues, 2002).

Near the end of the luteal phase of nonfertile ovulatory cycles, the nuclei of the uterine NK cell begin to disintegrate. But if implantation proceeds, they persist in large numbers in the decidua during early pregnancy. By term, however, there are relatively few uNK cells in the decidua. In first-trimester decidua, there are many uNK cells in close proximity to extravillous trophoblast where it is speculated that they serve to regulate trophoblast invasion. These uNK cells secrete large amounts of granulocyte-macrophage–colony-stimulating factor (GM-CSF), which suggests that they are in an activated state. Jokhi and co-workers (1999) speculate that GM-CSF may function primarily to forestall trophoblast apoptosis and not to promote trophoblast replication. Expression of angiogenic factors by uNK cells also suggests a role in decidual vascular remodeling (Li and colleagues, 2001). In this case, it is uNKs, rather than the T lymphocytes, that are primarily responsible for decidual immunosurveillance.

HLA-G Expression in Trophoblasts

This antigen is expressed only in humans, and it has a highly restricted tissue distribution. It is expressed in cytotrophoblasts contiguous with maternal tissues, that is, decidual and uNK cells. Indeed, HLA-G antigen expression is identified only in extravillous cytotrophoblasts in the decidua basalis and in the chorion laeve (McMaster and colleagues, 1995). During pregnancy, a soluble major isoform—HLA-G2—is increased (Hunt and colleagues, 2000a, b). Embryos used for in vitro fertilization do not implant if they do not express this soluble HLA-G isoform (Fuzzi and colleagues, 2002). Thus, HLA-G may be immunologically permissive of the maternal-fetal antigen mismatch (LeBouteiller and colleagues, 1999). Finally, Goldman-Wohl and associates (2000) have provided evidence for abnormal HLA-G expression in extravillous trophoblasts from women with preeclampsia.

The Amnion

At term, the amnion is a tough and tenacious but pliable membrane. This innermost avascular fetal membrane is contiguous with amnionic fluid and occupies a role of incredible importance in human pregnancy. The amnion provides almost all tensile strength of the fetal membranes. Thus, development of its components that protect against its rupture or tearing is vitally important to successful pregnancy outcome. Indeed, preterm rupture of fetal membranes is a major cause of preterm delivery (see Chap. 36, p. 817).

Structure

Bourne (1962) described five separate layers of amnion. The inner surface, which is bathed by amnionic fluid, is an uninterrupted, single layer of cuboidal epithelium believed to be derived from embryonic ectoderm (**Fig. 3-25**). This epithelium is attached firmly to a distinct basement membrane that is connected to the acellular compact layer, which is composed primarily of interstitial collagens. On the outer side of the compact layer, there is a row of fibroblast-like mesenchymal cells, which are widely dispersed at term. These are probably derived from embryonic disc mesoderm. There also are a few fetal macrophages in the amnion. The outermost layer of amnion is the relatively acellular zona spongiosa, which is contiguous with the second fetal membrane, the chorion laeve. The human amnion lacks smooth muscle cells, nerves, lymphatics, and importantly, blood vessels.

Development

Early during implantation, a space develops between the embryonic cell mass and adjacent trophoblasts (see Fig. 3-11). Small cells that line this inner surface of trophoblasts have been called

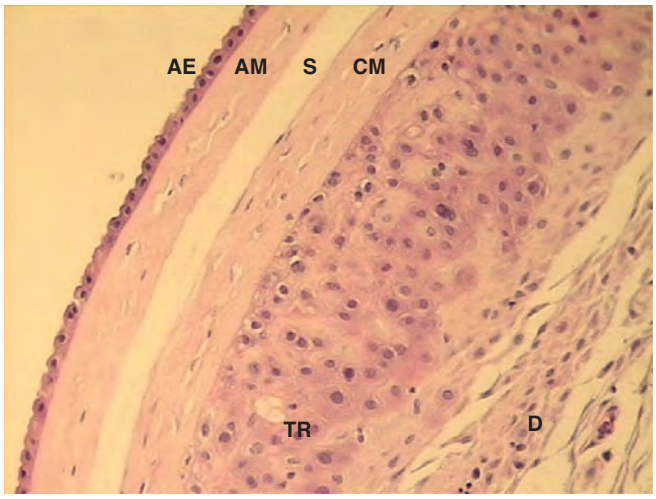

FIGURE 3-25 Photomicrograph of fetal membranes. From left to right: AE = amnion epithelium; AM = amnion mesenchyme; S = zona spongiosa; CM = chorionic mesenchyme; TR = trophoblast; D = decidua. (Used with permission from Dr. Judith R. Head.)

amniogenic cells—precursors of amnionic epithelium. The amnion is first identifiable about the seventh or eighth day of embryo development. It is initially a minute vesicle, which then develops into a small sac that covers the dorsal surface of the embryo. As the amnion enlarges, it gradually engulfs the growing embryo, which prolapses into its cavity (Benirschke and Kaufmann, 2000).

Distension of the amnionic sac eventually brings it into contact with the interior surface of the chorion laeve. Apposition of the chorion laeve and amnion near the end of the first trimester then causes an obliteration of the extraembryonic coelom. The amnion and chorion laeve, although slightly adherent, are never intimately connected and can be separated easily.

Amnion Cell Histogenesis. It is now generally accepted that the epithelial cells of the amnion are derived from fetal ectoderm of the embryonic disc. They do not arise by delamination from trophoblasts. This is an important consideration from both embryological and functional perspectives. For example, HLA class I gene expression in amnion is more akin to that in cells of the embryo than that in trophoblasts.

In addition to the epithelial cells that line the amnionic cavity, there is a layer of fibroblast-like mesenchymal cells that are likely derived from embryonic mesoderm. Early in human embryogenesis, the amnionic mesenchymal cells lie immediately adjacent to the basal surface of the epithelium. At this time, the amnion surface is a two-cell-layer structure with approximately equal numbers of epithelial and mesenchymal cells. Simultaneously with growth and development, interstitial collagens are deposited between these two layers of cells. This marks formation of the compact layer of the amnion, which also brings about a distinct separation of the two layers of amnion cells.

As the amnionic sac expands to line the placenta and then the chorion frondosum at 10 to 14 weeks, there is a progressive reduction in the compactness of the mesenchymal cells. These cells continue to separate and become sparsely distributed. Early in pregnancy, amnionic epithelium replicates at a rate appreciably faster than mesenchymal cells. At term, these cells form a continuous uninterrupted epithelium on the fetal amnionic surface. Conversely, mesenchymal cells are widely dispersed, being connected by a fine lattice network of extracellular matrix with the appearance of long slender fibrils.

Amnion Epithelial Cells. The apical surface of amnionic epithelium is replete with highly developed microvilli that are consistent with a major site of transfer between amnionic fluid and amnion. This epithelium is active metabolically, and these cells synthesize tissue inhibitor of metalloproteinase-1, PGE_2, and fetal fibronectin (Rowe and colleagues, 1997). In term pregnancies, amnionic expression of prostaglandin endoperoxide H synthase correlates with elevated fetal fibronectin (Mijovic and co-workers, 2000). By prostaglandin production, amnionic epithelium participates in the "final common pathway" of labor initiation. Epithelial cells may respond to signals derived from the fetus or the mother, and they are responsive to a variety of endocrine or paracrine modulators. Examples include oxytocin and vasopressin, both of which increase PGE_2 production in vitro (Moore and associates, 1988). They may also produce cytokines such as IL-8 during initiation of labor (Elliott and colleagues, 2001).

Amnionic epithelium also synthesizes vasoactive peptides, including endothelin and parathyroid hormone-related protein (Economos and associates, 1992; Germain and colleagues, 1992). The tissue produces brain natriuretic peptide and corticotropin-releasing hormone (CRH), which are peptides that are smooth muscle relaxants (Riley and colleagues, 1991; Warren and Silverman, 1995). It seems reasonable that vasoactive peptides produced in amnion gain access to adventitial surface of chorionic vessels. Thus, amnion may be involved in modulating chorionic vessel tone and blood flow. Amnion-derived vasoactive peptides function in other tissues in diverse physiological processes. After their secretion, these bioactive agents enter amnionic fluid and thereby are available to the fetus by swallowing and inhalation.

Amnion Mesenchymal Cells. Mesenchymal cells of the amnionic fibroblast layer are responsible for other major functions. Synthesis of interstitial collagens that comprise the compact layer of the amnion—the major source of its tensile strength—takes place in mesenchymal cells (Casey and MacDonald, 1996). These cells also synthesize cytokines that include IL-6, IL-8, and monocyte chemoattractant protein-1 (MCP-1). Cytokine synthesis increases in response to bacterial toxins and IL-1. This functional capacity of amnion mesenchymal cells is an important consideration in the study of amnionic fluid for evidence of labor-associated accumulation of inflammatory mediators (Garcia-Velasco and Arici, 1999). Finally, mesenchymal cells may be a greater source of PGE_2 than epithelial cells (Whittle and colleagues, 2000).

Anatomy of the Amnion

Reflected amnion is fused to the chorion laeve. Placental amnion covers the placenta surface and thereby is in contact with the adventitial surface of chorionic vessels. Umbilical amnion covers the umbilical cord. In the conjoined portion of membranes of diamnionic-dichorionic twin placentas, fused amnions are separated by fused chorion laeve. Thus, aside from the small area of

the membranes immediately over the cervical os, this is the only site at which the reflected chorion laeve is not contiguous with decidua. With diamnionic-monochorionic placentas, there is no intervening tissue between the fused amnions.

Amnion Tensile Strength

More than 135 years ago, Matthew Duncan examined the forces involved in fetal membrane rupture. During tests of tensile strength—resistance to tearing and rupture—he found that the decidua and then the chorion laeve gave way long before the amnion ruptured. Indeed, the membranes are quite elastic and can expand to twice normal size during pregnancy (Benirschke and Kaufmann, 2000). The amnion provides the major strength of the membranes. Its tensile strength resides almost exclusively in the compact layer, which is composed of cross-linked interstitial collagens I and III and lesser amounts of collagens V and VI.

Interstitial Collagens. Collagens are the major macromolecules of most connective tissues and the most abundant proteins in the body. Collagen I is the major interstitial collagen in tissues characterized by great tensile strength, such as bone and tendon. In other tissues, collagen III is believed to make a unique contribution to tissue integrity, serving to increase tissue extensibility and tensile strength. For example, the ratio of collagen III to collagen I in the walls of a number of highly extensible tissues—amnionic sac, blood vessels, urinary bladder, bile ducts, intestine, and gravid uterus—is greater than that in nonelastic tissues (Jeffrey, 1991). Although collagen III provides some of the extensibility of this membrane, elastin microfibrils have also been identified (Bryant-Greenwood, 1998).

The tensile strength of amnion is regulated in part by interaction of fibrillar collagen with proteoglycans such as *decorin,* which promote tissue strength. Compositional changes at the time of labor include a decline in decorin and increase in hyaluronan resulting in loss of tensile strength (Chap. 6, p. 140)(Meinert and associates, 2007). Fetal membranes overlying the cervix have a reported regional decline in expression of matrix proteins such as fibulins. This change is suggested to contribute to tissue remodeling and loss of tensile strength (Moore and co-workers, 2009).

Metabolic Functions

From the foregoing, it is apparent that the amnion is clearly more than a simple avascular membrane that contains amnionic fluid. It is metabolically active, is involved in solute and water transport for amnionic fluid homeostasis, and produces an impressive array of bioactive compounds. The amnion is responsive both acutely and chronically to mechanical stretch, which alters amnionic gene expression (Nemeth and colleagues, 2000). This in turn may trigger both autocrine and paracrine responses to include production of matrix metalloproteinases, IL-8, and collagenase (Bryant-Greenwood, 1998; Maradny and colleagues, 1996). Such factors may modulate changes in membrane properties during labor.

Amnionic Fluid

The normally clear fluid that collects within the amnionic cavity increases as pregnancy progresses until about 34 weeks, when there is a decrease in volume. At term, the average volume is about 1000 mL, although this may vary widely in abnormal conditions. The origin, composition, circulation, and function of amnionic fluid are discussed further in Chapter 21 (p. 490).

Umbilical Cord and Related Structures

Cord Development

The yolk sac and the umbilical vesicle into which it develops are prominent early in pregnancy. At first, the embryo is a flattened disc interposed between amnion and yolk sac (see Fig. 3-15). Because its dorsal surface grows faster than the ventral surface, in association with the elongation of the neural tube, the embryo bulges into the amnionic sac and the dorsal part of the yolk sac is incorporated into the body of the embryo to form the gut. The allantois projects into the base of the body stalk from the caudal wall of the yolk sac and later, from the anterior wall of the hindgut.

As pregnancy advances, the yolk sac becomes smaller and its pedicle relatively longer. By about the middle of the third month, the expanding amnion obliterates the exocoelom, fuses with the chorion laeve, and covers the bulging placental disc and the lateral surface of the body stalk. The latter is then called the *umbilical cord*—or *funis.* Remnants of the exocoelom in the anterior portion of the cord may contain loops of intestine, which continue to develop outside the embryo. Although the loops are later withdrawn into the peritoneal cavity, the apex of the midgut loop retains its connection with the attenuated vitelline duct.

The cord at term normally has two arteries and one vein (**Fig. 3-26**). The right umbilical vein usually disappears early during fetal development, leaving only the original left vein. In sections of any portion of the cord near the center, the small

FIGURE 3-26 Cross-section of umbilical cord. The large umbilical vein carries oxygenated blood to the fetus *(above)*. Below it, are the two smaller umbilical arteries, carrying deoxygenated blood from the fetus to the placenta. (Used with permission from Dr. Mandolin S. Ziadie.)

duct of the umbilical vesicle can usually be seen. The vesicle is lined by a single layer of flattened or cuboidal epithelium. In sections just beyond the umbilicus, another duct representing the allantoic remnant is occasionally found. The intra-abdominal portion of the duct of the umbilical vesicle, which extends from umbilicus to intestine, usually atrophies and disappears, but occasionally it remains patent, forming the *Meckel diverticulum*. The most common vascular anomaly is the absence of one umbilical artery which may be associated with fetal anomalies (see Chap. 27, p. 582).

Cord Structure and Function

The umbilical cord, or funis, extends from the fetal umbilicus to the fetal surface of the placenta or chorionic plate. Its exterior is dull white, moist, and covered by amnion, through which three umbilical vessels may be seen. Its diameter is 0.8 to 2.0 cm, with an average length of 55 cm and a range of 30 to 100 cm. Generally, cord length less than 30 cm is considered abnormally short (Benirschke and Kaufmann, 2000). Folding and tortuosity of the vessels, which are longer than the cord itself, frequently create nodulations on the surface, or false knots, which are essentially varices. The extracellular matrix is a specialized connective tissue referred to as *Wharton jelly*. After fixation, the umbilical vessels appear empty, but normally the vessels are not emptied of blood. The two arteries are smaller in diameter than the vein. The mesoderm of the cord, which is of allantoic origin, fuses with that of the amnion.

Blood flows from the umbilical vein and takes a path of least resistance via two routes within the fetus. One is the ductus venosus, which empties directly into the inferior vena cava (see Fig. 4-12, p. 90). The other route consists of numerous smaller openings into the hepatic circulation. Blood from the liver flows into the inferior vena cava via the hepatic vein. Resistance in the ductus venosus is controlled by a sphincter situated at the origin of the ductus at the umbilical recess and innervated by a branch of the vagus nerve.

Blood exits the fetus via the two umbilical arteries. These are anterior branches of the internal iliac artery and become obliterated after birth. Remnants can be seen as the medial umbilical ligaments.

Anatomically, the umbilical cord can be regarded as a component of the fetal membranes. Vessels contained in the cord spiral or twist. Spiraling may occur in a clockwise (dextral) or anticlockwise (sinistral) direction. Anticlockwise spiral is present in 50 to 90 percent of fetuses. It is believed that the spiraling serves to prevent crimping, which occurs in all hollow cylinders subjected to torsion. Boyd and Hamilton (1970) note that these twists are not true spirals, but rather they are cylindrical helices in which a constant curvature is maintained equidistant from the central axis. Benirschke and Kaufmann (2000) reported that there is an average of 11 helices in a cord.

PLACENTAL HORMONES

The production of steroid and protein hormones by human trophoblasts is greater in amount and diversity than that of any single endocrine tissue in all of mammalian physiology. A compendium of average production rates for various steroid hormones in nonpregnant and in near-term pregnant women is given in Table 3-1. It is apparent that alterations in steroid hormone production that accompany normal human pregnancy are incredible. The human placenta also synthesizes an enormous amount of protein and peptide hormones. This includes nearly 1 gram of placental lactogen (hPL) every 24 hours, massive quantities of chorionic gonadotropin (hCG), adrenocorticotropin (ACTH), growth hormone variant (hGH-V), parathyroid hormone–related protein (PTH-rP), calcitonin, relaxin, inhibins, activins, and atrial natriuretic peptide. In addition, there are various hypothalamic-like releasing and inhibiting hormones such as thyrotropin-releasing hormone (TRH), gonadotropin-releasing hormone (GnRH), corticotropin-releasing hormone (CRH), somatostatin, and growth hormone–releasing hormone (GHRH).

TABLE 3-1. Steroid Production Rates in Nonpregnant and Near-Term Pregnant Women

	Production Rates (mg/24 hr)	
Steroid[a]	Nonpregnant	Pregnant
Estradiol-17β	0.1–0.6	15–20
Estriol	0.02–0.1	50–150
Progesterone	0.1–40	250–600
Aldosterone	0.05–0.1	0.250–0.600
Deoxycorticosterone	0.05–0.5	1–12
Cortisol	10–30	10–20

[a]Estrogens and progesterone are produced by placenta. Aldosterone is produced by the maternal adrenal in response to the stimulus of angiotensin II. Deoxycorticosterone is produced in extraglandular tissue sites by way of the 21-hydroxylation of plasma progesterone. Cortisol production during pregnancy is not increased, even though the blood levels are elevated because of decreased clearance caused by increased cortisol-binding globulin.

It is understandable, therefore, that yet another remarkable feature of human pregnancy is the successful physiological adaptations of pregnant women to the unique endocrine milieu as discussed throughout Chapter 6.

Human Chorionic Gonadotropin (hCG)

This so-called pregnancy hormone is a glycoprotein with biological activity similar to luteinizing hormone (LH). Both act via the plasma membrane LH-hCG receptor. Although hCG is produced almost exclusively in the placenta, it also is synthesized in fetal kidney. Other fetal tissues produce either the β-subunit or intact hCG molecule (McGregor and associates, 1981, 1983).

Various malignant tumors also produce hCG, sometimes in large amounts—especially trophoblastic neoplasms (Chap. 11, p. 257). Chorionic gonadotropin is produced in very small amounts in tissues of men and nonpregnant women, perhaps primarily in the anterior pituitary gland. Nonetheless, the detection of hCG in blood or urine is almost always indicative of pregnancy (see Chap. 8, p. 192).

Chemical Characteristics

Chorionic gonadotropin is a glycoprotein with a molecular weight of 36,000 to 40,000 Da. It has the highest carbohydrate content of any human hormone—30 percent. The carbohydrate component, and especially the terminal sialic acid, protects the molecule from catabolism. The 36-hour plasma half-life of intact hCG is much longer than the 2 hours for LH. The hCG molecule is composed of two dissimilar subunits. One is designated α and is composed of 92 amino acids, whereas the β subunit contains 145 amino acids. These are noncovalently linked and are held together by electrostatic and hydrophobic forces. Isolated subunits are unable to bind the LH receptor and thus lack biological activity.

This hormone is structurally related to three other glycoprotein hormones—LH, FSH, and TSH. The amino-acid sequence of the α-subunits of all four glycoproteins is identical. The β-subunits, although sharing certain similarities, are characterized by distinctly different amino-acid sequences. Recombination of an α- and a β-subunit of the four glycoprotein hormones gives a molecule with biological activity characteristic of the hormone from which the β-subunit was derived.

Biosynthesis

Both α- and β-chain synthesis of hCG are regulated separately. A single gene located on chromosome 6 encodes the α-subunit for hCG, LH, FSH, and TSH. There are seven separate genes on chromosome 19 for the β-hCG–β-LH family. Six genes code for β-hCG and one for β-LH (Miller-Lindholm and colleagues, 1997). Both subunits are synthesized as larger precursors, which are then cleaved by endopeptidases. Intact hCG is then assembled and rapidly released by exocytosis of secretory granules (Morrish and colleagues, 1987).

Site of hCG Synthesis

Before 5 weeks, hCG is expressed in both syncytiotrophoblast and cytotrophoblast (Maruo and colleagues, 1992). Later, when maternal serum levels peak, hCG is produced almost solely in syncytiotrophoblasts (Beck and associates, 1986; Kurman and colleagues, 1984). At this time, hCG mRNAs for both α- and β-subunits in syncytiotrophoblast are greater than at term (Hoshina and co-workers, 1982). This may be an important consideration when hCG is used as a screening procedure to identify abnormal fetuses.

Molecular Forms of hCG in Plasma and Urine

There are multiple forms of hCG in maternal plasma and urine. Some result from enzymatic degradation, and others by modifications during molecular synthesis and processing. These multiple forms of hormone vary enormously in bioactivity and immunoreactivity.

Free Subunits. Circulating free β-subunit levels are low to undetectable throughout pregnancy. In part, this is the result of its rate-limiting synthesis. Free α-subunits that do not combine with the β-subunit are found in placental tissue and maternal plasma. These levels increase gradually and steadily until they plateau at about 36 weeks. At this time, they account for from 30 to 50 percent of hormone (Cole, 1997). Thus, α-hCG secretion roughly corresponds to placental mass, whereas secretion of complete hCG molecules is maximal at 8 to 10 weeks.

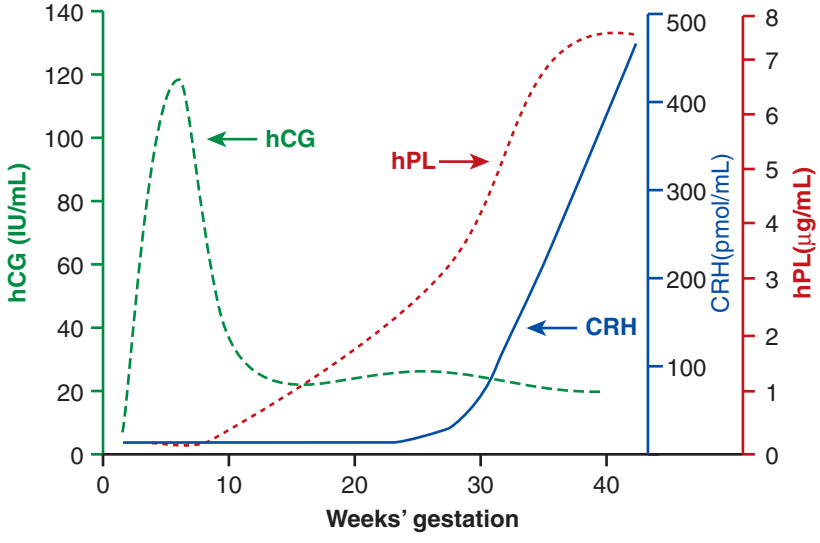

FIGURE 3-27 Distinct profiles for the concentrations of human chorionic gonadotropin (hCG), human placental lactogen (hPL), and corticotropin-releasing hormone (CRH) in serum of women throughout normal pregnancy.

Concentrations of hCG in Serum and Urine

The intact hCG molecule is detectable in plasma of pregnant women 7 to 9 days after the midcycle surge of LH that precedes ovulation. Thus, it is likely that hCG enters maternal blood at the time of blastocyst implantation. Plasma levels increase rapidly, doubling every 2 days, with maximal levels being attained at 8 to 10 weeks (Fig. 3-27). Appreciable fluctuations in levels for a given patient are observed on the same day—evidence that trophoblast secretion

of protein hormones is episodic (Barnea and Kaplan, 1989; Diaz-Cueto and colleagues, 1994).

Because hCG circulates as multiple highly related isoforms with variable cross-reactivity between commercial assays, there is considerable variation in calculated serum hCG levels among the more than 100 assays. Peak maternal plasma levels reach about 100,000 mIU/mL between the 60th and 80th days after menses (see Fig. 3-27). At 10 to 12 weeks, plasma levels begin to decline, and a nadir is reached by about 16 weeks. Plasma levels are maintained at this lower level for the remainder of pregnancy.

The pattern of hCG appearance in fetal blood is similar to that in the mother. Fetal plasma levels, however, are only about 3 percent of those in maternal plasma. Amnionic fluid hCG concentration early in pregnancy is similar to that in maternal plasma. As pregnancy progresses, hCG concentration in amnionic fluid declines, and near term the levels are about 20 percent of those in maternal plasma.

Maternal urine contains the same variety of hCG degradation products as maternal plasma. The principal urinary form is the terminal degradation hCG product—the β-core fragment. Its concentrations follow the same general pattern as that in maternal plasma, peaking at about 10 weeks. It is important to recognize that the so-called β-subunit antibody used in most pregnancy tests reacts with both intact hCG—the major form in the plasma, and with fragments of hCG—the major forms found in urine.

Significance of Abnormally High or Low hCG Levels. There are a number of clinical circumstances in which substantively higher maternal plasma hCG levels are found. Some examples are multifetal pregnancy, erythroblastosis fetalis associated with fetal hemolytic anemia, and gestational trophoblastic disease. Relatively higher hCG levels may be found at midtrimester in women carrying a fetus with Down syndrome—an observation used in biochemical screening tests (see Chap. 13, p. 293). The reason for this is not clear, but it has been speculated that it is due to reduced placental maturity. Relatively lower hCG plasma levels are found in women with early pregnancy wastage, including ectopic pregnancy (see Chap. 10, p. 245).

Regulation of hCG Synthesis

Placental GnRH is likely involved in the regulation of hCG formation. Both GnRH and its receptor are expressed on cytotrophoblasts and syncytiotrophoblast (Wolfahrt and colleagues, 1998). Also, GnRH administration elevates circulating hCG levels, and cultured trophoblast cells respond to GnRH treatment with increased hCG secretion (Iwashita and colleagues, 1993; Siler-Khodr and Khodr, 1981). Pituitary GnRH production also is regulated by inhibin and activin. In cultured placental cells, activin stimulates and inhibin inhibits GnRH and hCG production (Petraglia and co-workers, 1989; Steele and colleagues, 1993).

Metabolic Clearance of hCG

Renal clearance of hCG accounts for 30 percent of its metabolic clearance. The remainder is likely cleared by metabolism in the liver (Wehmann and Nisula, 1980). Clearances of β- and α-subunit are about 10-fold and 30-fold, respectively, greater than that of intact hCG. By contrast, renal clearance of these subunits is considerably lower than that of dimeric hCG.

Biological Functions of hCG

Both hCG subunits are required for binding to the LH-hCG receptor in the corpus luteum and the fetal testis. LH-hCG receptors are present in a variety of tissues, but their role there is less defined. The best-known biological function of hCG is the so-called rescue and maintenance of function of the corpus luteum—that is, continued progesterone production. Bradbury and colleagues (1950) found that the progesterone-producing life span of a corpus luteum of menstruation could be prolonged perhaps for 2 weeks by hCG administration. This is only an incomplete explanation for the physiological role of hCG in pregnancy. For example, maximum plasma hCG concentrations are attained well after hCG-stimulated corpus luteum secretion of progesterone has ceased. Specifically, progesterone luteal synthesis begins to decline at about 6 weeks despite continued and increasing hCG production.

It is also known that hCG stimulates fetal testicular testosterone secretion, which is maximum approximately when peak levels of hCG are attained. Thus, at a critical time in sexual differentiation of the male fetus, hCG enters fetal plasma from the syncytiotrophoblast. In the fetus, it acts as an LH surrogate to stimulate replication of Leydig cells and testosterone synthesis to promote male sexual differentiation (see Chap. 4, p. 101). Before about 110 days, there is no vascularization of the fetal anterior pituitary from the hypothalamus. Thus, there is little pituitary LH secretion and hCG acts as LH before this time. Thereafter, as hCG levels fall, pituitary LH maintains a modest level of testicular stimulation.

The maternal thyroid gland is also stimulated by large quantities of hCG. In some women with gestational trophoblastic disease, biochemical and clinical evidence of hyperthyroidism sometimes develops (see Chap. 11, p. 260). This once was attributed to formation of *chorionic thyrotropins* by neoplastic trophoblasts. It was subsequently, however, shown that some forms of hCG bind to TSH receptors on thyrocytes (Hershman, 1999). And treatment of men with exogenous hCG increases thyroid activity. The thyroid-stimulatory activity in plasma of first-trimester pregnant women varies appreciably from sample to sample. Modifications of hCG oligosaccharides likely are important in the capacity of hCG to stimulate thyroid function. For example, acidic isoforms stimulate thyroid activity, and some more basic isoforms stimulate iodine uptake (Kraiem, 1994; Tsuruta, 1995; Yoshimura, 1994, and all their colleagues). Finally, the LH-hCG receptor is expressed by thyrocytes, which suggests that hCG stimulates thyroid activity via the LH-hCG receptor and by the TSH receptor (Tomer and colleagues, 1992).

Other hCG functions include *promotion of* relaxin secretion by the corpus luteum (Duffy and co-workers, 1996). LH-hCG receptors are found in myometrium and in uterine vascular tissue. It has been hypothesized that hCG may act to promote uterine vascular vasodilatation and myometrial smooth muscle relaxation (Kurtzman and colleagues, 2001).

Human Placental Lactogen (hPL)

Prolactin-like activity in the human placenta was first described by Ehrhardt (1936). The responsible protein was

isolated from placental extracts and retroplacental blood (Ito and Higashi, 1961; Josimovich and MacLaren, 1962). Because of its potent lactogenic and growth hormone-like bioactivity, as well as an immunochemical resemblance to human growth hormone (hGH), it was called human placental lactogen or chorionic growth hormone. It also has been referred to as chorionic somatomammotropin. Currently, *human placental lactogen* (hPL) is used by most. Grumbach and Kaplan (1964) showed that this hormone, like hCG, was concentrated in syncytiotrophoblast. It is detected as early as the second or third week after fertilization. Also similar to hCG, hPL is demonstrated in cytotrophoblasts before 6 weeks (Maruo and associates, 1992).

Chemical Characteristics

Human placental lactogen is a single nonglycosylated polypeptide chain with a molecular weight of 22,279 Da. It is derived from a 25,000-Da precursor. There are 191 amino-acid residues in hPL compared with 188 in hCG. The sequence of each hormone is strikingly similar, with 96-percent homology. HPL also is structurally similar to human prolactin (hPRL), with a 67-percent amino-acid sequence similarity. For these reasons, it has been suggested that the genes for hPL, hPRL, and hGH evolved from a common ancestral gene—probably that for prolactin—by repeated gene duplication (Ogren and Talamantes, 1994).

Gene Structure and Expression

There are five genes in the growth hormone–placental lactogen gene cluster that are linked and located on chromosome 17. Two of these—*hPL2* and *hPL3*—both encode hPL, and the amount of mRNA in the term placenta is similar for each. In contrast, the prolactin gene is located on chromosome 6 (Owerbach and colleagues, 1980, 1981). **The production rate of hPL near term—approximately 1 g/day—is by far the greatest of any known hormone in humans.**

Serum Concentration

HPL is demonstrable in the placenta within 5 to 10 days after conception and can be detected in maternal serum as early as 3 weeks. Maternal plasma concentrations are linked to placental mass, and they rise steadily until 34 to 36 weeks. Serum concentrations reach levels in late pregnancy of 5 to 15 μg/mL—higher than those of any other protein hormone (see Fig. 3-27). The half-life of hPL in maternal plasma is between 10 and 30 minutes (Walker and co-workers, 1991).

Very little hPL is detected in fetal blood or in the urine of the mother or newborn. Amnionic fluid levels are somewhat lower than in maternal plasma. Because hPL is secreted primarily into the maternal circulation, with only very small amounts in cord blood, it appears that its role in pregnancy, if any, is mediated through actions in maternal rather than in fetal tissues. Nonetheless, there is continuing interest in the possibility that hPL serves select functions in fetal growth.

Regulation of hPL Biosynthesis

Levels of mRNA for hPL in syncytiotrophoblast remain relatively constant throughout pregnancy. This finding is supportive of the idea that the rate of hPL secretion is proportional to placental mass. There are very high plasma levels of hCG in women with trophoblastic neoplasms, but only low levels of hPL in these same women.

Prolonged maternal starvation in the first half of pregnancy leads to an increase in the plasma concentration of hPL. Short-term changes in plasma glucose or insulin, however, have relatively little effect on plasma hPL levels. In vitro studies of syncytiotrophoblast suggest that hPL synthesis is stimulated by insulin and insulin-like growth factor-1 and inhibited by PGE_2 and $PGF_{2\alpha}$ (Bhaumick and associates, 1987; Genbacev and colleagues, 1977).

Metabolic Actions

HPL has putative actions in a number of important metabolic processes. These include:

1. Maternal lipolysis with increased levels of circulating free fatty acids. This provides a source of energy for maternal metabolism and fetal nutrition. In vitro studies suggest that hPL inhibits leptin secretion by term trophoblast (Coya and associates, 2005).
2. An anti-insulin or "diabetogenic" action that leads to increased maternal insulin levels. This favors protein synthesis and provides a readily available source of amino acids to the fetus.
3. A potent angiogenic hormone that may play an important role in the formation of fetal vasculature (Corbacho and coworkers, 2002).

Other Placental Protein Hormones

Chorionic Adrenocorticotropin

ACTH, lipotropin, and β-endorphin—all proteolytic products of proopiomelanocortin—are recovered from placental extracts (Genazzani and associates, 1975; Odagiri and colleagues, 1979). The physiological role of placental ACTH is unclear. Although maternal plasma levels of ACTH increase during pregnancy, they remain lower than those in men and nonpregnant women, except during labor (Carr and colleagues, 1981a). Placental ACTH is secreted into both maternal and fetal circulations, however, maternal ACTH is not transported to the fetus. Importantly, placental ACTH is not under feedback regulation by glucocorticoids, which may explain maternal partial resistance to dexamethasone suppression (Nolten and Rueckert, 1981). Placental corticotropin-releasing hormone (CRH) stimulates synthesis and release of chorionic ACTH. Placental CRH production is positively regulated by cortisol, producing a novel positive feedback loop. As discussed later, this system may be important for controlling fetal lung maturation and timing of parturition.

Relaxin

Relaxin expression has been demonstrated in human corpus luteum, decidua, and placenta (Bogic and colleagues, 1995). This peptide is synthesized as a single 105 amino-acid preprorelaxin molecule that is cleaved to A and B molecules. Relaxin is structurally similar to insulin and insulin-like growth factor. Two of the three relaxin genes—*H2* and *H3*—are transcribed in the corpus luteum (Bathgate and associates, 2002; Hudson and colleagues, 1983, 1984). Other tissues, including decidua, placenta, and membranes, express *H1* and *H2* (Hansell and colleagues, 1991).

The rise in maternal circulating relaxin levels seen in early pregnancy is attributed to secretion by the corpus luteum, and levels parallel those seen for hCG. The uterine relaxin receptor was cloned by Hsu and colleagues (2002). It has been proposed that relaxin, along with rising progesterone levels, acts on myometrium to promote relaxation and the quiescence observed in early pregnancy (see Chap. 6, p. 153). In addition, the production of relaxin and relaxin-like factors within the placenta and fetal membranes is believed to play an autocrine-paracrine role in postpartum regulation of extracellular matrix degradation (Qin and colleagues, 1997a, b).

Parathyroid Hormone-Related Protein (PTH-rP)

Circulating levels of PTH-rP are significantly elevated in pregnancy within maternal but not fetal circulation (Bertelloni and colleagues, 1994; Saxe and associates, 1997). Although not clear, many potential functions of this hormone have been proposed. PTH-rP synthesis is found in several normal adult tissues, especially in reproductive organs that include myometrium, endometrium, corpus luteum, and lactating mammary tissue. PTH-rP is not produced in the parathyroid glands of normal adults. Placental-derived PTH-rP may have an important autocrine–paracrine role within the fetal–maternal unit as well as on the adjacent myometrium. It may activate trophoblast receptors to promote calcium transport for fetal bone growth and ossification.

Growth Hormone Variant (hGH-V)

The placenta expresses a growth hormone variant that is not expressed in the pituitary. The gene encoding hGH-V is located in the hGH–hPL gene cluster on chromosome 17. Sometimes referred to as *placental growth hormone*, hGH-V is a 191 amino-acid protein that differs in 15 amino-acid positions from the sequence for hGH. Placental hGH-V presumably is synthesized in the syncytium, but its pattern of synthesis and secretion during gestation is not precisely known because antibodies against hGH-V cross-react with hGH. It is believed that hGH-V is present in maternal plasma by 21 to 26 weeks, increases in concentration until approximately 36 weeks, and remains relatively constant thereafter. There is a correlation between the levels of hGH-V in maternal plasma and those of insulin-like growth factor-1. Also, the secretion of hGH-V by trophoblasts in vitro is inhibited by glucose in a dose-dependent manner (Patel and colleagues, 1995). Overexpression of hGH-V in mice causes severe insulin resistance, and thus it is a likely candidate to mediate insulin resistance of pregnancy (Barbour and associates, 2002).

Hypothalamic-Like Releasing Hormones

For each of the known hypothalamic-releasing or -inhibiting hormones described—GnRH, TRH, CRH, GHRH, and somatostatin—there is an analogous hormone produced in human placenta (Petraglia and colleagues, 1992; Siler-Khodr, 1988). Many investigators have proposed that this is indicative of a hierarchy of control in the synthesis of chorionic trophic agents.

Gonadotropin-Releasing Hormone (GnRH). There is a reasonably large amount of immunoreactive GnRH in the placenta (Siler-Khodr, 1988; Siler-Khodr and Khodr, 1978). Interestingly, it is found in cytotrophoblasts, but not syncytiotrophoblast. Gibbons and co-workers (1975) and Khodr and Siler-Khodr (1980) demonstrated that the human placenta could synthesize both GnRH and TRH in vitro. Placental-derived GnRH functions to regulate trophoblast hCG production, hence the observation that GnRH levels are higher early in pregnancy. Placental-derived GnRH is also the likely cause of elevated maternal GnRH levels in pregnancy (Siler-Khodr and colleagues, 1984).

Corticotropin-Releasing Hormone (CRH). This hormone is a member of a larger family of CRH-related peptides that includes CRH, urocortin, urocortin II, and urocortin III (Dautzenberg and Hauger, 2002). CRH produced in nonpregnant women has relatively low serum levels of 5 to 10 pmol/L. During pregnancy, these increase to about 100 pmol/L in the early third trimester and to almost 500 pmol/L abruptly during the last 5 to 6 weeks (see Fig. 3-27). Urocortin also is produced by the placenta and secreted into the maternal circulation, but at much lower levels than seen for CRH (Florio and co-workers, 2002). After labor begins, maternal plasma CRH levels increase further by two- to threefold (Petraglia and colleagues, 1989, 1990).

The biological function of CRH synthesized in the placenta, membranes, and decidua has been somewhat defined. CRH receptors are present in many tissues: placenta, adrenal gland, sympathetic ganglia, lymphocytes, gastrointestinal tract, pancreas, gonads, and myometrium. Some findings suggest that CRH can act through two major families—the type 1 and type 2 CRH receptors (CRH-R1 and CRH-R2). Trophoblast, amniochorion, and decidua express both CRH-R1 and CRH-R2 receptors, as well as several variant receptors (Florio and colleagues, 2000). Both CRH and urocortin increase trophoblast ACTH secretion, supporting an autocrine-paracrine role (Petraglia and co-workers, 1999). Large amounts of CRH from trophoblast enter maternal blood, but there also is a large concentration of a specific CRH-binding protein in maternal plasma, and the bound CRH seems to be biologically inactive.

Other proposed biological roles include induction of smooth muscle relaxation in vascular and myometrial tissue and immunosuppression. The physiological reverse, however, induction of myometrial contractions, has been proposed for the rising levels of CRH seen near the end of gestation. One hypothesis suggests that CRH may be involved with parturition initiation (Wadhwa and colleagues, 1998). Prostaglandin formation in the placenta, amnion, chorion laeve, and decidua is increased with CRH treatment (Jones and Challis, 1989b). This latter observation further supports a potential role in the timing of parturition.

Glucocorticoids act in the hypothalamus to *inhibit CRH release,* but in the trophoblast, glucocorticoids *stimulate* CRH gene expression (Jones and colleagues, 1989a; Robinson and co-workers, 1988). Thus, there may be a novel positive feedback loop in the placenta by which placental CRH stimulates placental ACTH to stimulate fetal and maternal adrenal glucocorticoid production with subsequent stimulation of placental CRH expression (Nicholson and King, 2001; Riley and colleagues, 1991).

Growth Hormone-Releasing Hormone (GHRH). The role of placental GHRH is not known (Berry and associates, 1992). *Ghrelin* is another regulator of hGH secretion that is produced by

placental tissue (Horvath and colleagues, 2001). Trophoblast ghrelin expression peaks at midpregnancy and is a potential regulator of hGH-V production or a paracrine regulator of differentiation (Fuglsang and associates, 2005; Gualillo and co-workers, 2001).

Other Placental Peptide Hormones

Leptin

This hormone is normally secreted by adipocytes. It functions as an anti-obesity hormone that decreases food intake through its hypothalamic receptor. It also regulates bone growth and immune function (Cock and Auwerx, 2003; La Cava and colleagues, 2004). Leptin also is synthesized by both cytotrophoblast and syncytiotrophoblast (Henson and Castracane, 2002). Relative contributions of leptin from maternal adipose tissue versus placenta are currently not well defined. Maternal serum levels are significantly higher than those in nonpregnant women. Fetal leptin levels are correlated positively with birthweight and likely play an important role in fetal development and growth. Recent studies suggest that leptin inhibits apoptosis and promotes trophoblast proliferation (Magarinos and associates, 2007).

Neuropeptide Y

This 36 amino-acid peptide is widely distributed in brain. It also is found in sympathetic neurons innervating the cardiovascular, respiratory, gastrointestinal, and genitourinary systems. Neuropeptide Y has been isolated from the placenta and localized in cytotrophoblasts (Petraglia and colleagues, 1989). There are receptors for neuropeptide Y on trophoblast, and treatment of placental cells with neuropeptide Y causes CRH release (Robidoux and colleagues, 2000).

Inhibin and Activin

Inhibin is a glycoprotein hormone that acts preferentially to inhibit pituitary FSH release. It is produced by human testis and by ovarian granulosa cells, including the corpus luteum. Inhibin is a heterodimer made up of an α-subunit and one of two distinct β-subunits, βA or βB. All three are produced by trophoblast, and maternal serum levels peak at term (Petraglia and co-workers, 1991). One function may be to act in concert with the large amounts of sex steroid hormones to inhibit FSH secretion and thereby inhibit ovulation during pregnancy. Inhibin may act via GnRH to regulate placental hCG synthesis (Petraglia and colleagues, 1987).

Activin is closely related to inhibin and is formed by the combination of the two β-subunits. Its receptor is expressed in the placenta and amnion. Activin A is not detectable in fetal blood before labor but is present in umbilical cord blood after labor begins. Petraglia and colleagues (1994) found that serum activin A levels decline rapidly after delivery. It is not clear if chorionic activin and inhibin are involved in placental metabolic processes other than GnRH synthesis.

Placental Progesterone Production

After 6 to 7 weeks' gestation, little progesterone is produced in the ovary (Diczfalusy and Troen, 1961). Surgical removal of the corpus luteum or even bilateral oophorectomy during the 7th to 10th week does not cause a decrease in excretion of urinary pregnanediol, the principal urinary metabolite of progesterone. Before this time, however, removal of the corpus luteum will result in miscarriage unless an exogenous progestin is given (see Chap. 40, p. 906). After approximately 8 weeks, the placenta assumes progesterone secretion, which continues to increase such that there is a gradual increase in maternal serum levels throughout pregnancy (Fig. 3-28). By the end of pregnancy, these levels are 10 to 5000 times those found in nonpregnant women, depending on the stage of the ovarian cycle.

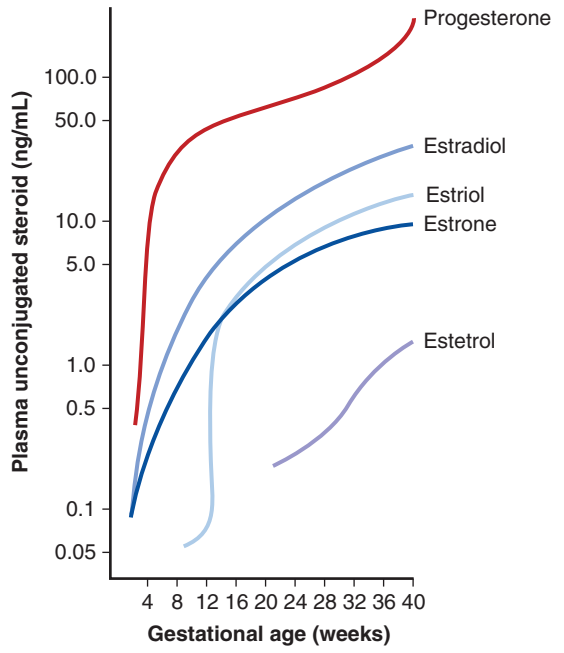

FIGURE 3-28 Plasma levels of progesterone, estradiol, estrone, estetrol, and estriol in women during the course of gestation. (From Mesiano, 2001. This figure was published in Yen SSC, Endocrine-metabolic adaptations in pregnancy, in *Reproductive Endocrinology: Physiology, Pathophysiology, and Clinical Management*, 3rd ed., SSC Yen and RB Jaffe (eds.), pp. 936–981, Copyright Elsevier/Saunders 1991, with permission.)

Progesterone Production Rates

The daily production rate of progesterone in late, normal, singleton pregnancies is about 250 mg. In multifetal pregnancies, the daily production rate may exceed 600 mg/day. Progesterone is synthesized from cholesterol in a two-step enzymatic reaction. First, cholesterol is converted to pregnenolone within the mitochondria, in a reaction catalyzed by cytochrome P_{450} cholesterol side-chain cleavage enzyme. Pregnenolone leaves the mitochondria and is converted to progesterone in the endoplasmic reticulum by 3β-hydroxysteroid dehydrogenase. Progesterone is released immediately through a process of diffusion.

Even though the placenta produces a prodigious amount of progesterone, there is limited capacity for trophoblast cholesterol biosynthesis. Radiolabeled acetate is incorporated into cholesterol by placental tissue at a slow rate. The rate-limiting enzyme in cholesterol biosynthesis is 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase. Because of this, the placenta must rely on exogenous cholesterol for progesterone formation. Bloch (1945) and Werbin and co-workers (1957) found that after intravenous administration of radiolabeled cholesterol to pregnant women, the amount of radioactivity of urinary pregnanediol was

similar to that of plasma cholesterol. Hellig and associates (1970) also found that maternal plasma cholesterol was the principal precursor—as much as 90 percent—of progesterone biosynthesis. The trophoblast preferentially uses LDL cholesterol for progesterone biosynthesis (Simpson and Burkhart, 1980; Simpson and colleagues, 1979). In studies of pregnant baboons, when maternal serum LDL levels were reduced, there was a significant drop in placental progesterone production (Henson and associates, 1997). Thus, placental progesterone is formed through the uptake and use of a maternal circulating precursor. This mechanism is unlike the placental production of estrogens, which relies principally on fetal adrenal precursors.

Progesterone Synthesis and Fetal Relationships

Although there is a relationship between fetal well-being and placental production of estrogen, this is not the case for placental progesterone. Fetal demise, ligation of the umbilical cord with the fetus and placenta remaining in situ, and anencephaly are all conditions associated with very low maternal plasma levels and low urinary excretion of estrogens. In these circumstances, there is not a concomitant decrease in progesterone levels until some indeterminate time after fetal death. Thus, placental endocrine function, including the formation of protein hormones such as hCG and progesterone biosynthesis, may persist for long periods (weeks) after fetal demise.

Progesterone Metabolism During Pregnancy

The metabolic clearance rate of progesterone in pregnant women is similar to that found in men and nonpregnant women. This is an important consideration in evaluating the role of progesterone in initiation of parturition (see Chap. 6, p. 154). During pregnancy, there is a disproportionate increase in the plasma concentration of 5α-dihydroprogesterone as a result of synthesis in syncytiotrophoblast from both placenta-produced progesterone and fetal-derived precursor (Dombroski and co-workers, 1997). Thus, the concentration ratio of this progesterone metabolite to progesterone is increased in pregnancy. The mechanisms for this are not defined completely but may be relevant to the resistance to pressor agents that normally develops in pregnant women (see Chap. 5, p. 120). Progesterone also is converted to the potent mineralocorticoid deoxycorticosterone in pregnant women and in the fetus. The concentration of deoxycorticosterone is increased strikingly in both maternal and fetal compartments (see Table 3-1). The extra-adrenal formation of deoxycorticosterone from circulating progesterone accounts for most of its production in pregnancy (Casey and MacDonald, 1982a, 1982b).

Placental Estrogen Production

The placenta produces huge amounts of estrogens using blood-borne steroidal precursors from the maternal and fetal adrenal glands. Near-term, normal human pregnancy is a hyperestrogenic state. The amount of estrogen produced each day by syncytiotrophoblast during the last few weeks of pregnancy is equivalent to that produced in 1 day by the ovaries of no fewer than 1000 ovulatory women. The hyperestrogenic state of human pregnancy is one of continually increasing magnitude as pregnancy progresses, terminating abruptly after delivery.

During the first 2 to 4 weeks of pregnancy, rising hCG levels maintain production of estradiol in the maternal corpus luteum. Production of both progesterone and estrogens in the maternal ovaries decreases significantly by the seventh week of pregnancy. At this time, there is a luteal-placental transition. By the seventh week, more than half of estrogen entering maternal circulation is produced in the placenta (MacDonald, 1965; Siiteri and MacDonald, 1963, 1966). These studies support the transition of a steroid milieu dependent on the maternal corpus luteum to one dependent on the developing placenta.

Placental Estrogen Biosynthesis

The pathways of estrogen synthesis in the placenta differ from those in the ovary of nonpregnant women. Estrogen production in the ovary takes place during the follicular and luteal phase through the interaction of theca and granulosa cells. Specifically, androstenedione is synthesized in ovarian theca and then transferred to adjacent granulosa cells for estradiol synthesis. Estradiol production within the corpus luteum of nonpregnant women as well as in early pregnancy continues to require interaction between the luteinized theca and granulosa cells. In human trophoblast, neither cholesterol nor progesterone can serve as precursor for estrogen biosynthesis. A crucial enzyme necessary for sex steroid synthesis—steroid 17α-hydroxylase/17,20-lyase (CYP17)—is not expressed in the human placenta. Consequently, the conversion of C_{21}-steroids to C_{19}-steroids—the latter being the immediate and obligatory precursors of estrogens—is not possible.

Although C_{19}-steroids—dehydroepiandrosterone (DHEA) and its sulfate (DHEA-S)—often are called adrenal androgens, these steroids can also serve as estrogen precursors (**Fig. 3-29**). Ryan (1959a) found that there was an exceptionally high capacity of placenta to convert appropriate C_{19}-steroids to estrone and estradiol. The conversion of DHEA-S to estradiol requires placental expression of four key enzymes that are located principally in syncytiotrophoblast (Bonenfant and colleagues, 2000; Salido and co-workers, 1990). First, the placenta expresses high levels of steroid sulfatase (STS), which converts the conjugated DHEA-S to DHEA. DHEA is then acted upon by 3β-hydroxysteroid dehydrogenase type 1 (3βHSD) to produce androstenedione. Cytochrome P_{450} aromatase (CYP19) then converts androstenedione to estrone, which is then converted to estradiol by 17β-hydroxysteroid dehydrogenase type 1 (17βHSD1).

Plasma C_{19}-Steroids as Estrogen Precursors

Frandsen and Stakemann (1961) found that levels of urinary estrogens in women pregnant with an anencephalic fetus were only about 10 percent found in normal pregnancy. The adrenal glands of anencephalic fetuses are atrophic because of absent hypothalamic-pituitary function, which precludes ACTH stimulation. Thus, it seemed reasonable that fetal adrenal glands might provide substance(s) used for placental estrogen formation.

In subsequent studies, DHEA-S was found to be a major precursor of estrogens in pregnancy (Baulieu and Dray, 1963; Siiteri and MacDonald, 1963). The large amounts of DHEA-S in plasma and its much longer half-life uniquely qualify it as

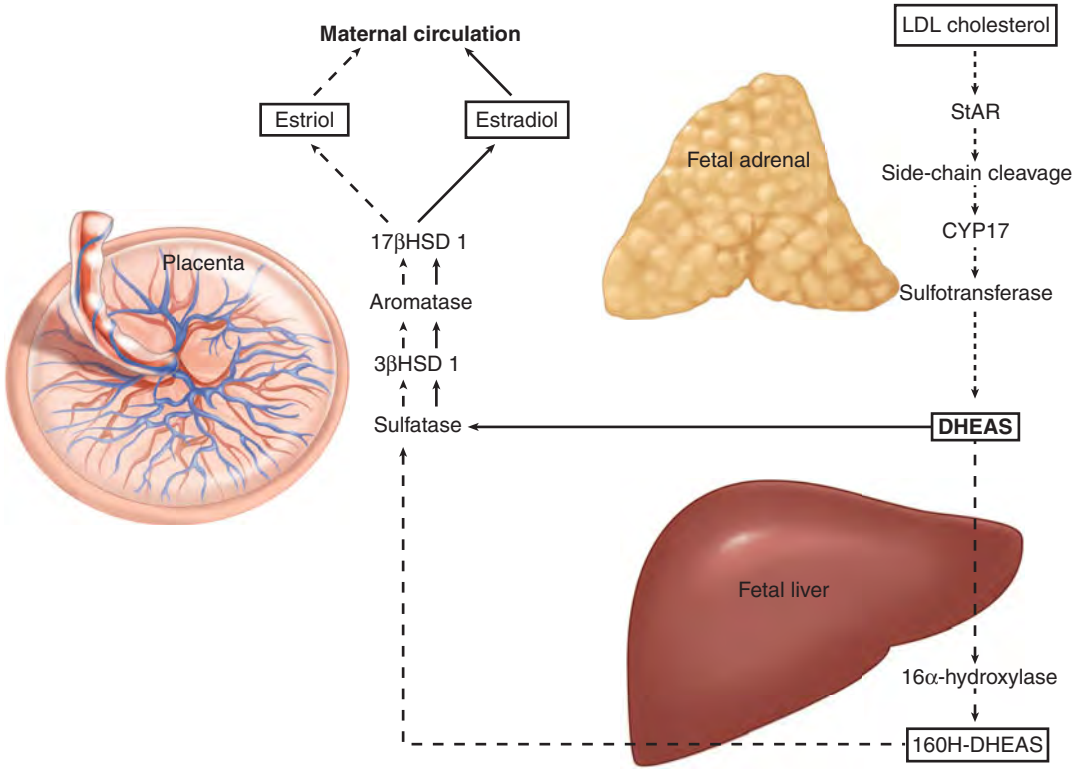

FIGURE 3-29 Schematic presentation of the biosynthesis of estrogens in the human placenta. Dehydroepiandrosterone sulfate (DHEA-S), secreted in prodigious amounts by the fetal adrenal glands, is converted to 16α-hydroxydehydroepiandrosterone sulfate (16αOHDHEA-S) in the fetal liver. These steroids, DHEA-S and 16αOHDHEA-S, are converted in the placenta to estrogens, that is, 17β-estradiol (E2) and estriol (E3). Near term, half of E2 is derived from fetal adrenal DHEA-S and half from maternal DHEA-S. On the other hand, 90 percent of E3 in the placenta arises from fetal 16αOHDHEA-S and only 10 percent from all other sources.

the principal precursor for placental estradiol synthesis. There is a 10- to 20-fold increase in the metabolic clearance rate of plasma DHEA-S in women at term compared with that in men and nonpregnant women (Gant and co-workers, 1971). This rapid use results in a progressive decrease in plasma DHEA-S concentration as pregnancy progresses (Milewich and co-workers, 1978). However, maternal adrenal glands do not produce sufficient amounts of DHEA-S to account for more than a fraction of total placental estrogen biosynthesis. **The fetal adrenal glands are quantitatively the most important source of placental estrogen precursors in human pregnancy.** A schematic representation of the pathways of estrogen formation in the placenta is presented in Figure 3-29. As shown, the estrogen products released from the placenta are dependent on the substrate available. Thus, estrogen production during pregnancy reflects the unique interactions between fetal adrenal glands, fetal liver, placenta, and maternal adrenal glands.

Directional Secretion of Steroids from Syncytiotrophoblast

More than 90 percent of estradiol and estriol formed in syncytiotrophoblast enters maternal plasma (Gurpide and co-workers, 1966) (see Table 3-1). And 85 percent or more of placental progesterone enters maternal plasma, with little maternal progesterone crossing the placenta to the fetus (Gurpide and co-workers, 1972).

The major reason for directional movement of newly formed steroid into the maternal circulation is the nature of hemochorioendothelial placentation. In this system, steroids secreted from syncytiotrophoblast can enter maternal blood directly. Steroids that leave the syncytium do not enter fetal blood directly. They must first traverse the cytotrophoblasts and then enter connective tissue of the villous core and then fetal capillaries. From either of these spaces, steroids can reenter the syncytium. The net result of this hemochorial arrangement is that there is substantially greater entry of steroids into the maternal circulation compared with the amount that enters fetal blood.

FETAL ADRENAL GLAND HORMONES

Morphologically, functionally, and physiologically, the fetal adrenal glands are remarkable organs. At term, the fetal adrenal glands weigh the same as those of the adult. More than 85 percent of the fetal gland is composed of a unique fetal zone, which has a great capacity for steroid biosynthesis. Daily steroid production of fetal adrenal glands near term is 100 to 200 mg/day. This compares with resting adult steroid secretion of 30 to 40 mg/day. Thus, the fetal adrenal gland is a truly prodigious steroidogenic tissue.

The fetal zone is lost in the first year of life and is not present in the adult. In addition to ACTH, fetal adrenal gland growth is influenced by factors secreted by the placenta. This is exemplified by the continued growth of the fetal glands throughout gestation, but rapid involution immediately after birth when placenta-derived factors dissipate.

Placental Estriol Synthesis

The estrogen products released from the placenta are dependent on the substrate available. Estradiol is the primary placental estrogen secretory product at term. In addition, significant levels of estriol and estetrol are found in the maternal circulation, and they increase, particularly late in gestation (see Fig. 3-28). These hydroxylated forms of estrogen are produced in the placenta using substrates formed by the combined efforts of the fetal adrenal gland and liver.

There are important fetal-maternal interactions through the fetal liver (see Fig. 3-29). High levels of fetal hepatic 16α-hydroxylase act on adrenal derived steroids. Ryan (1959b) and MacDonald and Siiteri (1965) found that 16α-hydroxylated C_{19}-steroids, particularly 16α-hydroxydehydroepiandrosterone (16-OHDHEA), were converted to estriol by placental tissue. Thus, the disproportionate increase in estriol formation during pregnancy is accounted for by placental synthesis of estriol principally from plasma-borne 16-OHDHEA-S. Near term, the fetus is the source of 90 percent of placental estriol and estetrol precursor in normal human pregnancy.

Thus, the placenta secretes several estrogens, including estradiol, estrone, estriol, and estetrol. Because of its hemochorial nature, most placental estrogens are released into the maternal circulation. Maternal estriol and estetrol are produced almost solely by fetal steroid precursors. Thus, levels of these steroids were used in the past as an indicator of fetal well-being. However, low sensitivity and specificity of such tests have caused them to be discarded.

Enzymatic Considerations

There is a severe deficiency in the expression of the microsomal enzyme 3α-hydroxysteroid dehydrogenase, $\Delta^{5\text{-}4}$-isomerase (3βHSD) in adrenal fetal zone cells (Doody and co-workers, 1990; Rainey and colleagues, 2001). This limits the conversion of pregnenolone to progesterone and of 17α-hydroxypregnenolone to 17α-hydroxyprogesterone, an obligatory step in cortisol biosynthesis. There is, however, very active steroid sulfotransferase activity in the fetal adrenal glands. As a consequence, the principal secretory products of the fetal adrenal glands are pregnenolone sulfate and DHEA-S. Comparatively, cortisol, which likely arises primarily in the neocortex and transitional zone of the fetal adrenal glands and not in the fetal zone, is a minor secretory product until late in gestation.

Fetal Adrenal Steroid Precursor

The precursor for fetal adrenal steroidogenesis is cholesterol. The rate of steroid biosynthesis in the fetal gland is so great that its steroidogenesis alone is equivalent to a fourth of the total daily LDL cholesterol turnover in adults. Fetal adrenal glands synthesize cholesterol from acetate. All enzymes involved in cholesterol biosynthesis are elevated compared with that of the adult adrenal gland (Rainey and colleagues, 2001). Thus, the rate of de novo cholesterol synthesis by fetal adrenal tissue is extremely high. Even so, it is insufficient to account for the steroids produced by these glands. Therefore, cholesterol must be assimilated from the fetal circulation. Plasma cholesterol and its esters are present in the form of very-low-density lipoprotein (VLDL), low-density lipoprotein (LDL), and high-density lipoprotein (HDL).

Simpson and colleagues (1979) found that fetal glands take up lipoproteins as a source of cholesterol for steroidogenesis. LDL was most effective, HDL was much less, and VLDL was devoid of stimulatory activity. They also evaluated relative contributions of cholesterol synthesized de novo and that of cholesterol derived from LDL uptake. These authors confirmed that fetal adrenal glands are highly dependent on circulating LDL as a source of cholesterol for optimum steroidogenesis (Carr and colleagues, 1980, 1982; Carr and Simpson, 1981).

Most fetal plasma cholesterol arises by de novo synthesis in the fetal liver (Carr and Simpson, 1984). The low level of LDL cholesterol in fetal plasma is not the consequence of impaired fetal LDL synthesis, but instead, it results from the rapid use of LDL by the fetal adrenal glands for steroidogenesis (Parker and colleagues, 1980, 1983). As expected, in the anencephalic newborn with atrophic adrenal glands, the LDL cholesterol levels in umbilical cord plasma are high.

Fetal Conditions That Affect Estrogen Production

Several fetal disorders alter the availability of substrate for placental steroid synthesis. A schematic representation of the pathways of placental estrogen formation is presented in Figure 3-29.

Fetal Demise

It has been known for many decades that fetal death is followed by a striking reduction in levels of urinary estrogens. It was also known that there was an abrupt and striking decrease in the production of placental estrogens after ligation of the umbilical cord with the fetus and placenta left in situ (Cassmer, 1959). These findings led to at least two interpretations. The first was that maintenance of the fetal placental circulation is essential to the functional integrity of the placenta. This was unlikely to be correct because placental production of progesterone was maintained after occlusion of the umbilical cord. A second explanation was that after umbilical cord ligation, an important source of precursors of placental estrogen—but not progesterone—biosynthesis was eliminated upon fetal death.

Fetal Anencephaly

In the absence of the fetal zone of the adrenal cortex, as in anencephaly, the formation rate of placental estrogens—especially estriol—is severely limited because of diminished availability of C_{19}-steroid precursors. Therefore, almost all estrogens produced in women pregnant with an anencephalic fetus arise by placental use of maternal plasma DHEA-S. Furthermore, in such pregnancies, the production of estrogens can be increased by the maternal administration of ACTH, which stimulates the rate of DHEA-S secretion by the maternal adrenal gland. Because ACTH does not cross the placenta, there is no fetal adrenal stimulation. Finally, placental estrogen production is decreased in women pregnant with an anencephalic fetus when a potent glucocorticoid is given to the mother. This suppresses ACTH secretion and thus decreases the rate of DHEA-S secretion from the maternal adrenal cortex (MacDonald and Siiteri, 1965).

Fetal Adrenal Hypoplasia

Congenital adrenal cortical hypoplasia occurs in perhaps 1 in 12,500 births (McCabe, 2001). There appear to be two primary forms. In the *miniature adult form*, which results from anencephaly or abnormal pituitary function, there is a very small adrenal cortical zone. The *cytomegalic form* is so called because of nodular formation of eosinophilic cells in the fetal zone. Estrogen production in pregnancies with either form is limited and suggests the absence of C_{19}-precursors. The cytomegalic form results from disruptive mutations in the gene known as the *dosage-sensitive sex reversal–adrenal hypoplasia congenita critical region on the X chromosome, gene 1(DAX1)* (McCabe, 2001).

Fetal-Placental Sulfatase Deficiency

Placental estrogen formation is generally regulated by the availability of C_{19}-steroid prohormones in fetal and maternal plasma. Specifically, there is no rate-limiting enzymatic reaction in the placental pathway from C_{19}-steroids to estrogen biosynthesis. An exception to this generalization is placental sulfatase deficiency, which is associated with very low estrogen levels in otherwise normal pregnancies (France and Liggins, 1969). Sulfatase deficiency precludes the hydrolysis of C_{19}-steroid sulfates, the first enzymatic step in the placental use of these circulating prehormones for estrogen biosynthesis. This deficiency is an X-linked disorder, and all affected fetuses are male. Its estimated frequency is 1 in 2000 to 5000 births and is associated with delayed onset of labor. It also is associated with the development of ichthyosis in affected males later in life (Bradshaw and Carr, 1986).

Fetal-Placental Aromatase Deficiency

There are a few well-documented examples of aromatase deficiency (Simpson, 2000). Fetal adrenal DHEA-S, which is produced in large quantities, is converted in the placenta to androstenedione, but in cases of placental aromatase deficiency, androstenedione cannot be converted to estradiol. Rather, androgen metabolites of DHEA produced in the placenta, including androstenedione and some testosterone, are secreted into the maternal or fetal circulation, or both, causing virilization of the mother and the female fetus (Harada and colleagues, 1992; Shozu and associates, 1991). Although pregnancies with aromatase deficiency and a male fetus may be uneventful, these estrogen-deficient males have delayed epiphyseal closure during puberty. As a consequence, affected men continue to grow during adulthood, becoming very tall and displaying deficient bone mineralization (Morishima and colleagues, 1995).

Trisomy 21—Down Syndrome

Second-trimester maternal serum screening for abnormal levels of hCG, alpha-fetoprotein, and other analytes has become universal (see Chap. 13, p. 292). As a result, it was discovered that serum unconjugated estriol levels were low in women with Down syndrome fetuses (Benn, 2002). The likely reason for this is inadequate formation of C19-steroids in the adrenal glands of these trisomic fetuses. This supposition is supported by reduced DHEA-S levels in both amnionic fluid and maternal serum in Down syndrome pregnancies (Newby and colleagues, 2000).

Deficiency in Fetal LDL Cholesterol Biosynthesis

A successful pregnancy in a woman with β-lipoprotein deficiency has been described (Parker and co-workers, 1986). The absence of LDL in the maternal serum restricted progesterone formation in both the corpus luteum and placenta. In addition, levels of estriol were lower than normal. Presumably, the diminished estrogen production was the result of decreased fetal LDL formation, which limited fetal adrenal production of estrogen precursor.

Fetal Erythroblastosis

In some cases of severe fetal D-antigen isoimmunization, estrogen levels in maternal plasma are elevated above normal. This is likely due to an increased placental mass from hypertrophy. This is seen with other causes of hyperplacentosis with a fetal hemocytic anemia, which occurs in such pregnancies (see Chap. 29, p. 618).

Maternal Conditions That Affect Placental Estrogen Production

Glucocorticoid Treatment

The administration of glucocorticoids in moderate to high doses to pregnant women causes a striking reduction in placental estrogen formation. Glucocorticoids act to inhibit ACTH secretion by the maternal and fetal pituitary glands, resulting in decreased maternal and fetal adrenal secretion of the placental estrogen precursor, DHEA-S.

Maternal Adrenal Dysfunction

In pregnant women with Addison disease, maternal urinary estrogen levels are decreased (Baulieu and colleagues, 1956). The decrease principally affects estrone and estradiol, because the fetal adrenal contribution to the synthesis of estriol, particularly in the latter part of pregnancy, is quantitatively much more important.

Maternal Ovarian Androgen-Producing Tumors

The extraordinary efficiency of the placenta in the aromatization of C_{19}-steroids may be exemplified by two considerations. First, Edman and associates (1981) found that virtually all of the androstenedione entering the intervillous space is taken up by syncytiotrophoblast and converted to estradiol, and none of this C_{19}-steroid enters the fetus. Second, it is relatively rare that a female fetus is virilized when there is a maternal androgen-secreting ovarian tumor. This finding also indicates that the placenta efficiently converts aromatizable C_{19}-steroids, including testosterone, to estrogens, thus precluding transplacental passage. Indeed, it may be that virilized female fetuses of women with an androgen-producing tumor are cases in which a nonaromatizable C_{19}-steroid androgen is produced by the tumor–for example, 5α-dihydrotestosterone. Another explanation is that testosterone is produced very early in pregnancy in amounts that exceed the capacity of placental aromatase.

Gestational Trophoblastic Disease

In the case of complete hydatidiform mole or choriocarcinoma, there is no fetal adrenal source of C_{19}-steroid precursor for

trophoblast estrogen biosynthesis. Consequently, placental estrogen formation is limited to the use of C_{19}-steroids in the maternal plasma, and therefore the estrogen produced is principally estradiol (MacDonald and Siiteri, 1964, 1966). Great variation is observed in the rates of both estradiol and progesterone formation in molar pregnancies.

CHAPTER 4

Fetal Growth and Development

DETERMINATION OF GESTATIONAL AGE 78
MORPHOLOGICAL GROWTH 78
THE PLACENTA AND FETAL GROWTH 83
FETAL NUTRITION 87
FETAL PHYSIOLOGY 88
DEVELOPMENT OF GENITALIA 98

Contemporary obstetrical research focuses on the physiology and pathophysiology of the fetus, its development, and its environment. An important result is that the status of the fetus has been elevated to that of a patient who, in large measure, can be given the same meticulous care that obstetricians provide for pregnant women. In the course of these studies, it has become apparent that the conceptus is a dynamic force in the pregnancy unit. Normal fetal development is considered in this chapter. Anomalies, injuries, and diseases that affect the fetus and newborn are addressed in Chapter 29.

DETERMINATION OF GESTATIONAL AGE

Several terms are used to define the duration of pregnancy, and thus fetal age, but these are somewhat confusing. They are shown schematically in **Figure 4-1**. *Gestational age* or *menstrual age* is the time elapsed since the first day of the last menstrual period, a time that actually precedes conception. This starting time, which is usually about 2 weeks before ovulation and fertilization and nearly 3 weeks before implantation of the blastocyst, has traditionally been used because most women know their last period. Embryologists describe embryofetal development in *ovulation age,* or the time in days or weeks from ovulation. Another term is *postconceptional age,* nearly identical to ovulation age.

Clinicians customarily calculate gestational age as menstrual age. About 280 days, or 40 weeks, elapse on average between the first day of the last menstrual period and the birth of the fetus. This corresponds to 9 and 1/3 calendar months. A quick estimate of the due date of a pregnancy based on menstrual data can be made as follows: add 7 days to the first day of the last period and subtract 3 months. For example, if the first day of the last menses was July 5, the due date is 07-05 minus 3 (months) plus 7 (days) = 04-12, or April 12 of the following year. This calculation has been termed Naegele's rule. Many women undergo first- or early second-trimester sonographic examination to confirm gestational age. In these cases, the sonographic estimate is usually a few days later than that determined by the last period. To rectify this inconsistency—and to reduce the number of pregnancies diagnosed as postterm—some have suggested assuming that the average pregnancy is actually 283 days long and that 10 days be added to the last menses instead of 7 (Olsen and Clausen, 1998).

The period of gestation can also be divided into three units of three calendar months (13 weeks) each. These three *trimesters* have become important obstetrical milestones.

MORPHOLOGICAL GROWTH

Ovum, Zygote, and Blastocyst

During the first 2 weeks after ovulation, development phases include: (1) fertilization, (2) blastocyst formation, and (3) blastocyst implantation. Primitive chorionic villi are formed soon after implantation. With the development of chorionic villi, it is conventional to refer to the products of conception as an *embryo.* The early stages of preplacental development and formation of the placenta are described in Chapter 3 (p. 47).

Embryonic Period

The embryonic period commences at the beginning of the third week after ovulation and fertilization, which coincides in time with the expected day that the next menstruation would have started. The embryonic period lasts 8 weeks and is when organogenesis takes place (see Fig. 4-1). The embryonic disc is well defined, and most pregnancy tests that measure human chorionic gonadotropin (hCG) become positive by this time (see Chap. 8, p. 192). As shown in **Figure 4-2**, the body stalk is now differentiated, and the chorionic sac is approximately 1 cm in diameter. There is a true intervillous space that contains maternal blood and villous cores in which angioblastic chorionic mesoderm can be distinguished.

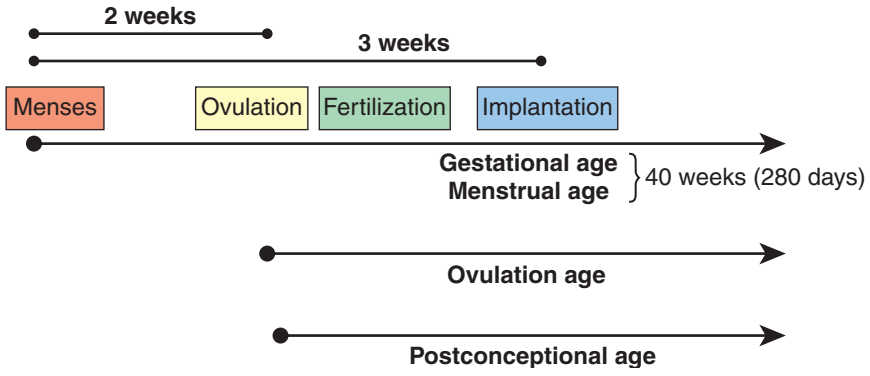

FIGURE 4-1 Terminology used to describe the duration of pregnancy.

The schematic timeline is shown in **Figure 4-3**. During the third week, fetal blood vessels in the chorionic villi appear (**Fig. 4-4**). In the fourth week a cardiovascular system has formed, and thereby, a true circulation is established both within the embryo and between the embryo and the chorionic villi. By the end of the fourth week, the chorionic sac is 2 to 3 cm in diameter, and the embryo is 4 to 5 mm in length (**Figs. 4-5**, **4-6**, and **4-7**). Partitioning of the primitive heart begins in the middle of the fourth week. Arm and leg buds are present, and the amnion is beginning to unsheathe the body stalk, which thereafter becomes the umbilical cord.

At the end of the sixth week, the embryo is 22 to 24 mm in length, and the head is large compared with the trunk. The heart is completely formed. Fingers and toes are present, and the arms bend at the elbows. The upper lip is complete, and the external ears form definitive elevations on either side of the head.

Fetal Period

The end of the embryonic period and the beginning of the fetal period is arbitrarily designated by most embryologists to begin 8 weeks after fertilization—or 10 weeks after onset of last menses. At this time, the embryofetus is nearly 4 cm long (**Fig. 4-8**).

Referring back to Figure 4-3, development during the fetal period consists of growth and maturation of structures that were formed during the embryonic period. Because of the variability in the length of the legs and the difficulty of maintaining them in extension, crown-to-rump measurements, which correspond to the sitting height, are more accurate than those corresponding to the standing height (**Table 4-1**).

12 Gestational Weeks

The uterus usually is just palpable above the symphysis pubis, and the fetal crown-rump length is 6 to 7 cm. Centers of ossification have appeared in most of the fetal bones, and the fingers and toes have become differentiated. Skin and nails have developed and scattered rudiments of hair appear. The external genitalia are beginning to show definitive signs of male or female gender. The fetus begins to make spontaneous movements.

16 Gestational Weeks

The fetal crown-rump length is 12 cm, and the weight is 110 g. Gender can be determined by experienced observers by inspection of the external genitalia by 14 weeks.

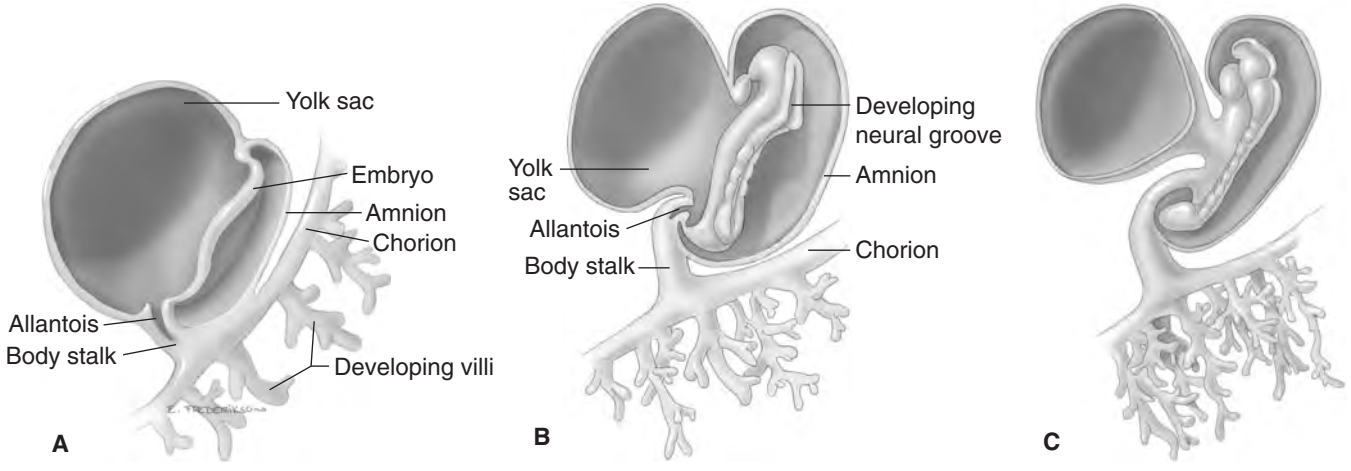

FIGURE 4-2 Early human embryos. Ovulation ages: **A.** 19 days (presomite). **B.** 21 days (7 somites). **C.** 22 days (17 somites). (After drawings and models in the Carnegie Institute.)

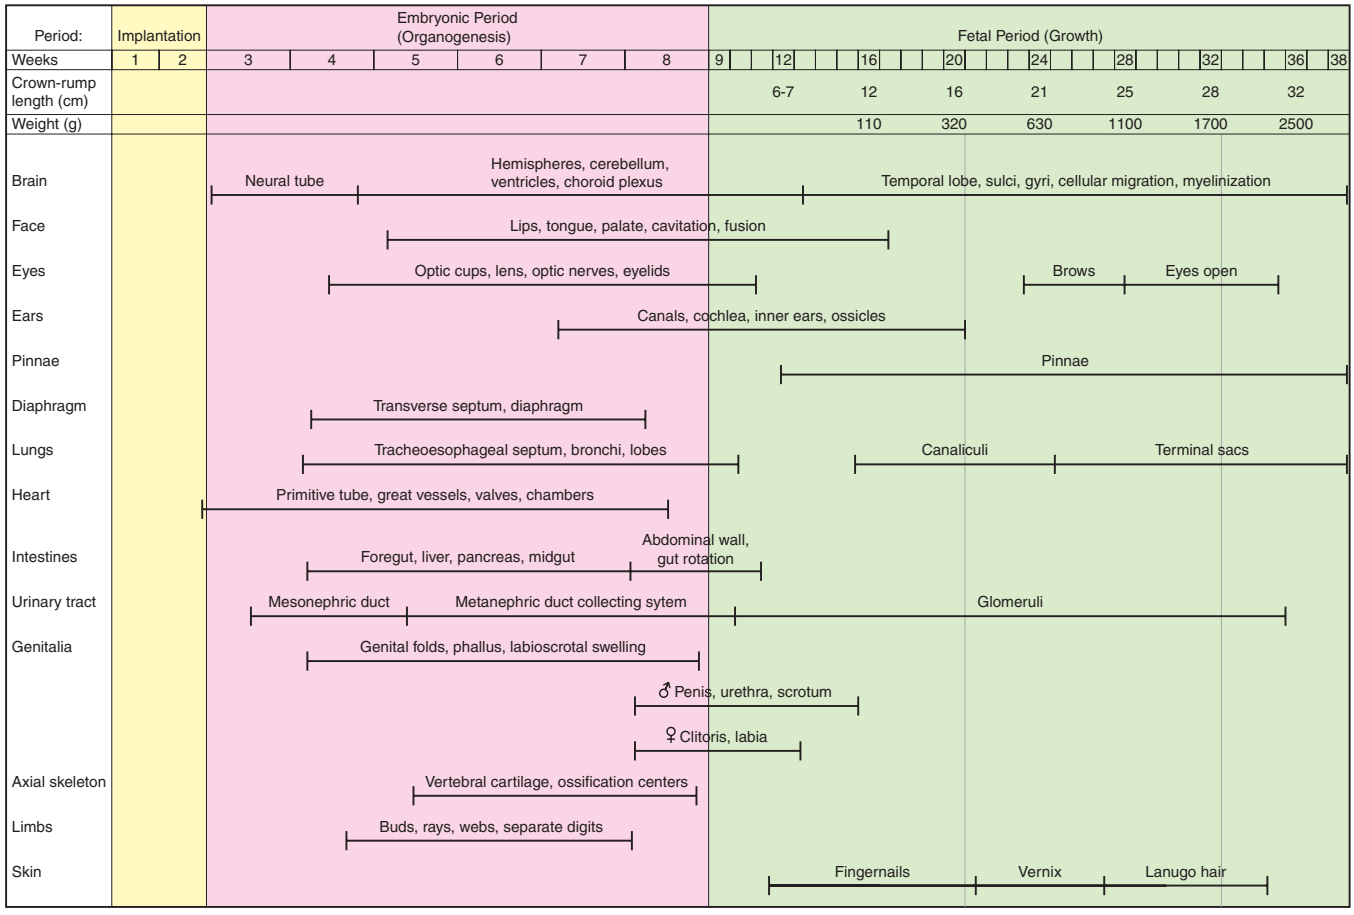

FIGURE 4-3 Embryofetal development according to gestational age determined by the first day of the last menses. Times are approximate.

20 Gestational Weeks

This is the midpoint of pregnancy as estimated from the beginning of the last menses. The fetus now weighs somewhat more than 300 g, and weight begins to increase in a linear manner. From this point onward, the fetus moves about every minute and is active 10 to 30 percent of the time (DiPietro, 2005). The fetal skin has become less transparent, a downy lanugo covers its entire body, and some scalp hair has developed.

24 Gestational Weeks

The fetus now weighs about 630 g. The skin is characteristically wrinkled, and fat deposition begins. The head is still comparatively large, and eyebrows and eyelashes are usually recognizable. The canalicular period of lung development, during which the bronchi and bronchioles enlarge and alveolar ducts develop, is nearly completed. A fetus born at this time will attempt to breathe, but many will die because the terminal sacs, required for gas exchange, have not yet formed.

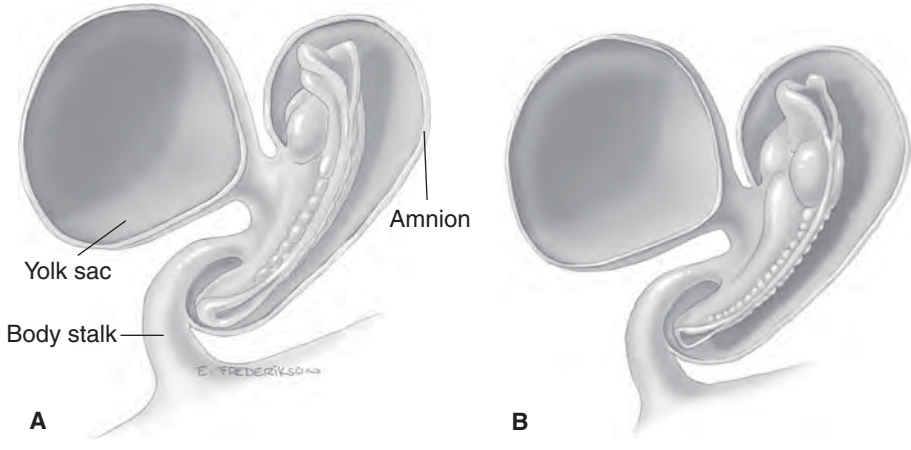

FIGURE 4-4 Early human embryos. Ovulation ages: **A.** 22 days. **B.** 23 days. (After drawings and models in the Carnegie Institute.)

28 Gestational Weeks

The crown-rump length is approximately 25 cm, and the fetus weighs about 1100 g. The thin skin is red and covered with *vernix caseosa*. The pupillary membrane has just disappeared from the eyes. The otherwise normal neonate born at this age has a 90-percent chance of survival without physical or neurological impairment.

32 Gestational Weeks

The fetus has attained a crown-rump length of about 28 cm and a weight of approximately 1800 g. The skin surface is still red and wrinkled.

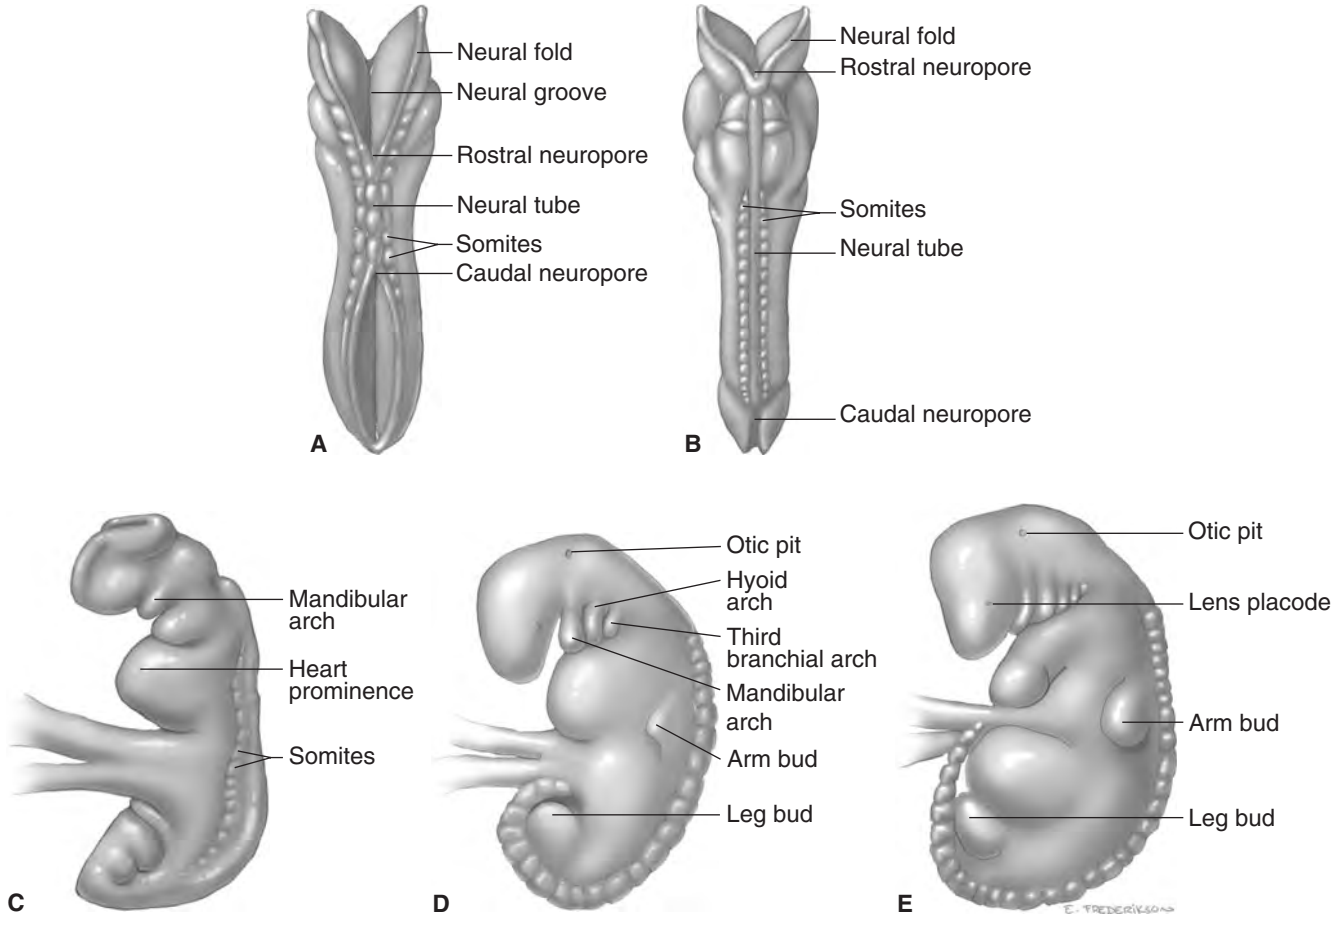

FIGURE 4-5 Three- to four-week-old embryos. **A, B.** Dorsal views of embryos during 22 to 23 days of development showing 8 and 12 somites, respectively. **C–E.** Lateral views of embryos during 24 to 28 days, showing 16, 27, and 33 somites, respectively. (Redrawn from Moore, 1988.)

36 Gestational Weeks

The average crown-rump length of the fetus is about 32 cm, and the weight is approximately 2500 g. Because of the deposition of subcutaneous fat, the body has become more rotund, and the previous wrinkled appearance of the face has been lost.

40 Gestational Weeks

This is considered term from the onset of the last menstrual period. The fetus is now fully developed. The average crown-rump length is about 36 cm, and the weight is approximately 3400 g.

Fetal Head

From an obstetrical viewpoint, the fetal head size is important because an essential feature of labor is the adaptation between the head and the maternal bony pelvis. Only a comparatively small part of the head at term is represented by the face. The rest of the head is composed of the firm skull, which is made up of two frontal, two parietal, and two temporal bones, along with the upper portion of the occipital bone and the wings of the sphenoid. These bones are separated by membranous spaces that are termed *sutures* (Fig. 4-9).

The most important sutures are the frontal, between the two frontal bones; the sagittal, between the two parietal bones; the two coronal, between the frontal and parietal bones; and the two lambdoid, between the posterior margins of the parietal bones and upper margin of the occipital bone. Where several sutures meet, an irregular space forms, which is enclosed by a membrane and designated as a *fontanel* (see Fig. 4-9). The greater, or anterior, fontanel is a lozenge-shaped space that is situated at the junction of the sagittal and the coronal sutures. The lesser, or posterior, fontanel is represented by a small triangular area at the intersection of the sagittal and lambdoid sutures. The localization of these fontanels gives important information concerning the presentation and position of the fetus during labor.

It is customary to measure certain critical diameters and circumferences of the newborn head (see Fig. 4-9). The diameters include:

1. The *occipitofrontal* (11.5 cm), which follows a line extending from a point just above the root of the nose to the most prominent portion of the occipital bone.
2. The *biparietal* (9.5 cm), the greatest transverse diameter of the head, which extends from one parietal boss to the other.
3. The *bitemporal* (8.0 cm), which is the greatest distance between the two temporal sutures.
4. The *occipitomental* (12.5 cm), which extends from the chin to the most prominent portion of the occiput.

FIGURE 4-6 Photograph of dorsal view of embryo at 24 to 26 days and corresponding to Figure 4–4B. (Visualization is provided by www.theVisualMD.com.)

FIGURE 4-8 Lateral view of embryofetus at 56 days, which marks the end of the embryonic period and the beginning of the fetal period. The liver is within the dotted-line circle. (Visualization is provided by www.theVisualMD.com.)

FIGURE 4-7 Photograph of lateral view of embryo at about 28 days and corresponding to Figure 4–4E. (Visualization is provided by www.theVisualMD.com.)

5. The *suboccipitobregmatic* (9.5 cm), which follows a line drawn from the middle of the large fontanel to the undersurface of the occipital bone just where it joins the neck.

The greatest circumference of the head, which corresponds to the plane of the occipitofrontal diameter, averages 34.5 cm, a size too large to fit through the pelvis without flexion. The smallest circumference, corresponding to the plane of the suboccipitobregmatic diameter, is 32 cm. The bones of the cranium are normally connected only by a thin layer of fibrous tissue. This allows considerable shifting or sliding of each bone to accommodate the size and shape of the maternal pelvis. This process is termed *molding*. The head position and degree of skull ossification result in a spectrum of cranial plasticity from minimal to great. In some cases, this undoubtedly contributes to fetopelvic disproportion, a leading indication for cesarean delivery (see Chap. 20, p. 472).

Fetal Brain

There is a steady gestational age-related change in the appearance of the fetal brain so that it is possible to identify fetal age from its external appearance (Dolman, 1977). Neuronal proliferation and migration proceed along with gyral growth and maturation (**Fig. 4-10**). Manganaro and colleagues (2007) have provided sequential maturation studies of the developing fetal brain imaged with magnetic resonance imaging. Myelination of the ventral roots of the cerebrospinal nerves and brainstem begins at

TABLE 4-1. Criteria for Estimating Age During the Fetal Period

Age (weeks)					
Menstrual	Fertilization	Crown-Rump Length (mm)[a]	Foot Length (mm)[a]	Fetal Weight (g)[b]	Main External Characteristics
11	9	50	7	8	Eyes closing or closed. Head more rounded. External genitalia still not distinguishable as male or female. Intestines are in the umbilical cord.
12	10	61	9	14	Intestines in abdomen. Early fingernail development.
14	12	87	14	45	Sex distinguishable externally. Well-defined neck.
16	14	120	20	110	Head erect. Lower limbs well developed.
18	16	140	27	200	Ears stand out from head.
20	18	160	33	320	Vernix caseosa present. Early toenail development.
22	20	190	39	460	Head and body (lanugo) hair visible.
24	22	210	45	630	Skin wrinkled and red.
26	24	230	50	820	Fingernails present. Lean body.
28	26	250	55	1000	Eyes partially open. Eyelashes present.
30	28	270	59	1300	Eyes open. Good head of hair. Skin slightly wrinkled.
32	30	280	63	1700	Toenails present. Body filling out. Testes descending.
34	32	300	68	2100	Fingernails reach fingertips. Skin pink and smooth.
38	36	340	79	2900	Body usually plump. Lanugo hairs almost absent. Toenails reach toe tips.
40	38	360	83	3400	Prominent chest; breasts protrude. Testes in scrotum or palpable in inguinal canals. Fingernails extend beyond fingertips.

[a]These measurements are average and so may not apply to specific cases; dimensional variations increase with age.
[b]These weights refer to fetuses that have been fixed for about 2 weeks in 10-percent formalin.
Fresh specimens usually weigh approximately 5 percent less.
Reprinted from *The Developing Human: Clinically Oriented Embryology,* 2nd ed., by KL Moore, Copyright 1977, with permission from Elsevier.

approximately 6 months, but the major portion of myelination occurs after birth. The lack of myelin and the incomplete ossification of the fetal skull permit the structure of the brain to be seen with sonography throughout gestation.

THE PLACENTA AND FETAL GROWTH

The placenta is the organ of transfer between mother and fetus. At the maternal-fetal interface, there is transfer of oxygen and nutrients from the mother to the fetus and carbon dioxide and metabolic wastes from fetus to mother. There are no direct communications between fetal blood, which is contained in the fetal capillaries of the chorionic villi, and maternal blood, which remains in the intervillous space. Bidirectional transfer depends on the processes that permit or aid the transport through the syncytiotrophoblast of the intact chorionic villi.

That said, there are occasional breaks in the chorionic villi, which permit escape of various numbers of fetal cells into the maternal circulation. This leakage is the mechanism by which some D-negative women become sensitized by the erythrocytes of their D-positive fetus (see Chap. 29, p. 618). It can also lead to *chimerism* from entrance of allogeneic fetal cells, including trophoblasts, into maternal blood. These are estimated to range from 1 to 6 cells/mL around midpregnancy, and some are "immortal" (Lissauer and colleagues, 2007). A clinical corollary is that some maternal autoimmune diseases may be provoked by such chimerism (see Chap. 54, p. 1146).

The Intervillous Space

Maternal blood in the extravascular compartment, that is, the intervillous space, is the primary biologic unit of maternal–fetal transfer. Blood from the maternal spiral arteries directly bathes the trophoblasts. Substances transferred from mother to fetus first enter the intervillous space and are then transported to the syncytiotrophoblast. Substances transported from the fetus to the mother are transferred from the syncytium into the same space. Thus, the chorionic villi and the intervillous space function together as the fetal lung, gastrointestinal tract, and kidney.

Circulation within the intervillous space is described in Chapter 3 (p. 55). Intervillous and uteroplacental blood flow increases throughout the first trimester of normal pregnancies (Mercé and associates, 2009). At term, the residual volume of

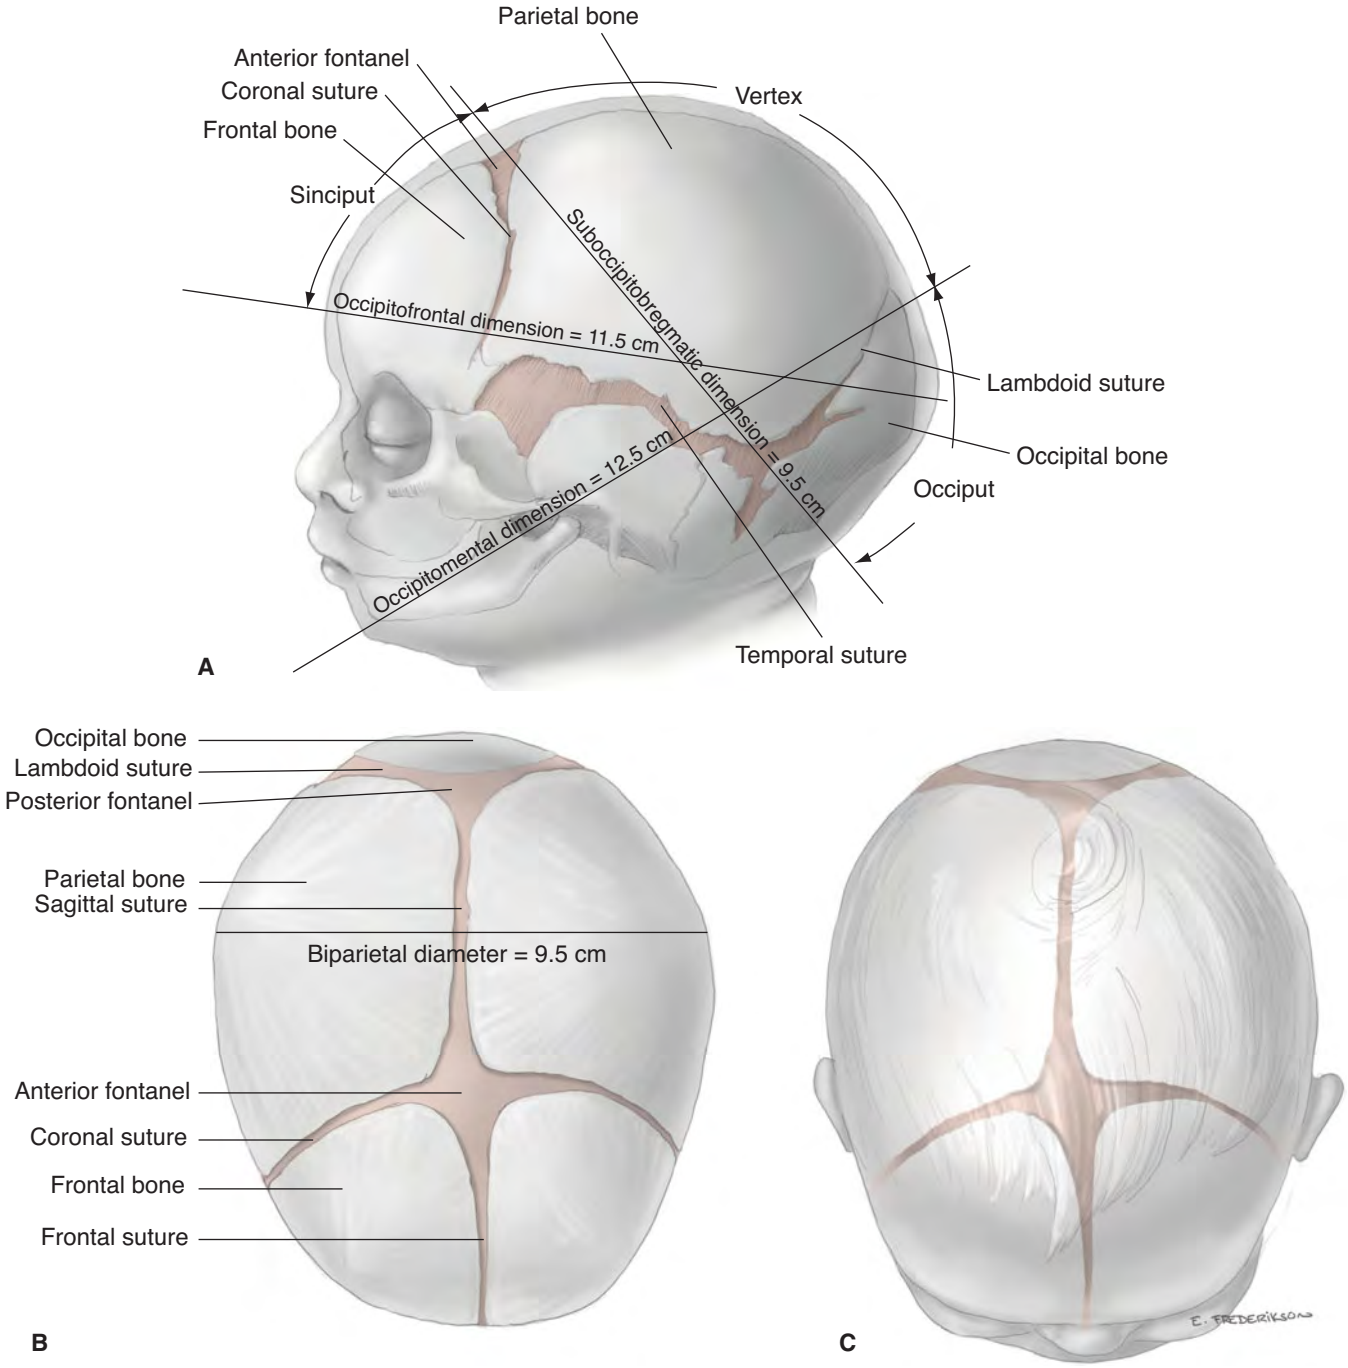

FIGURE 4-9 Fetal head **(A-C)** at term showing fontanels, sutures, and the various dimensions.

the intervillous space measures about 140 mL. Before delivery, however, the volume of this space may be twice this value (Aherne and Dunnill, 1966). Uteroplacental blood flow near term has been estimated to be 700 to 900 mL/min, with most of the blood apparently going to the intervillous space.

Active labor contractions reduce blood flow into the intervillous space, the degree of which depends on the intensity of the contraction. Blood pressure within the intervillous space is significantly less than uterine arterial pressure, but somewhat greater than venous pressure. The latter, in turn, varies depending on several factors, including maternal position. When supine, for example, pressure in the lower part of the inferior vena cava is elevated, and consequently, pressure in the uterine and ovarian veins, and in turn in the intervillous space, is increased.

Placental Transfer

Chorionic Villus

Substances that pass from maternal blood to fetal blood must first traverse the syncytiotrophoblast, then stroma of the intravillous space, and finally the fetal capillary wall. Although this histological barrier separates the blood in the maternal and fetal

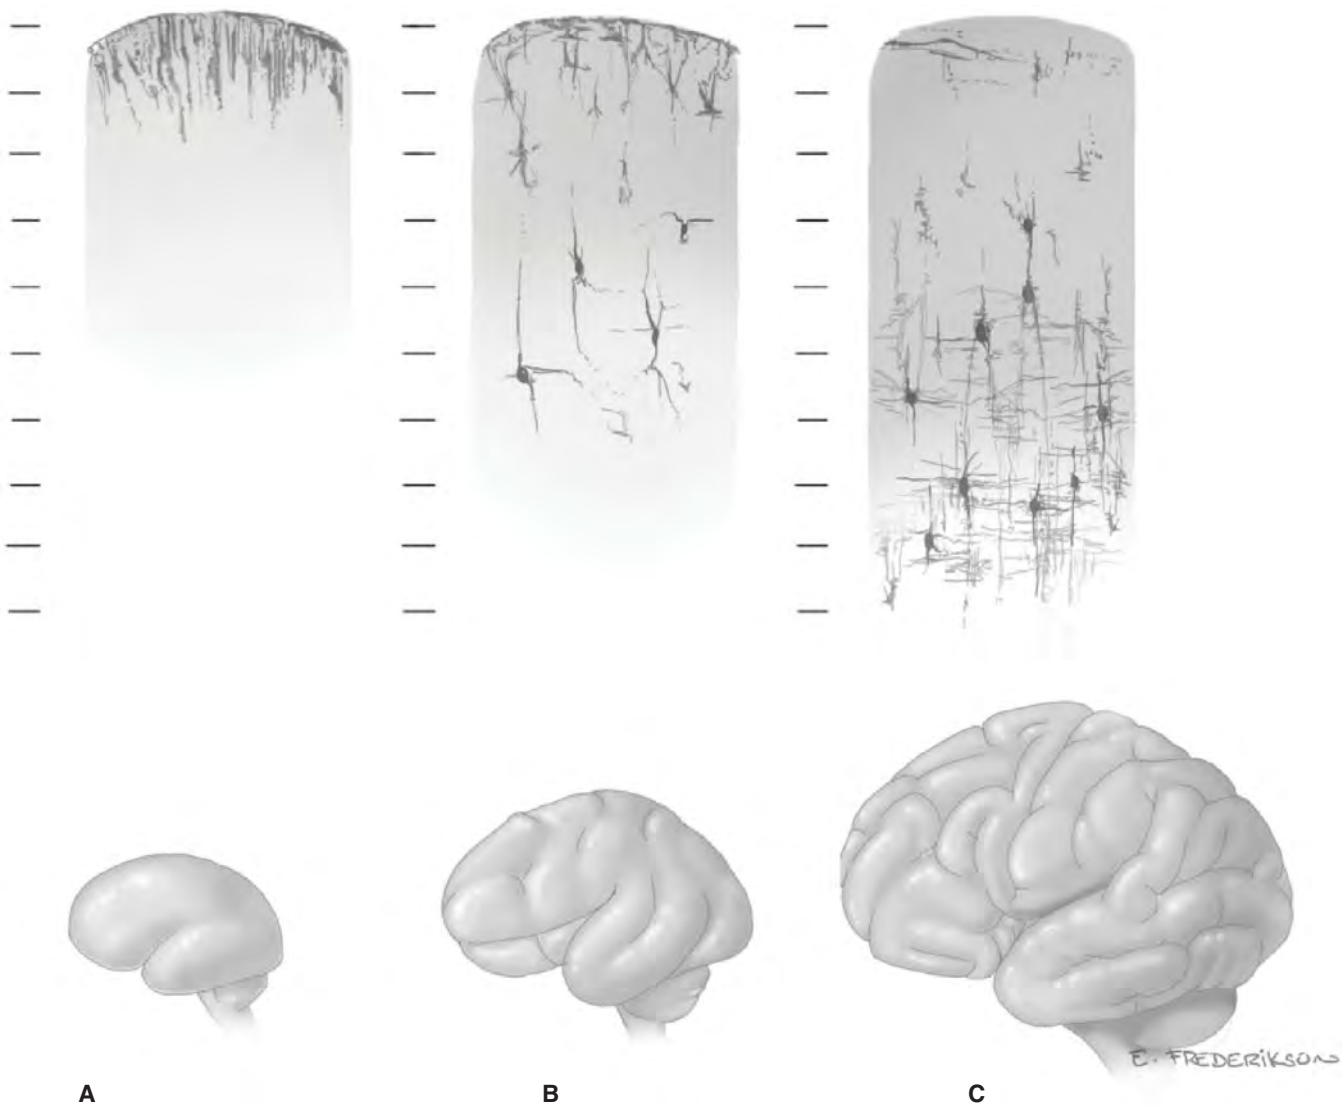

FIGURE 4-10 Neuronal proliferation and migration are complete at 20 to 24 weeks. During the second half of gestation, organizational events proceed with gyral formation and proliferation, differentiation, and migration of cellular elements. Approximate gestational ages are listed. **A.** 20 weeks. **B.** 35 Weeks. **C.** 40 Weeks.

circulations, it does not function like a simple physical barrier. In fact, throughout pregnancy, syncytiotrophoblast actively or passively permits, facilitates, and adjusts the amount and rate of transfer of a wide range of substances to the fetus.

Regulation of Placental Transfer

The syncytiotrophoblast is the fetal tissue interface. Its maternal-facing surface is characterized by a complex microvillus structure. The fetal-facing basal cell membrane of the trophoblast is the site of transfer to the intravillous space through which the fetal capillaries traverse. These capillaries are an additional site for transport from the intravillous space into fetal blood, or vice versa.

In determining the effectiveness of the human placenta as an organ of transfer, at least 10 variables are important.

1. The concentration of the substance in maternal plasma, and the extent to which it is bound to another compound, such as a carrier protein.
2. The rate of maternal blood flow through the intervillous space.
3. The area available for exchange across the villous trophoblast epithelium.
4. If the substance is transferred by simple diffusion, the physical properties of the trophoblastic tissue.
5. For any substance actively transported, the capacity of the biochemical machinery of the placenta for effecting active transfer, for example, specific receptors on the plasma membrane of the trophoblast.
6. The amount of the substance metabolized by the placenta during transfer.
7. The area for exchange across the fetal intervillous capillaries.
8. The concentration of the substance in the fetal blood.

10. The rate of fetal blood flow through the villous capillaries.

Mechanisms of Transfer

Most substances with a molecular mass less than 500 Da pass readily through placental tissue by simple diffusion. Also, some low-molecular-weight compounds undergo transfer facilitated by syncytiotrophoblast. These are usually those that are in low concentration in maternal plasma but are essential for normal fetal development. Simple diffusion appears to be the mechanism involved in the transfer of oxygen, carbon dioxide, water, and most electrolytes. Anesthetic gases also pass through the placenta rapidly by simple diffusion.

Insulin, steroid hormones, and thyroid hormones cross the placenta, but at very slow rates. The hormones synthesized in situ in the trophoblasts enter both the maternal and fetal circulations, but not equally (see Chap. 3, p. 62). Examples are concentrations of chorionic gonadotropin and placental lactogen, which are much lower in fetal plasma than in maternal plasma. Substances of high molecular weight usually do not traverse the placenta, but there are important exceptions, such as immunoglobulin G—molecular weight 160,000 Da—which is transferred by way of a specific trophoblast receptor–mediated mechanism.

Transfer of Oxygen and Carbon Dioxide

It has long been recognized that the placenta serves as the fetal lung. As early as 1674, Mayow suggested that the placenta served as the fetal lung (Morriss and associates, 1994). In 1796, Erasmus Darwin, only 22 years after the discovery of oxygen, observed that the color of blood passing through lungs and gills became bright red. He deduced, from the structure as well as the position of the placenta, that it likely was the source of fetal oxygen.

Placental oxygen transfer is blood-flow limited. Using estimated uteroplacental blood flow, Longo (1991) calculated oxygen delivery to be about 8 mL O_2/min/kg of fetal weight. And because fetal blood oxygen stores are sufficient for only 1 to 2 minutes, this supply must be continuous. Normal values for oxygen, carbon dioxide, and pH in fetal blood are presented in Figure 4-11. Because of the continuous passage of oxygen from maternal blood in the intervillous space to the fetus, its oxygen saturation resembles that in the maternal capillaries. The average oxygen saturation of intervillous blood is estimated to be 65 to 75 percent, with a partial pressure (P_{O_2}) of 30 to 35 mm Hg. The oxygen saturation of umbilical vein blood is similar, but with a somewhat lower oxygen partial pressure.

In general, transfer of fetal carbon dioxide is accomplished by diffusion. The placenta is highly permeable to carbon dioxide, which traverses the chorionic villus more rapidly than oxygen. Near term, the partial pressure of carbon dioxide (P_{CO_2}) in the umbilical arteries averages about 50 mm Hg, or approximately 5 mm Hg more than in the maternal intervillous blood. Fetal blood has less affinity for carbon dioxide than does maternal blood, thereby favoring the carbon dioxide transfer from fetus to mother. Also, mild maternal hyperventilation results in a fall in P_{CO_2} levels, favoring a transfer of carbon dioxide from the fetal compartment to maternal blood (see Chap. 5, p. 122).

Selective Transfer and Facilitated Diffusion

Although simple diffusion is an important method of placental transfer, the trophoblast and chorionic villus unit demonstrate enormous selectivity in transfer. This results in different concentrations of a variety of metabolites on the two sides of the villus. The concentrations of a number of substances that are not synthesized by the fetus are several times higher in fetal than in maternal blood. Ascorbic acid is a good example. This relatively low-molecular-weight substance resembles pentose and hexose sugars and might be expected to traverse the placenta by simple diffusion. The concentration of ascorbic acid, however, is two to four times higher in fetal plasma than in maternal plasma (Morriss and associates, 1994). Another example is the unidirectional transfer of iron across the placenta. Typically, maternal plasma iron concentration is much lower than that in her fetus. Even with severe maternal iron-deficiency anemia, the fetal hemoglobin mass is normal.

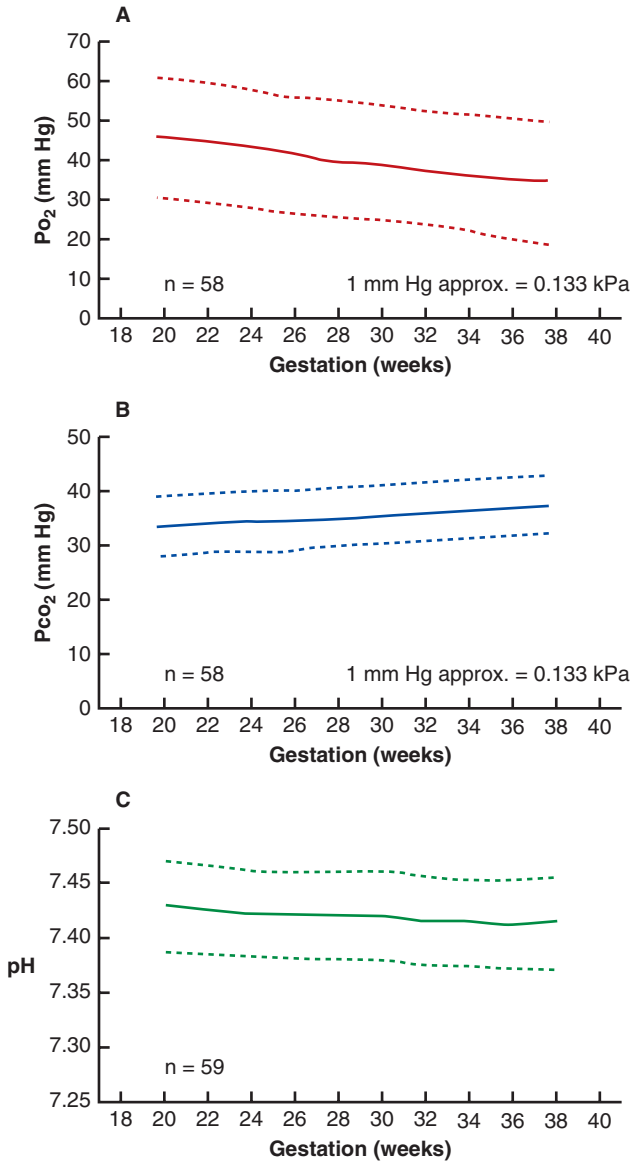

FIGURE 4-11 Umbilical venous oxygen pressure (P_{O_2}) **(A)**, carbon dioxide pressure (P_{CO_2}) **(B)**, and pH **(C)** from cordocentesis performed in fetuses being evaluated for possible intrauterine infections or hemolysis, but who were found to be healthy at birth and appropriately grown. FETAL NUTRITION

Because of the small amount of yolk in the human ovum, growth of the embryofetus is dependent on maternal nutrients during the first 2 months. During the first few days after implantation, the nutrition of the blastocyst comes from the interstitial fluid of the endometrium and the surrounding maternal tissue.

Maternal adaptations to store and transfer nutrients to the fetus are discussed in Chapter 5 and summarized here. The maternal diet is transferred into storage forms to meet her demands for energy, tissue repair, and new growth, including maternal needs for pregnancy. Three major maternal storage depots—the liver, muscle, and adipose tissue—and the storage hormone insulin are intimately involved in the metabolism of the nutrients absorbed from the maternal gut.

Insulin secretion is sustained by increased serum levels of glucose and amino acids. The net effect is storage of glucose as glycogen primarily in liver and muscle, retention of some amino acids as protein, and storage of the excess as fat. Storage of maternal fat peaks in the second trimester, and then declines as fetal demands increase in late pregnancy (Pipe and colleagues, 1979). Interestingly, the placenta appears to act as a nutrient sensor, altering transport based on the maternal supply and environmental stimuli (Fowden and colleagues, 2006; Jansson and Powell, 2006).

During times of fasting, glucose is released from glycogen, but maternal glycogen stores cannot provide an adequate amount of glucose to meet requirements for maternal energy and fetal growth. Augmentation is provided by cleavage of triacylglycerols, stored in adipose tissue, which result in free fatty acids. Lipolysis is activated, directly or indirectly, by hormones that include glucagon, norepinephrine, placental lactogen, glucocorticosteroids, and thyroxine.

Glucose and Fetal Growth

Although dependent on the mother for nutrition, the fetus also actively participates in providing for its own nutrition. At midpregnancy, fetal glucose concentration is independent of and may exceed maternal levels (Bozzetti and colleagues, 1988). Glucose is the major nutrient for fetal growth and energy. It is logical that mechanisms exist during pregnancy to minimize maternal glucose use so that the limited maternal supply is available to the fetus. It is believed that placental lactogen (hPL), a hormone normally present in abundance in the mother but not the fetus, blocks the peripheral uptake and use of glucose, while promoting the mobilization and use of free fatty acids by maternal tissues (see Chap. 3, p. 65).

Glucose Transport

The transfer of D-glucose across cell membranes is accomplished by a carrier-mediated, stereospecific, nonconcentrating process of *facilitated diffusion.* At least 14 separate glucose transport proteins (GLUTs) have been discovered (Leonce and colleagues, 2006). They belong to the 12-transmembrane segment transporter superfamily and are characterized further by tissue-specific distribution. GLUT-1 and GLUT-3 primarily facilitate glucose uptake by the placenta and are located in the plasma membrane of the microvilli of the syncytiotrophoblast (Korgun and colleagues, 2005). GLUT-1 expression increases as pregnancy advances and is induced by almost all growth factors (Sakata and colleagues, 1995).

Glucose, Insulin, and Fetal Macrosomia

The precise biomolecular events in the pathophysiology of fetal macrosomia are not defined. Nonetheless, it seems clear that fetal hyperinsulinemia is one driving force (Schwartz and colleagues, 1994). As discussed in Chapter 38 (p. 842), insulin-like growth factor, as well as fibroblast growth factor, also is involved (Giudice and associates, 1995; Hill and colleagues, 1995). Therefore, a hyperinsulinemic state with increased levels of selected growth factors, together with increased expression of GLUT proteins in syncytiotrophoblast, may promote excessive fetal growth.

Leptin

Leptin was originally identified as a product of adipocytes and a regulator of energy homeostasis. However, this polypeptide also contributes to angiogenesis, hematopoiesis, osteogenesis, pulmonary maturation, and neuroendocrine, immune, and reproductive functions (Henson and Castracane, 2006; Maymo and colleagues, 2009).

During pregnancy, leptin is produced by the mother, fetus, and placenta. It is expressed in syncytiotrophoblasts and fetal vascular endothelial cells. Of placental production, 5 percent enters fetal circulation, whereas 95 percent is transferred to the mother (Hauguel de Mouzon and associates, 2006) As a result, the placenta greatly contributes to maternal leptin levels.

Fetal levels begin rising approximately at 34 weeks and are correlated with fetal weight. Abnormal levels have been associated with growth disorders and preeclampsia. Postpartum, leptin levels decline in both the newborn and mother (Grisaru-Granovsky and co-workers, 2008).

Lactate

Lactate is transported across the placenta by facilitated diffusion. By way of co-transport with hydrogen ions, lactate is probably transported as lactic acid.

Free Fatty Acids and Triglycerides

The human newborn has a large proportion of fat, which averages 15 percent of body weight (Kimura, 1991). This indicates that late in pregnancy, a substantial part of the substrate transferred to the human fetus is stored as fat. Neutral fat in the form of triacylglycerols does not cross the placenta, but glycerol does, and fatty acids are synthesized in the placenta. Lipoprotein lipase is present on the maternal but not on the fetal side of the placenta. This arrangement favors hydrolysis of triacylglycerols in the maternal intervillous space while preserving these neutral lipids in fetal blood. Fatty acids transferred to the fetus can be converted to triacylglycerols in the fetal liver.

The placental uptake and use of low-density lipoprotein (LDL) is an alternative mechanism for fetal assimilation of essential fatty acids and amino acids (see Chap. 3, p. 67). The LDL particles from maternal plasma bind to specific LDL receptors in the coated-pit regions of the microvilli on the maternal-facing side of the syncytiotrophoblast. The large—about 250,000

Da—LDL particle is taken up by a process of receptor-mediated endocytosis. The apoprotein and cholesterol esters of LDL are hydrolyzed by lysosomal enzymes in the syncytium to give: (1) cholesterol for progesterone synthesis; (2) free amino acids, including essential amino acids; and (3) essential fatty acids, primarily linoleic acid. Indeed, the concentration of arachidonic acid, which is synthesized from linoleic acid in fetal plasma, is greater than that in maternal plasma. Linoleic acid or arachidonic acid or both must be assimilated from maternal dietary intake.

Amino Acids

The placenta concentrates a large number of amino acids (Lemons, 1979). Neutral amino acids from maternal plasma are taken up by trophoblasts by at least three specific processes. Presumably, amino acids are concentrated in the syncytiotrophoblasts and thence transferred to the fetal side by diffusion. Based on data from cordocentesis blood samples, the concentration of amino acids in umbilical cord plasma is greater than in maternal venous or arterial plasma (Morriss and associates, 1994). Activity of the transport systems is influenced by gestational age and environmental factors including heat stress, hypoxia, under- and overnutrition, as well as hormones such as glucocorticoids, growth hormone, and leptin (Fowden and colleagues, 2006). Recent in vivo studies suggest an upregulation of transport for certain amino acids and an increased fetal delivery in women with gestational diabetes associated with fetal overgrowth (Jansson and colleagues, 2006).

Proteins

Generally, there is very limited placental transfer of larger proteins. There are important exceptions, for example, immunoglobulin G (IgG) crosses the placenta in large amounts via endocytosis via trophoblast Fc receptors. IgG is present in approximately the same concentrations in cord and maternal sera, but IgA and IgM of maternal origin are effectively excluded from the fetus (Gitlin and colleagues, 1972).

Ions and Trace Metals

Iodide transport is clearly attributable to a carrier-mediated, energy-requiring active process. And indeed, the placenta concentrates iodide. The concentrations of zinc in the fetal plasma also are greater than those in maternal plasma. Conversely, copper levels in fetal plasma are less than those in maternal plasma. This fact is of particular interest because important copper-requiring enzymes are necessary for fetal development.

Placental Sequestration of Heavy Metals

The heavy metal–binding protein, metallothionein-1, is expressed in human syncytiotrophoblast. This protein binds and sequesters a host of heavy metals, including zinc, copper, lead, and cadmium.

The most common source of cadmium in the environment is cigarette smoke. Cadmium levels in maternal blood and placenta are increased with maternal smoking, but there is no increase in cadmium transfer into the fetus. Presumably, the low levels of cadmium in the fetus are attributable to the sequestration of cadmium by metallothionein(s) in trophoblast. This comes about because cadmium acts to increase the transcription of the metallothionein gene(s). Thus, cadmium-induced increases in trophoblast metallothionein levels result in placental cadmium accumulation by sequestration. In the rat, data suggest that cadmium reduces the number of trophoblast cells, leading to poor placental growth (Lee and co-workers, 2009).

Metallothionein also binds and sequesters copper (Cu^{2+}) in placental tissue, thus accounting for the low levels of Cu^{2+} in cord blood (Iyengar and Rapp, 2001). A number of enzymes require Cu^{2+}, and its deficiency results in inadequate collagen cross-linking and in turn, diminished tensile strength of tissues. This may be important because the concentration of cadmium in amnionic fluid is similar to that in maternal blood. The incidence of preterm membrane rupture is increased in women who smoke. It is possible that cadmium provokes metallothionein synthesis in amnion, causing sequestration of Cu^{2+} and a pseudocopper deficiency.

Calcium and Phosphorus

These minerals also are actively transported from mother to fetus. A calcium-binding protein is present in placenta. Parathyroid hormone-related protein (PTH-rP), as the name implies, acts as a surrogate PTH in many systems, including the activation of adenylate cyclase and the movement of calcium ions (see also Chap. 3, p. 66, and Chap. 6, p. 149). PTH-rP is produced by the placenta as well as in fetal parathyroid glands, kidney, and other fetal tissues. Moreover, PTH is not demonstrable in fetal plasma, but PTH-rP is present. For these reasons, some refer to PTH-rP as the fetal parathormone (Abbas and associates, 1990). There is a Ca^{2+}-sensing receptor in trophoblast, as there is in the parathyroid glands (Juhlin and colleagues, 1990). The expression of PTH-rP in cytotrophoblasts is modulated by the extracellular concentration of Ca^{2+} (Hellman and co-workers, 1992). It seems possible, therefore, that PTH-rP synthesized in decidua, placenta, and other fetal tissues is important in fetal Ca^{2+} transfer and homeostasis.

Vitamins

The concentration of *vitamin A (retinol)* is greater in fetal than in maternal plasma and is bound to retinol-binding protein and to prealbumin. Retinol-binding protein is transferred from the maternal compartment across the syncytium. The transport of *vitamin C—ascorbic acid*—from mother to fetus is accomplished by an energy-dependent, carrier-mediated process. The levels of the principal *vitamin D—cholecalciferol*–metabolites, including 1,25-dihydroxycholecalciferol, are greater in maternal plasma than are those in fetal plasma. The 1β-hydroxylation of 25-hydroxyvitamin D_3 is known to take place in placenta and in decidua.

FETAL PHYSIOLOGY

Amnionic Fluid

In early pregnancy, amnionic fluid is an ultrafiltrate of maternal plasma. By the beginning of the second trimester, it consists largely of extracellular fluid that diffuses through the fetal skin and thus reflects the composition of fetal plasma (Gilbert and Brace, 1993). After 20 weeks, the cornification of fetal skin prevents this diffusion, and amnionic fluid is composed largely of fetal urine. Fetal kidneys start producing urine at 12 weeks, and

by 18 weeks, they are producing 7 to 14 mL per day. Fetal urine contains more urea, creatinine, and uric acid than fetal plasma. Amnionic fluid also contains desquamated fetal cells, vernix, lanugo, and various secretions. Because these are hypotonic, the net effect is that amnionic fluid osmolality decreases with advancing gestation. Pulmonary fluid contributes a small proportion of the amnionic volume, and fluid filtering through the placenta accounts for the rest.

The volume of amnionic fluid at each week is quite variable. In general, the volume increases by 10 mL per week at 8 weeks and increases up to 60 mL per week at 21 weeks, then declines gradually back to a steady state by 33 weeks (Brace and Wolf, 1989).

Amnionic fluid serves to cushion the fetus, allowing musculoskeletal development and protecting it from trauma. It also maintains temperature and has a minimal nutritive function. Epidermal growth factor (EGF) and EGF-like growth factors, such as transforming growth factor-β, are present in amnionic fluid. Ingestion of fluid into the gastrointestinal tract and inhalation into the lung may promote growth and differentiation of these tissues. Animal studies have shown that pulmonary hypoplasia can be produced by draining off amnionic fluid, by chronically draining pulmonary fluid through the trachea, and by physically preventing the prenatal chest excursions that mimic breathing (Adzick and associates, 1984; Alcorn and colleagues, 1977). Thus, the formation of intrapulmonary fluid and, at least as important, the alternating egress and retention of fluid in the lungs by breathing movements are essential to normal pulmonary development. Clinical implications of oligohydramnios and pulmonary hypoplasia are discussed in Chapter 21 (p. 496).

Fetal Circulation

The fetal circulation is substantially different from that of the adult and functions until the moment of birth, when it is required to change dramatically. For example, because fetal blood does not need to enter the pulmonary vasculature to be oxygenated, most of the right ventricular output bypasses the lungs. In addition, the fetal heart chambers work in parallel, not in series, which effectively supplies the brain and heart with more highly oxygenated blood than the rest of the body.

Oxygen and nutrient materials required for fetal growth and maturation are delivered from the placenta by the single umbilical vein (**Fig. 4-12**). The vein then divides into the ductus venosus and the portal sinus. The ductus venosus is the major branch of the umbilical vein and traverses the liver to enter the inferior vena cava directly. Because it does not supply oxygen to the intervening tissues, it carries well-oxygenated blood directly to the heart. In contrast, the portal sinus carries blood to the hepatic veins primarily on the left side of the liver where oxygen is extracted. The relatively deoxygenated blood from the liver then flows back into the inferior vena cava, which also receives less oxygenated blood returning from the lower body. Blood flowing to the fetal heart from the inferior vena cava, therefore, consists of an admixture of arterial-like blood that passes directly through the ductus venosus and less well-oxygenated blood that returns from most of the veins below the level of the diaphragm. The oxygen content of blood delivered to the heart from the inferior vena cava is thus lower than that leaving the placenta.

In contrast to postnatal life, the ventricles of the fetal heart work in parallel, not in series. Well-oxygenated blood enters the left ventricle, which supplies the heart and brain, and less oxygenated blood enters the right ventricle, which supplies the rest of the body. The two separate circulations are maintained by the structure of the right atrium, which effectively directs entering blood to either the left atrium or the right ventricle, depending on its oxygen content. This separation of blood according to its oxygen content is aided by the pattern of blood flow in the inferior vena cava. The well-oxygenated blood tends to course along the medial aspect of the inferior vena cava and the less oxygenated blood stays along the lateral vessel wall. This aids their shunting into opposite sides of the heart. Once this blood enters the right atrium, the configuration of the upper interatrial septum—the *crista dividens*—is such that it preferentially shunts the well-oxygenated blood from the medial side of the inferior vena cava and the ductus venosus through the foramen ovale into the left heart and then to the heart and brain (Dawes, 1962). After these tissues have extracted needed oxygen, the resulting less oxygenated blood returns to the right heart through the superior vena cava.

The less oxygenated blood coursing along the lateral wall of the inferior vena cava enters the right atrium and is deflected through the tricuspid valve to the right ventricle. The superior vena cava courses inferiorly and anteriorly as it enters the right atrium, ensuring that less well-oxygenated blood returning from the brain and upper body also will be shunted directly to the right ventricle. Similarly, the ostium of the coronary sinus lies just superior to the tricuspid valve so that less oxygenated blood from the heart also returns to the right ventricle. As a result of this blood flow pattern, blood in the right ventricle is 15 to 20 percent less saturated than blood in the left ventricle.

Almost 90 percent of blood exiting the right ventricle is shunted through the ductus arteriosus to the descending aorta. High pulmonary vascular resistance and comparatively lower resistance in the ductus arteriosus and the umbilical–placental vasculature ensure that only about 15 percent of right ventricular output—8 percent of the combined ventricular output—goes to the lungs (Teitel, 1992). Thus, one third of the blood passing through the ductus arteriosus is delivered to the body. The remaining right ventricular output returns to the placenta through the two hypogastric arteries, which distally become the umbilical arteries. In the placenta, this blood picks up oxygen and other nutrients and is recirculated through the umbilical vein.

Circulatory Changes at Birth

After birth, the umbilical vessels, ductus arteriosus, foramen ovale, and ductus venosus normally constrict or collapse. With the functional closure of the ductus arteriosus and the expansion of the lungs, blood leaving the right ventricle preferentially enters the pulmonary vasculature to become oxygenated before it returns to the left heart. Virtually instantaneously, the ventricles, which had worked in parallel in fetal life, now effectively work in series. The more distal portions of the

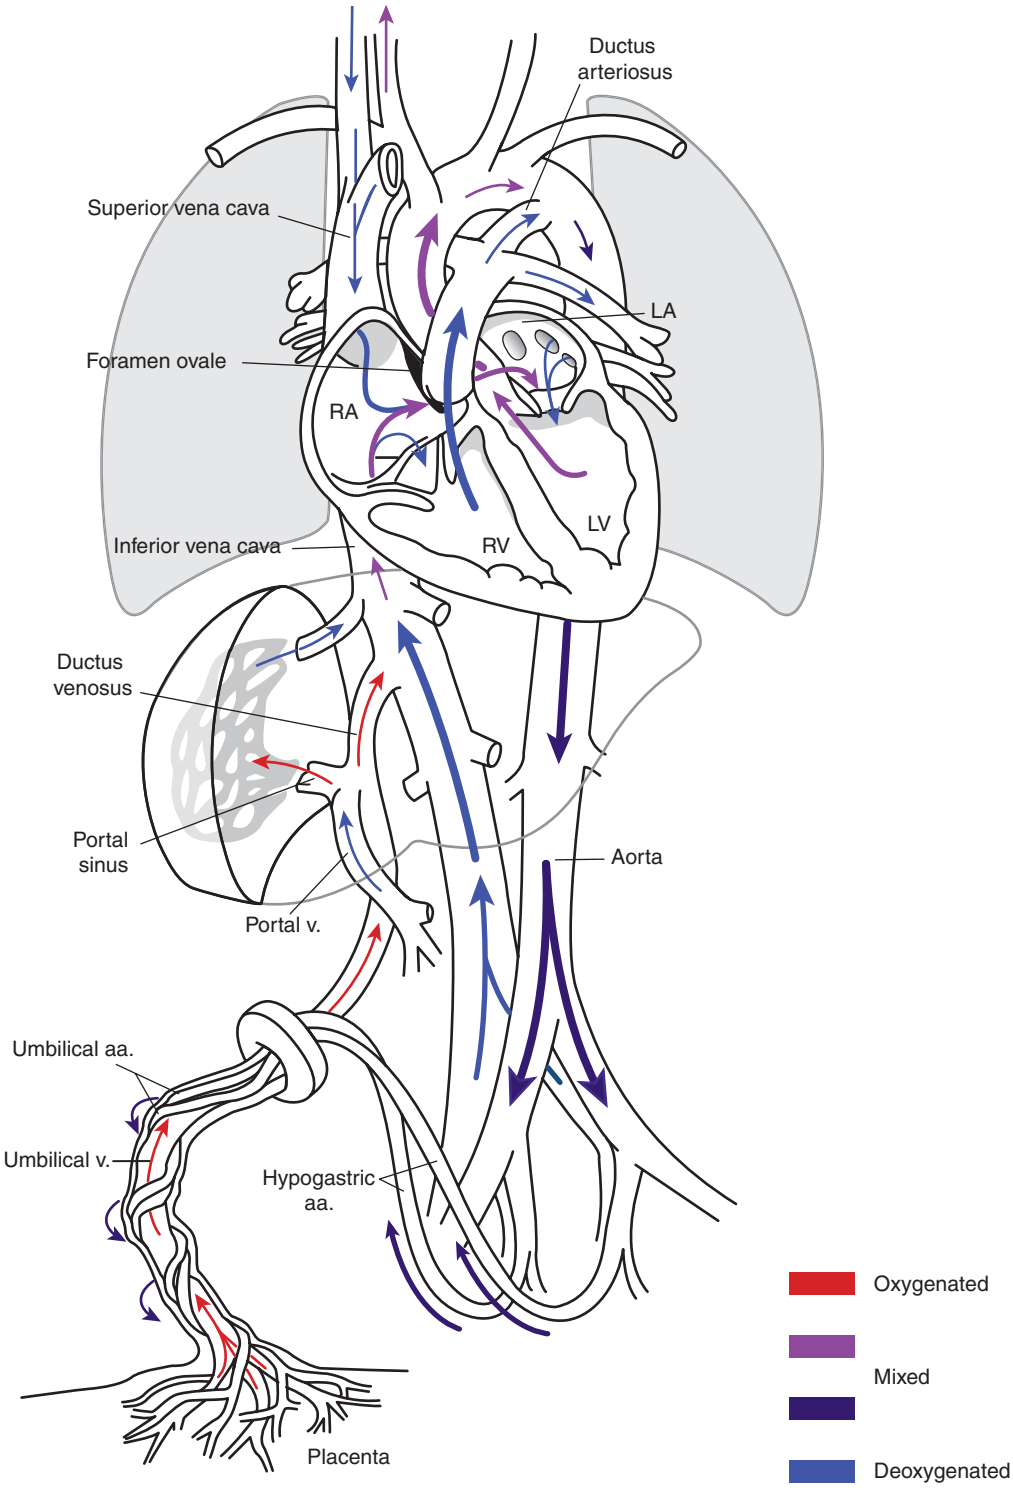

FIGURE 4-12 The intricate nature of the fetal circulation is evident. The degree of oxygenation of blood in various vessels differs appreciably from that in the postnatal state as the consequences of oxygenation being provided by the placenta rather than the lungs and the presence of three major vascular shunts—the ductus venosus, foramen ovale, and ductus arteriosus. (aa = arteries; LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle; v = vein.)

hypogastric arteries, which course from the level of the bladder along the abdominal wall to the umbilical ring and into the cord as the umbilical arteries, undergo atrophy and obliteration within 3 to 4 days after birth. These become the umbilical ligaments, whereas the intra-abdominal remnants of the umbilical vein form the ligamentum teres. The ductus venosus constricts by 10 to 96 hours after birth and is anatomically closed by 2 to 3 weeks, resulting in the formation of the ligamentum venosum (Clymann and Heymann, 1981).

Fetal Blood

Hemopoiesis

In the very early embryo, hemopoiesis is demonstrable first in the yolk sac. The next major site is the liver, and finally the bone marrow. The contributions made by each site are depicted in Figure 4-13.

The first erythrocytes released into the fetal circulation are nucleated and macrocytic. Mean cell volumes are expressed in femtoliters (fL), and one femtoliter equals one cubic micrometer. The mean cell volume is at least 180 fL in the embryo and decreases to 105 to 115 fL at term. The erythrocytes of aneuploid fetuses generally do not undergo this maturation and maintain high mean cell volumes—130 fL on average (Sipes and associates, 1991). As fetal development progresses, more and more of the circulating erythrocytes are smaller and nonnucleated. As the fetus grows, both the volume of blood in the common fetoplacental circulation and hemoglobin concentration increase. Hemoglobin content of fetal blood increases to about 12 g/dL at midpregnancy and to 18 g/dL at term (Walker and Turnbull, 1953). Because of their large size, fetal erythrocytes have a short life span, which progressively lengthens to approximately 90 days at term (Pearson, 1966). As a consequence, red blood cell production is increased. Reticulocytes are initially present at high levels, but decrease to 4 to 5 percent of the total at term. The fetal erythrocytes differ structurally and metabolically from those of the adult. They are more deformable, which serves to offset their higher viscosity, and contain several enzymes with appreciably different activities (Smith and co-workers, 1981).

Erythropoiesis

This process is controlled primarily by fetal erythropoietin because maternal erythropoietin does not cross the placenta. Fetal erythropoietin production is influenced by testosterone, estrogen, prostaglandins, thyroid hormone, and lipoproteins (Stockman and deAlarcon, 1992). Serum levels of erythropoietin increase with fetal maturity, as do the numbers of responsive erythrocytes. The exact site of erythropoietin production is disputed, but the fetal liver appears to be an important source until renal production begins. There is a close correlation between the concentration of erythropoietin in amnionic fluid and that in umbilical venous blood obtained by cordocentesis. After birth, erythropoietin normally may not be detectable for up to 3 months.

Fetal Blood Volume

Although precise measurements of human fetoplacental volume are lacking, Usher and associates (1963) reported values in term normal newborns to average 78 mL/kg when immediate cord-clamping was conducted. Gruenwald (1967) found the volume of fetal blood contained in the placenta after prompt cord clamping to average 45 mL/kg of fetal weight. Thus, fetoplacental blood volume at term is approximately 125 mL/kg of fetal weight.

Fetal Hemoglobin

This tetrameric protein is composed of two copies of two different peptide chains, which determine the type of hemoglobin produced. Normal adult hemoglobin A is made of α and β chains. During embryonic and fetal life, a variety of α and β chain

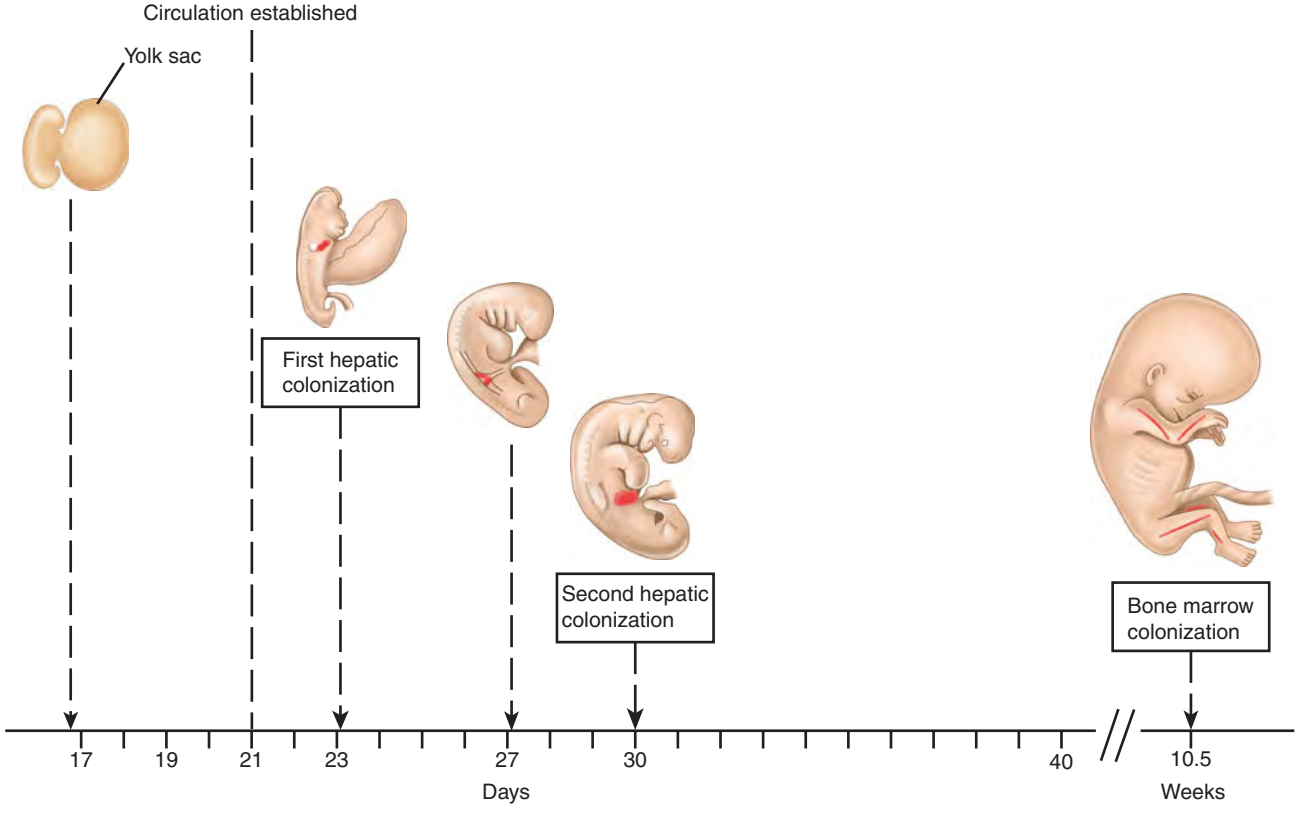

FIGURE 4-13 Chronological appearance of hemopoietic stem cells in the human embryo. (Modified from Tavian and Péault, 2005.)

precursors are produced, resulting in the serial production of several different embryonic hemoglobins. The genes that direct production of the various embryonic versions of these chains are arranged in the order in which they are temporally activated. Genes for β-type chains are on chromosome 11 and for α-type chains on chromosome 16. This sequence is shown in **Figure 4-14**. Each of these genes is turned on and then off during fetal life, until the α and β genes, which direct the production of hemoglobin A, are permanently activated.

The timing of the production of each of these early hemoglobin versions corresponds to changes in the site of hemoglobin production. As Figure 4-13 illustrates, fetal blood is first produced in the yolk sac, where hemoglobins Gower 1, Gower 2, and Portland are made. Erythropoiesis then moves to the liver, where fetal hemoglobin F is produced. When hemopoiesis finally moves to the bone marrow, adult-type hemoglobin A appears in fetal red blood cells and is present in progressively greater amounts as the fetus matures (Pataryas and Stamatoyannopoulos, 1972).

The final adult version of the α chain is produced exclusively by 6 weeks. After this, there are no functional alternative versions. If an α-gene mutation or deletion occurs, there is no alternate α-type chain that could substitute to form functional hemoglobin. In contrast, at least two versions of the β chain—δ and γ—remain in production throughout fetal life and beyond. In the case of a β-gene mutation or deletion, these two other versions of the β chain often continue to be produced, resulting in hemoglobin A_2 or hemoglobin F, which substitute for the abnormal or missing hemoglobin.

Genes are turned off by *methylation* of the control region, which is discussed in Chapter 12 (p. 278). In some situations, methylation does not occur, and in newborns of diabetic women, there may be persistence of hemoglobin F from hypomethylation of the γ gene (Perrine and associates, 1988). With sickle cell anemia, the γ gene remains unmethylated, and large quantities of fetal hemoglobin continue to be produced (see Chap. 51, p. 1085). Increased hemoglobin F levels are associated with fewer sickle-cell disease symptoms, and pharmacological modification of these levels by hemoglobin F-inducing drugs is one approach to disease treatment (Trompeter and Roberts, 2009).

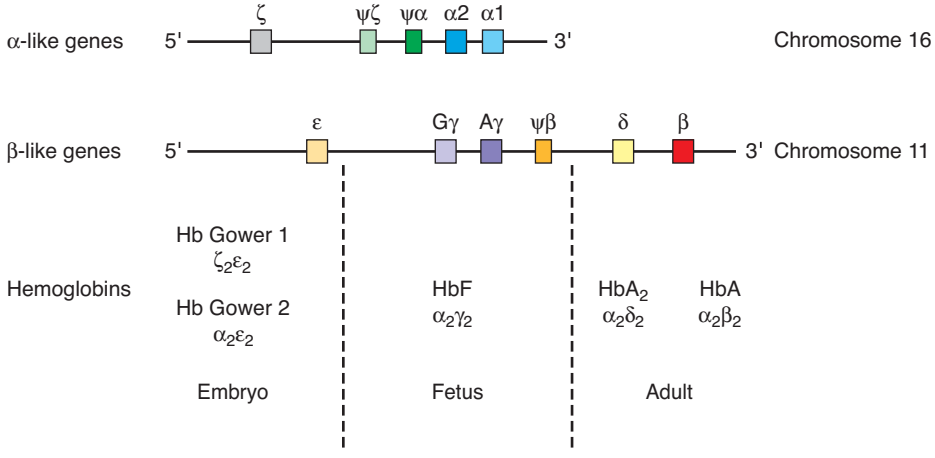

FIGURE 4-14 Schematic drawing of the arrangement of the α and β gene precursors on chromosomes 11 and 16 and the types of hemoglobin made from them. (Modified after Thompson and colleagues, 1991.)

There is a functional difference between hemoglobins A and F. At any given oxygen tension and at identical pH, fetal erythrocytes that contain mostly hemoglobin F bind more oxygen than do those that contain nearly all hemoglobin A (see Fig. 42-3, p. 931). This is because hemoglobin A binds 2,3-diphosphoglycerate (2,3-DPG) more avidly than does hemoglobin F, thus lowering the affinity of hemoglobin A for oxygen (De Verdier and Garby, 1969). During pregnancy, maternal 2,3-DPG levels are increased, and because fetal erythrocytes have lower concentrations of 2,3-DPG, the latter has increased oxygen affinity.

The amount of hemoglobin F in fetal erythrocytes begins to decrease in the last weeks of pregnancy so that at term, about three fourths of total hemoglobin is hemoglobin F. During the first 6 to 12 months of life, the proportion of hemoglobin F continues to decrease and eventually reaches the low levels found in adult erythrocytes. Glucocorticosteroids mediate the switch from fetal to adult hemoglobin, and the effect is irreversible (Zitnik and associates, 1995).

Fetal Coagulation Factors

There are no embryonic forms of the various hemostatic proteins. With the exception of fibrinogen, the fetus starts producing normal, adult-type procoagulant, fibrinolytic, and anticoagulant proteins by 12 weeks. Because they do not cross the placenta, their concentrations at birth are markedly below the levels that develop within a few weeks of life (Corrigan, 1992). In normal neonates, the levels of factors II, VII, IX, X, XI, and of prekallikrein, Protein S, Protein C, antithrombin, and plasminogen are all approximately 50 percent of adult levels. In contrast, levels of factors V, VIII, XIII, and fibrinogen are closer to adult values (Saracco and colleagues, 2009). Without prophylactic treatment, the vitamin K-dependent coagulation factors usually decrease even further during the first few days after birth. This decrease is amplified in breast-fed infants and may lead to hemorrhage in the newborn (see Chap. 29, p. 629).

Fetal *fibrinogen,* which appears as early as 5 weeks, has the same amino acid composition as adult fibrinogen but has different properties (Klagsbrun, 1988). It forms a less compressible clot, and the fibrin monomer has a lower degree of aggregation (Heimark and Schwartz, 1988). Plasma fibrinogen levels at birth are less than those in nonpregnant adults.

Levels of functional fetal *factor XIII—fibrin-stabilizing factor*—are significantly reduced compared with those in adults (Henriksson and coworkers, 1974). Severe deficiencies of *factors VIII, IX, XI,* or *XIII* are usually suspected after observing a continuous ooze from the umbilical stump. Nielsen (1969) described low levels of plasminogen and increased *fibrinolytic activity* in cord plasma compared with that of maternal plasma. *Platelet* counts in cord blood are in the normal range for nonpregnant adults.

Despite this relative reduction in procoagulants, the fetus appears to be protected from hemorrhage because fetal bleeding is a rare event. Excessive bleeding does not usually occur even after invasive fetal procedures such as cordocentesis. Ney and colleagues (1989) have shown that amnionic fluid thromboplastins and some factor in Wharton jelly combine to aid coagulation at the umbilical cord puncture site.

A variety of thrombophilias, such as protein C, S, antithrombin III deficiency, or the factor V Leiden mutation, may cause thromboses and pregnancy complications in adults (see Chap. 47, p. 1014). If the fetus inherits one of these mutations, thrombosis and infarction can develop. This is usually seen with homozygous inheritance, but Thorarensen and colleagues (1997) described three neonates with ischemic infarction or hemorrhagic stroke who were heterozygous for factor V Leiden mutation.

Fetal Plasma Proteins

Liver enzymes and other plasma proteins are produced by the fetus, and these levels do not correlate with maternal levels (Weiner and colleagues, 1992). Concentrations of plasma protein, albumin, lactic dehydrogenase, aspartate aminotransferase, γ-glutamyl transpeptidase, and alanine transferase all increase, whereas levels of prealbumin decrease with gestational age (Fryer and colleagues, 1993). At birth, mean total plasma protein and albumin concentrations in fetal blood are similar to maternal levels (Foley and associates, 1978).

Ontogeny of the Fetal Immune Response

Infections in utero have provided an opportunity to examine some of the mechanisms of the fetal immune response. Evidence of immunological competence has been reported as early as 13 weeks. Altshuler (1974) described infection of the placenta and fetus by cytomegalovirus with characteristic severe inflammatory cell proliferation as well as cellular viral inclusions. Fetal synthesis of complement late in the first trimester has been demonstrated by Kohler (1973) and confirmed by Stabile and co-workers (1988). In cord blood at or near term, the average level for most components is about half that of the adult values (Adinolfi, 1977).

Fetal Immunocompetence

In the absence of a direct antigenic stimulus such as infection, fetal plasma immunoglobulins consist almost totally of transferred maternal immunoglobulin G (IgG). Thus, antibodies in the newborn are most often reflective of maternal immunological experiences.

Immunoglobulin G

Maternal IgG transport to the fetus begins at about 16 weeks and increases thereafter. The bulk of IgG is acquired during the last 4 weeks of pregnancy (Gitlin, 1971). Accordingly, preterm neonates are endowed relatively poorly with protective maternal antibodies. Newborns begin to slowly produce IgG, and adult values are not attained until 3 years of age. In certain situations, the transfer of IgG antibodies from mother to fetus can be harmful rather than protective to the fetus. The classical example is hemolytic disease of the fetus and newborn resulting from D-antigen isoimmunization (see Chap. 29, p. 618).

Immunoglobulin M

In the adult, production of immunoglobulin M (IgM) in response to an antigenic stimulus is superseded in a week or so predominantly by IgG production. In contrast, very little IgM is produced by normal fetuses, and that produced may include antibody to maternal T lymphocytes (Hayward, 1983). With infection, the IgM response is dominant in the fetus and remains so for weeks to months in the newborn. And because IgM is not transported from the mother, any IgM in the fetus or newborn is that which it produced. Increased levels of IgM are found in newborns with congenital infection such as rubella, cytomegalovirus infection, or toxoplasmosis. Serum IgM levels in umbilical cord blood and identification of specific antibodies may be useful in the diagnosis of intrauterine infection. Adult levels of IgM are normally attained by 9 months of age.

Immunoglobulin A

Differing from many mammals, the human newborn does not acquire significant passive immunity from the absorption of humoral antibodies ingested in colostrum. Nevertheless, immunoglobulin A (IgA) ingested in colostrum provides mucosal protection against enteric infections. This may also explain the small amount of fetal secretory IgA found in amnionic fluid (Quan and colleagues, 1999).

Lymphocytes

The immune system begins to develop early and B lymphocytes appear in fetal liver by 9 weeks, and in blood and spleen by 12 weeks. T lymphocytes begin to leave the thymus at about 14 weeks (Hayward, 1983). Despite this, the newborn responds poorly to immunization, and especially poorly to bacterial capsular polysaccharides. This immature response may be due to either deficient response of newborn B cells to polyclonal activators, or lack of T cells that proliferate in response to specific stimuli (Hayward, 1983).

Monocytes

In the newborn, monocytes are able to process and present antigen when tested with maternal antigen-specific T cells.

Nervous System and Sensory Organs

The spinal cord extends along the entire length of the vertebral column in the embryo, but after that it grows more slowly. By 24 weeks, the spinal cord extends to S1, at birth to L3, and in the adult to L1. Myelination of the spinal cord begins at midgestation and continues through the first year of life. Synaptic function is sufficiently developed by the eighth week to demonstrate flexion of the neck and trunk (Temiras and co-workers, 1968). At 10 weeks, local stimuli may evoke squinting, opening of the mouth, incomplete finger closure, and flexion of the toes. Swallowing begins at about 10 weeks, and respiration is evident at 14 to 16 weeks (Miller, 1982). Rudimentary taste buds are present at 7 weeks, and mature receptors are present by 12 weeks (Mistretta and Bradley, 1975). The ability to suck is not present until at least

24 weeks (Lebenthal and Lee, 1983). During the third trimester, integration of nervous and muscular function proceeds rapidly.

The internal, middle, and external components of the ear are well developed by midpregnancy (see Fig. 4-3). The fetus apparently hears some sounds in utero as early as 24 to 26 weeks. By 28 weeks, the eye is sensitive to light, but perception of form and color is not complete until long after birth.

Gastrointestinal System

Swallowing begins at 10 to 12 weeks, coincident with the ability of the small intestine to undergo peristalsis and transport glucose actively (Koldovsky and colleagues, 1965; Miller, 1982). Much of the water in swallowed fluid is absorbed, and unabsorbed matter is propelled to the lower colon (**Fig. 4-15**). It is not clear what stimulates swallowing, but the fetal neural analogue of thirst, gastric emptying, and change in the amnionic fluid composition are potential factors (Boyle, 1992). The fetal taste buds may play a role because saccharin injected into amnionic fluid increases swallowing, whereas injection of a noxious chemical inhibits it (Liley, 1972).

Fetal swallowing appears to have little effect on amnionic fluid volume early in pregnancy because the volume swallowed is small compared with the total. Late in pregnancy, however, the volume appears to be regulated substantially by fetal swallowing, for when swallowing is inhibited, hydramnios is common (see Chap. 21, p. 492). Term fetuses swallow between 200 and 760 mL per day—an amount comparable to that of the neonate (Pritchard, 1966).

FIGURE 4-15 Radiograph of a 115-g fetus—about 16 weeks' gestational age—showing radiopaque dye in the lungs, esophagus, stomach, and entire intestinal tract after injection into the amnionic cavity 26 hours before delivery. These represent inhalation as well as active swallowing of amnionic fluid. (From Davis and Potter, 1946, with permission.)

Hydrochloric acid and some digestive enzymes are present in the stomach and small intestine in very small amounts in the early fetus. Intrinsic factor is detectable by 11 weeks, and pepsinogen by 16 weeks. The preterm neonate, depending on the gestational age when born, may have transient deficiencies of these enzymes (Lebenthal and Lee, 1983).

Stomach emptying appears to be stimulated primarily by volume. Movement of amnionic fluid through the gastrointestinal system may enhance growth and development of the alimentary canal. However, other regulatory factors likely are involved because anencephalic fetuses, in whom swallowing is limited, often have normal amnionic fluid volumes and normal-appearing gastrointestinal tracts. Gitlin (1974) demonstrated that late in pregnancy, about 800 mg of soluble protein is ingested daily by the fetus.

Several anomalies can affect normal fetal gastrointestinal function. *Hirschsprung disease*—known also as *congenital aganglionic megacolon,* prevents the bowel from undergoing parasympathetic-mediated relaxation and thus from emptying normally (Watkins, 1992). It may be recognized prenatally by grossly enlarged bowel during sonography. Obstructions such as duodenal atresia, megacystis-microcolon syndrome, or imperforate anus can also prevent the bowel from emptying normally. Meconium ileus, commonly found with fetal cystic fibrosis, is bowel obstruction caused by thick, viscid meconium that blocks the distal ileum (see Chap. 13, p. 298).

Meconium

Fetal bowel contents consist of various products of secretion, such as glycerophospholipids from the lung, desquamated fetal cells, lanugo, scalp hair, and vernix. It also contains undigested debris from swallowed amnionic fluid. The dark greenish-black appearance is caused by pigments, especially biliverdin. Meconium can pass from normal bowel peristalsis in the mature fetus or from vagal stimulation. It can also pass when hypoxia stimulates arginine vasopressin (AVP) release from the fetal pituitary gland. AVP stimulates the smooth muscle of the colon to contract, resulting in intra-amnionic defecation (DeVane and co-workers, 1982; Rosenfeld and Porter, 1985). Small bowel obstruction may lead to vomiting in utero (Shrand, 1972). Fetuses who suffer from congenital chloride diarrhea may have diarrhea in utero, which leads to hydramnios and preterm delivery (Holmberg and associates, 1977).

Liver

Serum liver enzyme levels increase with gestational age but in reduced amounts. The fetal liver has a gestational-age related diminished capacity for converting free unconjugated bilirubin to conjugated bilirubin (see Chap. 29, p. 625). Because the life span of normal fetal macrocytic erythrocytes is brief, relatively more unconjugated bilirubin is produced. The fetal liver conjugates only a small fraction, which is excreted into the intestine and ultimately oxidized to biliverdin. Most of the unconjugated bilirubin is excreted into the amnionic fluid after 12 weeks and is then transferred across the placenta (Bashore and colleagues, 1969).

Importantly, placental transfer is bidirectional. Thus, a pregnant woman with severe hemolysis from any cause has excess unconjugated bilirubin that readily passes to the fetus and then into the amnionic fluid. Conversely, conjugated bilirubin is not exchanged to any significant degree between mother and fetus.

Most fetal cholesterol is from hepatic synthesis, which satisfies the large demand for LDL cholesterol by the fetal adrenal glands. Hepatic glycogen is present in low concentration during the second trimester, but near term there is a rapid and marked increase to levels two to three times those in the adult liver. After birth, glycogen content falls precipitously.

Pancreas

The discovery of insulin by Banting and Best (1922) came in response to its extraction from the fetal calf pancreas. Insulin-containing granules can be identified by 9 to 10 weeks, and insulin in fetal plasma is detectable at 12 weeks (Adam and associates, 1969). The pancreas responds to hyperglycemia by secreting insulin (Obenshain and colleagues, 1970). Serum insulin levels are unusually high in newborns of diabetic mothers and other large-for-gestational age neonates, but insulin levels are low in those small-for-gestational age (Brinsmead and Liggins, 1979). This is further described in Chapter 38 (pp. 843 and 845).

Glucagon has been identified in the fetal pancreas at 8 weeks. In the adult rhesus monkey, hypoglycemia and infused alanine cause an increase in maternal glucagon levels. Although, in the human, similar stimuli do not evoke a fetal response, by 12 hours after birth, the newborn is capable of responding (Chez and co-workers, 1975). At the same time, however, fetal pancreatic α cells do respond to L-dopa infusions (Epstein and associates, 1977). Therefore, nonresponsiveness to hypoglycemia is likely the consequence of failure of glucagon release rather than inadequate production. This is consistent with findings of the developmental expression of pancreatic genes in the fetus (Mally and associates, 1994).

Most pancreatic enzymes are present by 16 weeks. Trypsin, chymotrypsin, phospholipase A, and lipase are found in the 14-week fetus at low levels, and they increase with gestation (Werlin, 1992). Amylase has been identified in amnionic fluid at 14 weeks (Davis and associates, 1986). The exocrine function of the fetal pancreas is limited. Physiologically important secretion occurs only after stimulation by a secretagogue such as acetylcholine, which is released locally after vagal stimulation (Werlin, 1992). Cholecystokinin normally is released only after protein ingestion and thus ordinarily would not be found in the fetus. Its release, however, can be stimulated experimentally. For example, Pritchard (1965) reported that radioiodine-labeled albumin injected into the amnionic sac was swallowed, digested, and absorbed from the fetal intestine.

Urinary System

Two primitive urinary systems—the pronephros and the mesonephros—precede the development of the metanephros (see Chap. 40, p. 890). The pronephros has involuted by 2 weeks, and the mesonephros is producing urine at 5 weeks and degenerates by 11 to 12 weeks. Failure of these two structures either to form or to regress may result in anomalous development of the definitive urinary system. Between 9 and 12 weeks, the ureteric bud and the nephrogenic blastema interact to produce the metanephros. The kidney and ureter develop from intermediate mesoderm. Greater maternal anthropometrics and fetal biometrics are associated with larger fetal kidneys, whereas preferential fetal blood flow to the brain is associated with smaller kidneys (Geelhoed and colleagues, 2009). The bladder and urethra develop from the urogenital sinus. The bladder also develops in part from the allantois.

By week 14, the loop of Henle is functional and reabsorption occurs (Smith and associates, 1992). New nephrons continue to be formed until 36 weeks. In preterm neonates, their formation continues after birth. Although the fetal kidneys produce urine, their ability to concentrate and modify the pH is limited even in the mature fetus. Fetal urine is hypotonic with respect to fetal plasma and has low concentrations of electrolytes.

Renal vascular resistance is high, and the filtration fraction is low compared with values in later life (Smith and colleagues, 1992). Fetal renal blood flow and thus urine production are controlled or influenced by the renin-angiotensin system, the sympathetic nervous system, prostaglandins, kallikrein, and atrial natriuretic peptide. The glomerular filtration rate increases with gestational age from less than 0.1 mL/min at 12 weeks to 0.3 mL/min at 20 weeks. In later gestation, the rate remains constant when corrected for fetal weight (Smith and colleagues, 1992). Hemorrhage or hypoxia generally results in a decrease in renal blood flow, glomerular filtration rate, and urine output.

Urine usually is found in the bladder even in small fetuses. The fetal kidneys start producing urine at 12 weeks. By 18 weeks, they are producing 7 to 14 mL/day, and at term, this increases to 27 mL/hr or 650 mL/day (Wladimiroff and Campbell, 1974). Maternally administered furosemide increases fetal urine formation, whereas uteroplacental insufficiency and other types of fetal stress decrease it. Kurjak and associates (1981) found that fetal glomerular filtration rates and tubular water reabsorption were decreased in a third of growth-restricted newborns and in a sixth of those of diabetic mothers. All values were normal in anencephalic neonates and in those with hydramnios.

Obstruction of the urethra, bladder, ureters, or renal pelves can damage renal parenchyma and distort fetal anatomy. With urethral obstruction, the bladder may become sufficiently distended that it ruptures or dystocia results. Kidneys are not essential for survival in utero, but are important in the control of amnionic fluid composition and volume. Furthermore, abnormalities that cause chronic anuria are usually accompanied by oligohydramnios and pulmonary hypoplasia. Pathological correlates and prenatal therapy of urinary tract obstruction are discussed in Chapter 13 (p. 307).

Lungs

The timetable of lung maturation and the identification of biochemical indices of functional fetal lung maturity are of considerable interest to the obstetrician. Morphological or functional immaturity at birth leads to the development of the *respiratory distress syndrome* (see Chap. 29, p. 605). The presence of a

sufficient amount of surface-active materials—collectively referred to as *surfactant*—in the amnionic fluid is evidence of fetal lung maturity. As Liggins (1994) emphasized, however, the structural and morphological maturation of fetal lung also is extraordinarily important to proper lung function.

Anatomical Maturation

Like the branching of a tree, lung development proceeds along an established timetable that apparently cannot be hastened by antenatal or neonatal therapy. The limits of viability, therefore, appear to be determined by the usual process of pulmonary growth. There are three essential stages of lung development as described by Moore (1983):

1. The *pseudoglandular stage* entails growth of the intrasegmental bronchial tree between the 5th and 17th weeks. During this period, the lung looks microscopically like a gland.
2. The *canalicular stage*, from 16 to 25 weeks, is when the bronchial cartilage plates extend peripherally. Each terminal bronchiole gives rise to several respiratory bronchioles, and each of these in turn divides into multiple saccular ducts.
3. The *terminal sac stage* begins after 25 weeks and during this, alveoli give rise to the primitive pulmonary alveoli—the terminal sacs. Simultaneously, an extracellular matrix develops from proximal to distal lung segments until term. An extensive capillary network is built, the lymph system forms, and type II pneumonocytes begin to produce surfactant. At birth, only about 15 percent of the adult number of alveoli are present, and thus the lung continues to grow, adding more alveoli for up to 8 years.

Various insults can upset this process, and their timing determines the sequela. With fetal renal agenesis, for example, there is no amnionic fluid at the beginning of lung growth, and major defects occur in all three stages. A fetus with membrane rupture before 20 weeks and subsequent oligohydramnios usually exhibits nearly normal bronchial branching and cartilage development but has immature alveoli. Membrane rupture after 24 weeks may have little long-term effect on pulmonary structure.

Surfactant

After the first breath, the terminal sacs must remain expanded despite the pressure imparted by the tissue-to-air interface, and surfactant keeps them from collapsing. There are more than 200 pulmonary cell types, but surfactant is formed specifically in type II pneumonocytes that line the alveoli. These cells are characterized by multivesicular bodies that produce the *lamellar bodies* in which surfactant is assembled. During late fetal life, at a time when the alveolus is characterized by a water-to-tissue interface, the intact lamellar bodies are secreted from the lung and swept into the amnionic fluid during respiratory-like movements that are termed fetal breathing. At birth, with the first breath, an air-to-tissue interface is produced in the lung alveolus. Surfactant uncoils from the lamellar bodies, and it then spreads to line the alveolus to prevent alveolar collapse during expiration. Thus, it is the capacity for fetal lungs to produce surfactant, and not the actual laying down of this material in the lungs in utero, that establishes lung maturity.

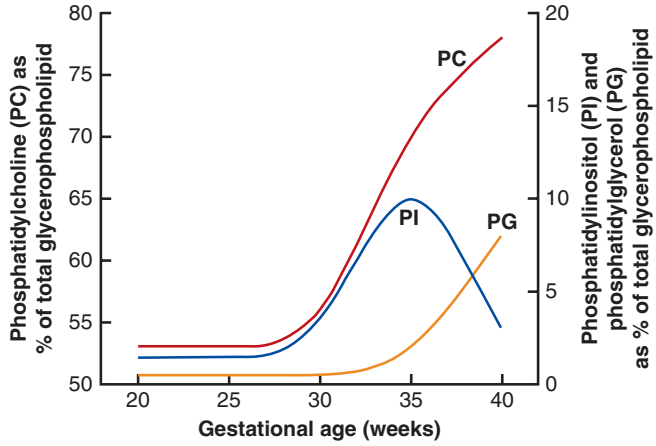

FIGURE 4-16 Relation between the levels of lecithin, or dipalmitoylphosphatidylcholine (PC), phosphatidylinositol (PI), and phosphatidylglycerol (PG) in amnionic fluid as a function of gestational age.

Surfactant Composition. Gluck and associates (1967, 1970, 1972) and Hallman and co-workers (1976) found that about 90 percent of surfactant dry-weight is lipid. Proteins account for the other 10 percent. Approximately 80 percent of the glycerophospholipids are phosphatidylcholines (lecithins). The principal active component of surfactant is a specific lecithin—*dipalmitoylphosphatidylcholine (DPPC* or *PC)*—which accounts for nearly 50 percent. *Phosphatidylglycerol (PG*) accounts for another 8 to 15 percent (Keidel and Gluck, 1975). Its precise role is unclear because newborns without phosphatidylglycerol usually do well. The other major constituent is *phosphatidylinositol (PI)*. The relative contributions of each component are shown in Figure 4-16.

Surfactant Synthesis. Biosynthesis takes place in the type II pneumocytes. The apoproteins are produced in the endoplasmic reticulum, and the glycerophospholipids are synthesized by cooperative interactions of several cellular organelles. Phospholipid is the primary surface tension-lowering component of surfactant, whereas the apoproteins aid the forming and reforming of a surface film. The surface properties of the surfactant phospholipids are determined principally by the composition and degree of saturation of their long-chain fatty acids.

The major apoprotein is surfactant A (SP-A), which is a glycoprotein with a molecular weight of 28,000 to 35,000 Da (Whitsett, 1992). It is synthesized in the type II cells, and its content in amnionic fluid increases with gestational age and fetal lung maturity. SP-A may also play a role in the onset of parturition (Mendelson and Condon, 2005). Synthesis of SP-A is increased by treatment of fetal lung tissue with cyclic adenosine monophosphate (AMP) analogues, epidermal growth factors, and triiodothyronine. Increased apoprotein synthesis precedes surfactant glycerophospholipid synthesis.

SP-A gene expression is demonstrable by 29 weeks (Snyder and colleagues, 1988). There are two separate genes on chromosome 10—SP-A1 and SP-A2—and their regulation is distinctive and different (McCormick and Mendelson, 1994). Specifically,

cyclic AMP is more important in SP-A2 expression, whereas dexamethasone decreases SP-A2 expression.

Several smaller apoproteins such as SP-B and SP-C are likely important in optimizing the action of surfactant. For example, deletions in SP-B gene are incompatible with survival despite production of large amounts of surfactant.

Corticosteroids and Fetal Lung Maturation. Since Liggins (1969) first observed lung maturation in lamb fetuses given glucocorticosteroids prior to preterm delivery, many suggested that fetal cortisol stimulates lung maturation and surfactant synthesis. It is unlikely that corticosteroids are the only stimulus for augmented surfactant formation, as clearly, respiratory distress syndrome is not universal in neonates with limited cortisol production. These include those with anencephaly, adrenal hypoplasia, or congenital adrenal hyperplasia. There is evidence, however, that glucocorticosteroids administered at certain critical times during gestation effect an increase in the rate of fetal lung maturation. The use of betamethasone and dexamethasone to accelerate fetal lung maturity, as well as neonatal replacement surfactant therapy, is discussed in Chapter 36 (p. 821).

Respiration. Within a few minutes after birth, the respiratory system must provide oxygen as well as eliminate carbon dioxide. Respiratory muscles develop early, and fetal chest wall movements are detected by sonographic techniques as early as 11 weeks (Boddy and Dawes, 1975). From the beginning of the fourth month, the fetus is capable of respiratory movement sufficiently intense to move amnionic fluid in and out of the respiratory tract.

Endocrine Glands

Pituitary Gland

The fetal endocrine system is functional for some time before the central nervous system reaches maturity (Mulchahey and co-workers, 1987). The pituitary adenohypophysis develops from oral ectoderm—Rathke pouch, whereas the neurohypophysis derives from neuroectoderm.

Anterior Pituitary. The adenohypophysis, or anterior pituitary, differentiates into five cell types that secrete six protein hormones: (1) lactotropes produce prolactin—PRL; (2) somatotropes produce growth hormone—GH; (3) corticotropes produce corticotrophin—ACTH; (4) thyrotropes produce thyrotropin or thyroid-stimulating hormone—TSH; and gonadotropes produce (5) luteinizing hormone—LH and (6) follicle-stimulating hormone—FSH.

ACTH is first detected in the fetal pituitary gland at 7 weeks, and GH and LH have been identified by 13 weeks. By the end of the 17th week, the fetal pituitary gland is able to synthesize and store all pituitary hormones. Moreover, the fetal pituitary is responsive to hormones and is capable of secreting these early in gestation (Grumbach and Kaplan, 1974). Levels of immunoreactive GH are high in cord blood, although its role in fetal growth and development is not clear. The fetal pituitary secretes β-endorphin, and cord blood levels of β-endorphin and β-lipotropin increase with fetal P_{CO_2} (Browning and colleagues, 1983).

Neurohypophysis. The posterior pituitary gland is well developed by 10 to 12 weeks, and oxytocin and arginine vasopressin (AVP) are demonstrable. Both hormones probably function in the fetus to conserve water by actions largely at the lung and placenta rather than kidney. Levels of AVP in umbilical cord plasma are increased strikingly compared with maternal levels (Chard and associates, 1971; Polin and co-workers, 1977). Elevated fetal blood AVP appears to be associated with fetal stress (DeVane and co-workers, 1982).

Intermediate Pituitary Gland. There is a well-developed intermediate lobe in the fetal pituitary gland. The cells of this structure begin to disappear before term and are absent from the adult pituitary. The principal secretory products of the intermediate lobe cells are α-melanocyte–stimulating hormone (α-MSH) and β-endorphin.

Thyroid Gland

The pituitary–thyroid system is functional by the end of the first trimester. The thyroid gland is able to synthesize hormones by 10 to 12 weeks, and TSH, thyroxine, and thyroid-binding globulin (TBG) have been detected in fetal serum as early as 11 weeks (Ballabio and colleagues, 1989). The placenta actively concentrates iodide on the fetal side, and by 12 weeks and throughout pregnancy, the fetal thyroid concentrates iodide more avidly than does the maternal thyroid. Thus, maternal administration of either radioiodide or appreciable amounts of ordinary iodide is hazardous after this time. Normal fetal levels of free thyroxine (T_4), free triiodothyronine (T_3), and thyroxin-binding globulin increase steadily throughout gestation (Ballabio and associates, 1989). Compared with adult levels, by 36 weeks, fetal serum concentrations of TSH are higher, total and free T_3 concentrations are lower, and T_4 is similar. This suggests that the fetal pituitary may not become sensitive to feedback until late in pregnancy (Thorpe-Beeston and co-workers, 1991; Wenstrom and colleagues, 1990).

Fetal thyroid hormone plays a role in the normal development of virtually all fetal tissues, but especially the brain. Its influence is illustrated by congenital hyperthyroidism, which occurs when maternal thyroid-stimulating antibody crosses the placenta to stimulate the fetal thyroid. These fetuses develop tachycardia, hepatosplenomegaly, hematological abnormalities, craniosynostosis, and growth restriction. As children, they have perceptual motor difficulties, hyperactivity, and reduced growth (Wenstrom and colleagues, 1990). Neonatal effects of fetal thyroid deficiency are discussed in Chapter 53 (p. 1126).

The placenta prevents substantial passage of maternal thyroid hormones to the fetus by rapidly deiodinating maternal T_4 and T_3 to form reverse T_3, a relatively inactive thyroid hormone (Vulsma and colleagues, 1989). A number of antithyroid antibodies—immunoglobulin G—cross the placenta when present in high concentrations. Those include the long-acting thyroid stimulators (LATS), LATS-protector (LATS-P), and thyroid-stimulating immunoglobulin (TSI). It was previously believed that normal fetal growth and development, which occurred despite fetal hypothyroidism, provided evidence that T_4 was not essential for fetal growth. It is now known, however, that growth proceeds normally because small quantities of maternal T_4 prevent antenatal cretinism in fetuses with thyroid

agenesis (Vulsma and colleagues, 1989). The fetus with congenital hypothyroidism typically does not develop stigmata of cretinism until after birth. Because administration of thyroid hormone will prevent this, all newborns are tested for high serum levels of TSH (Chap. 28, p. 598).

Immediately after birth, there are major changes in thyroid function and metabolism. Cooling to room temperature evokes sudden and marked increase in TSH secretion, which in turn causes a progressive increase in serum T_4 levels that are maximal 24 to 36 hours after birth. There are nearly simultaneous elevations of serum T_3 levels.

Adrenal Glands

The fetal adrenal glands are much larger in relation to total body size than in adults. The bulk is made up of the inner or *fetal zone* of the adrenal cortex and involutes rapidly after birth. This zone is scant to absent in rare instances in which the fetal pituitary gland is congenitally absent. The function of the fetal adrenal glands is discussed in detail in Chapter 3 (p. 69).

DEVELOPMENT OF GENITALIA

Embryology of Uterus and Oviducts

The uterus and tubes arise from the müllerian ducts, which first appear near the upper pole of the urogenital ridge in the fifth week of embryonic development (Fig. 4-17). This ridge is composed of the mesonephros, gonad, and associated ducts. The first indication of müllerian duct development is a thickening of the coelomic epithelium at approximately the level of the fourth thoracic segment. This becomes the fimbriated extremity of the fallopian tube, which invaginates and grows caudally to form a slender tube at the lateral edge of the urogenital ridge. In the sixth week, the growing tips of the two müllerian ducts approach each other in the midline. One week later, they reach the urogenital sinus. At that time, the two müllerian ducts fuse to form a single canal at the level of the inguinal crest. This crest gives rise to the gubernaculum, which is the primordium of the round ligament.

Thus, the upper ends of the müllerian ducts produce the oviducts, and the fused parts give rise to the uterus. The vaginal canal is not patent throughout its entire length until the sixth month (Koff, 1933). Because of the clinical importance of anomalies that arise from abnormal fusion and dysgenesis of these structures, their embryogenesis is discussed in detail in Chapter 40 (see also Fig. 40-1, p. 891).

Embryology of the Ovaries

At approximately 4 weeks, gonads form on the ventral surface of the embryonic kidney at a site between the eighth thoracic and fourth lumbar segments. The coelomic epithelium thickens, and clumps of cells bud off into the underlying mesenchyme. This circumscribed area of is called the *germinal epithelium*. By the fourth to sixth week, however, there are many large ameboid cells in this region that have migrated into the body of the embryo from the yolk sac (see Fig. 4-17). These *primordial germ cells* are distinguishable by their large size and certain morphological and cytochemical features.

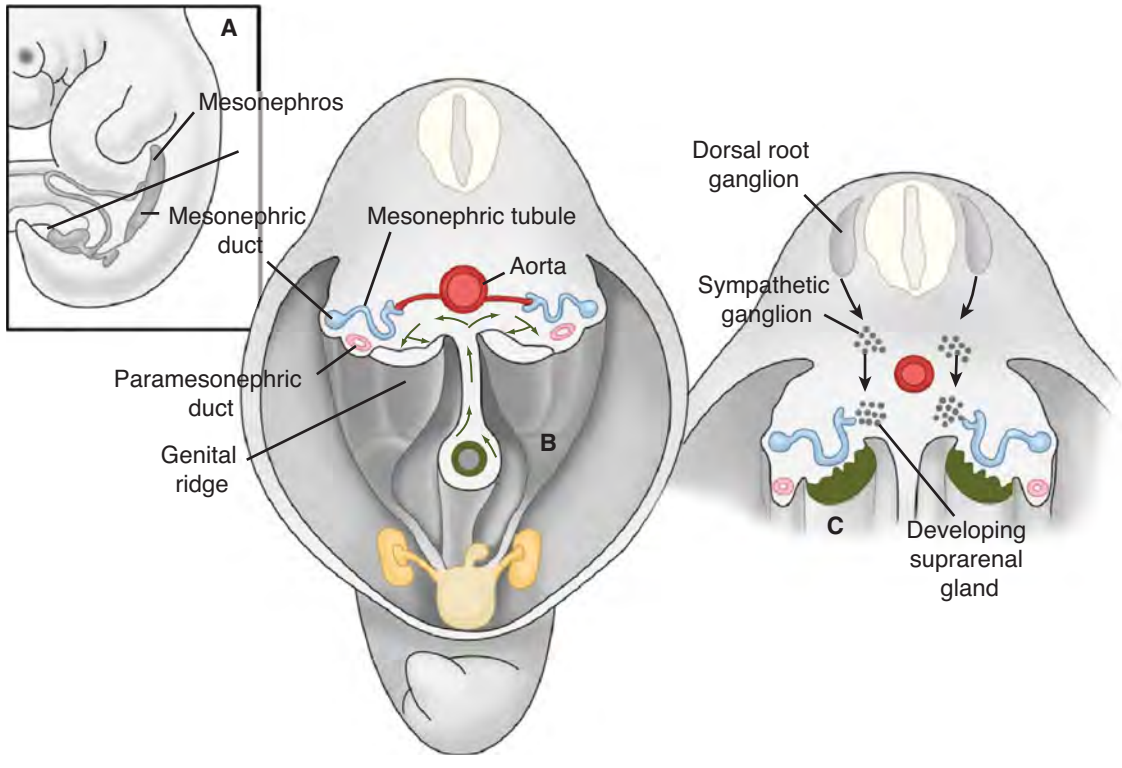

FIGURE 4-17 A. Cross-section of an embryo at 4 to 6 weeks. **B.** Large ameboid primordial germ cells migrate (*arrows*) from the yolk sac to the area of germinal epithelium, within the genital ridge. **C.** Migration of sympathetic cells from the spinal ganglia to a region above the developing kidney. (After Moore and colleagues, 2000.)

When the primordial germ cells reach the genital area, some enter the germinal epithelium and others mingle with groups of cells that proliferate from it or lie in the mesenchyme. By the end of the fifth week, rapid division of all these cell types results in development of a prominent *genital ridge*. The ridge projects into the body cavity medially to a fold in which there are the *mesonephric—wolffian* and *paramesonephric—müllerian ducts* (**Fig. 4-18**). By the seventh week, it is separated from the mesonephros except at the narrow central zone, the future hilum, where blood vessels enter. At this time, the sexes can be distinguished, because the testes can be recognized by well-defined radiating strands of cells termed sex cords. These cords are separated from the germinal epithelium by mesenchyme that is to become the tunica albuginea. The sex cords, which consist of large germ cells and smaller epithelioid cells derived from the germinal epithelium, develop into the seminiferous tubules and tubuli rete. The latter establishes connection with the mesonephric tubules that develop into the epididymis. The mesonephric ducts become the vas deferens.

In the female embryo, the germinal epithelium proliferates for a longer time. The groups of cells thus formed lie at first in the region of the hilum. As connective tissue develops between them, these appear as sex cords. These cords give rise to the medulla cords and persist for variable times (Forbes, 1942). By the third month, medulla and cortex are defined (see Fig. 4-18). The bulk of the ovary is made up of cortex, a mass of crowded germ and epithelioid cells that show some signs of grouping, but there are no distinct cords as in the testis. Strands of cells extend from the germinal epithelium into the cortical mass, and mitoses are numerous. The rapid succession of mitoses soon reduces the size of the germ cells to the extent that these no longer are differentiated clearly from the neighboring cells. These germ cells are now called *oogonia*.

By the fourth month, some germ cells in the medullary region begin to enlarge. These are called primary oocytes at the beginning of the phase of growth that continues until maturity is reached. During this period of cell growth, many oocytes undergo degeneration, both before and after birth. A single layer of flattened follicular cells that were derived originally from the germinal epithelium soon surrounds the primary oocytes. These structures are now called *primordial follicles* and are seen first in the medulla and later in the cortex. Some follicles begin to grow even before birth, and some are believed to persist in the cortex almost unchanged until menopause.

By 8 months, the ovary has become a long, narrow, lobulated structure that is attached to the body wall along the line of the hilum by the *mesovarium*, in which lies the *epoöphoron*. The germinal epithelium has been separated for the most part from the cortex by a band of connective tissue—*tunica albuginea*. This band is absent in many small areas where strands of cells, usually referred to as cords of Pflüger, are in contact with the germinal epithelium. Among these cords are cells believed by many to be oogonia that resemble the other epithelial cells as a result of repeated mitosis. In the underlying cortex, there are two distinct zones. Superficially, there are nests of germ cells in meiotic synapsis, interspersed with Pflüger cords and strands of connective tissue. In the deeper zone, there are many groups of germ cells in synapsis, as well as primary oocytes, prospective follicular cells, and a few primordial follicles.

Fetal Gender

Theoretically, there should be a primary gender ratio of 1:1 at the time of fertilization because there are equal numbers of X- and Y-bearing spermatozoa. This is not the case, however, and many factors have been shown to contribute to gender ratios at conception. These include differential susceptibility to environmental exposures as well as medical disorders. Also, couples with a large age discrepancy are more likely have a male offspring (Manning and associates, 1997). Whatever the cause, it is impossible to determine the primary gender ratio because this would require gender assignment to zygotes that fail to cleave, blastocysts that fail to implant, and other early pregnancy losses.

The secondary gender ratio is that of fetuses that reach viability and is usually held to be about 106 males to 100 females. The unbalanced secondary gender ratio is explicable by the loss of more female than male embryofetuses during early pregnancy. However, Davis and colleagues (1998) report a significant decline in male births since 1950 in Denmark, Sweden, the Netherlands, the United States, Germany, Norway, and Finland. Allan and coworkers (1997) reported that live births in Canada since 1970 dropped by 2.2 male births per 1000 live births.

Gender Assignment at Birth

The first thing that parents in the delivery room want to know is the gender of their newborn. If the external genitalia of the newborn are ambiguous, the obstetrician faces a profound dilemma because it is not possible to assign proper functional gender by simple inspection in the delivery room. Assignment requires knowledge of the karyotypic sex, gonadal sex, hormonal milieu to which the fetus was exposed, exact anatomy, and all possibilities for surgical correction. In the past, most newborns with a small or likely insufficient phallus were often assigned to the female gender. Based on what is now known of the role of fetal exposure to hormones in establishing gender preference and behavior, it can be seen why such a policy may have caused *gender identity disorder* (Slijper and colleagues, 1998). Thus, it seems best to inform the parents that although their newborn appears healthy, the gender will need to be determined by a series of tests. To develop a plan that can assist in determining the cause of ambiguous genitalia, the mechanisms of normal and abnormal sexual differentiation must be considered.

Sexual Differentiation

Phenotypic gender differentiation is determined by the chromosomal complement acting in conjunction with gonadal development.

Chromosomal Gender

Genetic gender—XX or XY—is established at the time of fertilization, but for the first 6 weeks, development of male and female embryos is morphologically indistinguishable. The differentiation of the primordial gonad into testis or ovary heralds the establishment of gonadal sex (see Fig. 4-18).

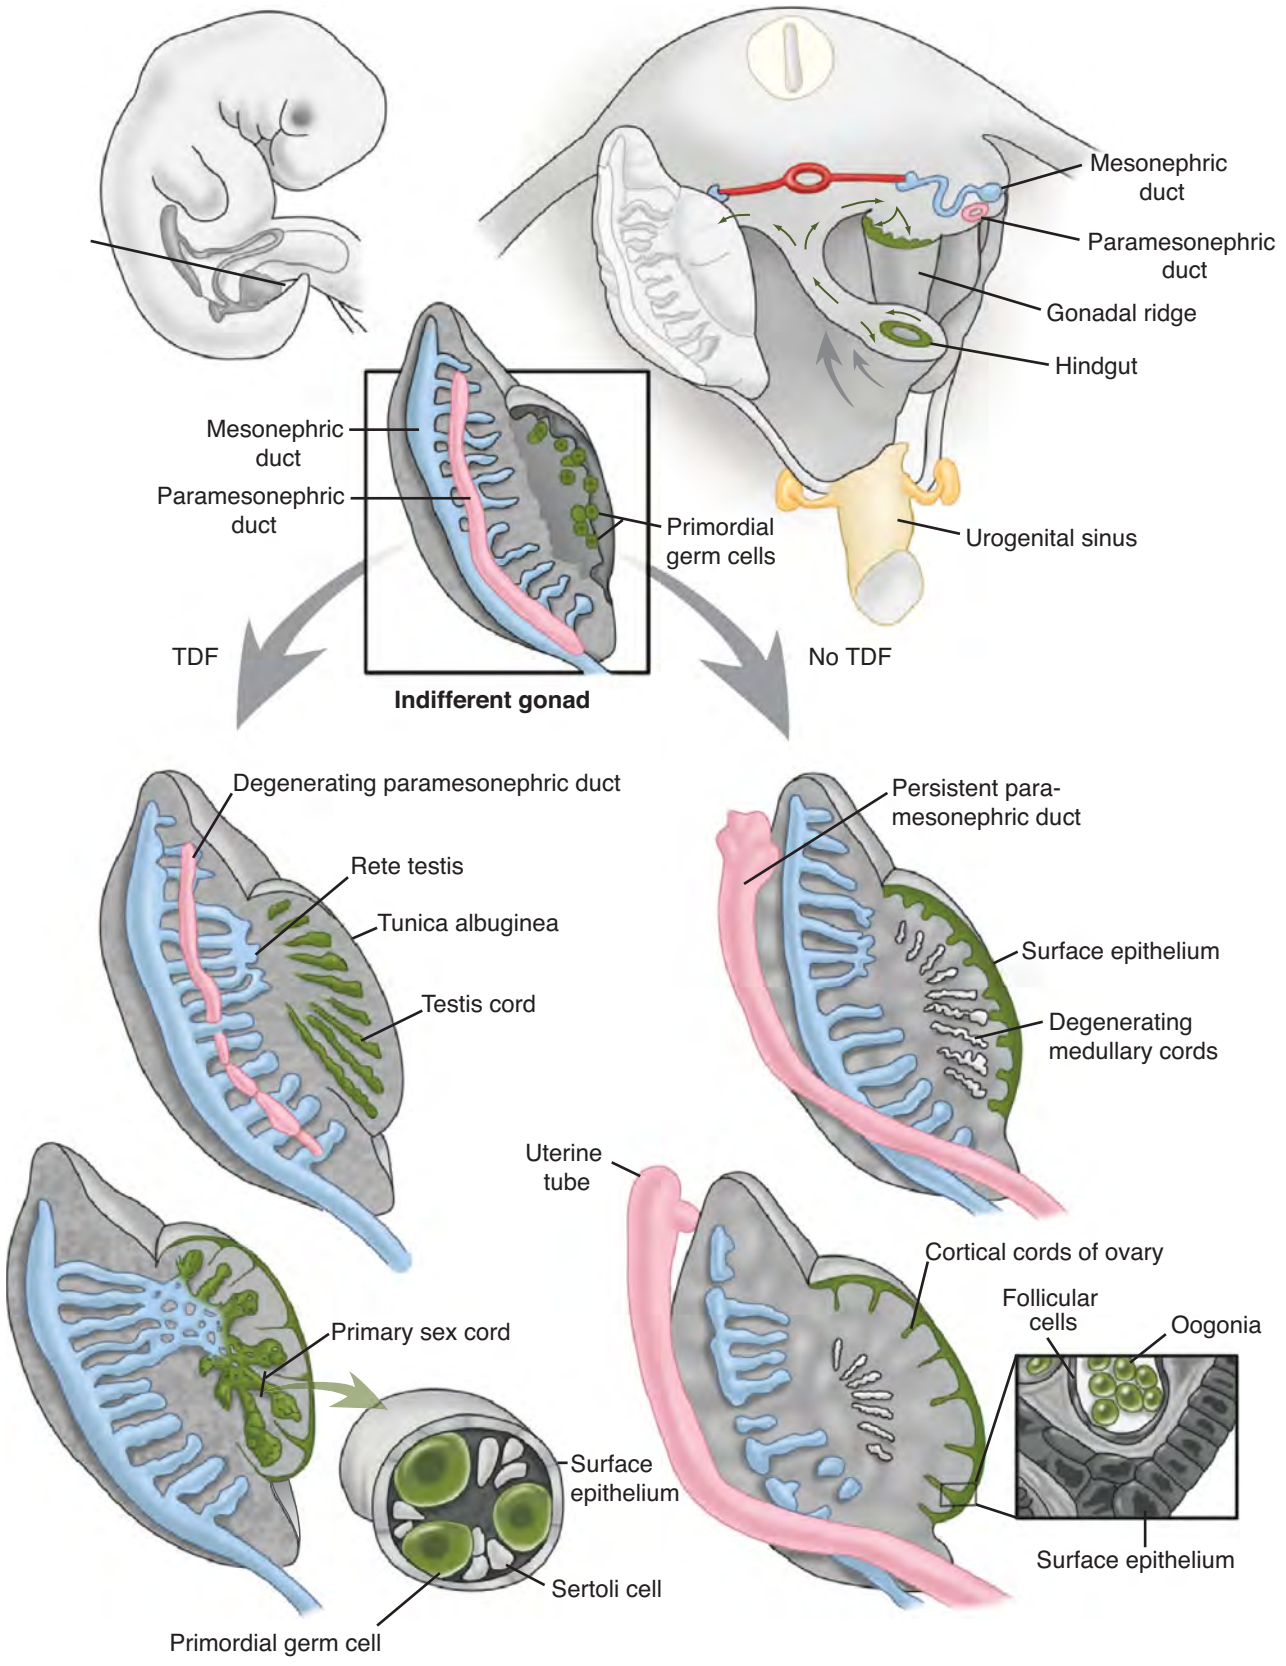

FIGURE 4-18 Continuation of sexual differentiation of embryo. See text for explanation. (TDF = testis-determining factor.) (After Moore and colleagues, 2000.)

Gonadal Gender

As described earlier and shown in Figure 4-17, primordial germ cells that originate in the yolk sac endoderm migrate to the genital ridge to form the indifferent gonad. If a Y chromosome is present, at about 6 weeks after conception, the gonad begins developing into a testis (Simpson, 1997). Testis development is directed by a gene located on the short arm of Y—*testis-determining factor (TDF),* also called *sex-determining region (SRY).* This gene encodes a transcription factor that acts to modulate the rate of transcription of a number of genes involved in gonadal differentiation. The *SRY* gene is specific to the Y chromosome and is expressed in the human single-cell zygote immediately after ovum fertilization. It is not expressed in spermatozoa (Fiddler and co-workers, 1995; Gustafson and Donahoe, 1994). In addition, testis development requires a *dose-dependent sex reversal (DDS)* region on the X chromosome, as well as other autosomal genes (Brown and Warne, 2005).

The contribution of chromosomal gender to gonadal gender is illustrated by several paradoxical conditions. The incidence of 46,XX phenotypic human males is estimated to be about 1 in 20,000 male births (Page and colleagues, 1985). These infants apparently result from translocation of the Y chromosome fragment containing *TDF* to the X chromosome during meiosis of male germ cells (George and Wilson, 1988). Similarly, individuals with XY chromosomes can appear phenotypically female if they carry a mutation in the *TDF/SRY* gene. There is evidence that genes on the short arm of the X chromosome are capable of suppressing testicular development, despite the presence of the *SRY* gene. Indeed, this accounts for a form of X-linked recessive gonadal dysgenesis.

The existence of autosomal sex-determining genes is supported by several genetic syndromes in which disruption of an autosomal gene causes, among other things, gonadal dysgenesis. For example, *camptomelic dysplasia,* localized to chromosome 17, is associated with XY phenotypic sex reversal. Similarly, *male pseudohermaphroditism* has been associated with a mutation in the Wilms tumor suppressor gene on chromosome 11.

Phenotypic Gender

After establishment of gonadal gender, phenotypic gender develops very rapidly. It is clear that male phenotypic sexual differentiation is directed by the function of the fetal testis. In the absence of a testis, female differentiation ensues irrespective of the genetic gender. The development of urogenital tracts in both sexes of human embryos is indistinguishable before 8 weeks. Thereafter, development and differentiation of the internal and external genitalia to the male phenotype is dependent on testicular function. The fundamental experiments to determine the role of the testis in male sexual differentiation were conducted by the French anatomist Alfred Jost. Ultimately, he established that the induced phenotype is male and that secretions from the gonads are not necessary for female differentiation. Specifically, the fetal ovary is not required for female sexual differentiation.

Jost and associates (1973) found that if castration of rabbit fetuses was conducted before differentiation of the genital anlagen, all newborns were phenotypic females with female external and internal genitalia. Thus, the müllerian ducts developed into uterus, fallopian tubes, and upper vagina.

If fetal castration was conducted before differentiation of the genital anlagen, and thereafter a testis was implanted on one side in place of the removed gonad, the phenotype of all fetuses was male. Thus, the external genitalia of such fetuses were masculinized. On the side of the testicular implant, the wolffian duct developed into the epididymis, vas deferens, and seminal vesicle. With castration, on the side without the implant, the müllerian duct developed but the wolffian duct did not.

Wilson and Gloyna (1970) and Wilson and Lasnitzki (1971) demonstrated that testosterone action was amplified by conversion to 5α-dihydrotestosterone (5α-DHT). They showed that in most androgen-responsive tissues, testosterone is converted by 5α-reductase to 5α-DHT. This hormone acts primarily and almost exclusively in the genital tubercle and labioscrotal folds.

Physiological and Biomolecular Basis of Gender Differentiation

Based on these observations, the physiological basis of gender differentiation can be summarized as follows. Genetic gender is established at fertilization. Gonadal gender is determined primarily by factors encoded by genes on the Y chromosome, such as the *SRY* gene. In a manner not yet understood, differentiation of the primitive gonad into a testis is accomplished.

Fetal Testicular Contributions to Male Sexual Differentiation

The fetal testis secretes a proteinaceous substance called *müllerian-inhibiting substance,* a dimeric glycoprotein with a molecular weight of about 140,000 Da. It acts locally as a paracrine factor to cause müllerian duct regression. Thus, it prevents the development of uterus, fallopian tube, and upper vagina. Müllerian-inhibiting substance is produced by the Sertoli cells of the seminiferous tubules. Importantly, these tubules appear in fetal gonads before differentiation of Leydig cells, which are the cellular site of testosterone synthesis. Thus, müllerian-inhibiting substance is produced by Sertoli cells even before differentiation of the seminiferous tubules and is secreted as early as 7 weeks. Müllerian duct regression is completed by 9 to 10 weeks, which is before testosterone secretion has commenced. Because it acts locally near its site of formation, if a testis were absent on one side, the müllerian duct on that side would persist, and the uterus and fallopian tube would develop on that side.

Female external genital differentiation is complete by 11 weeks, whereas male external genital differentiation is complete by 14 weeks (Sobel and colleagues, 2004).

Fetal Testosterone Secretion

Apparently through stimulation initially by human chorionic gonadotropin (hCG), and later by fetal pituitary LH, the fetal testes secrete testosterone. This hormone acts directly on the wolffian duct to effect the development of the vas deferens, epididymis, and seminal vesicles. Testosterone also enters fetal blood and acts on the anlagen of the external genitalia. In these tissues, however, testosterone is converted to 5α-DHT to cause virilization of the external genitalia.

Genital Ambiguity of the Newborn

Ambiguity of the neonatal genitalia results from excessive androgen action in a fetus that was destined to be female or from inadequate androgen representation for one destined to be male. Rarely, genital ambiguity indicates *true hermaphroditism.* Abnormalities of gender differentiation causing genital ambiguity can be assigned to one of four clinically defined categories that include: (1) female pseudohermaphroditism; (2) male pseudohermaphroditism; (3) dysgenetic gonads, including true hermaphroditism; and rarely (4) true hermaphroditism (Low and Hutson, 2003).

Category 1. Female Pseudohermaphroditism

In this condition, müllerian-inhibiting substance is not produced. Androgen exposure is excessive, but variable, for a fetus genetically predestined to be female. The karyotype is 46,XX and ovaries are present.

Therefore, by genetic and gonadal gender, all are predestined to be female, and the basic abnormality is androgen excess. Because müllerian-inhibiting substance is not produced, the uterus, fallopian tubes, and upper vagina develop.

If affected fetuses were exposed to a small amount of excess androgen reasonably late in fetal development, the only genital abnormality will be slight to modest clitoral hypertrophy, with an otherwise normal female phenotype.

With somewhat greater androgen exposure, clitoral hypertrophy will be more pronounced, and the posterior labia will fuse. If androgen levels increase earlier in embryonic development, then more severe virilization can be seen. This includes formation of labioscrotal folds; development of a urogenital sinus, in which the vagina empties into the posterior urethra; and development of a penile urethra with scrotal formation—the empty scrotum syndrome (**Fig. 4-19**).

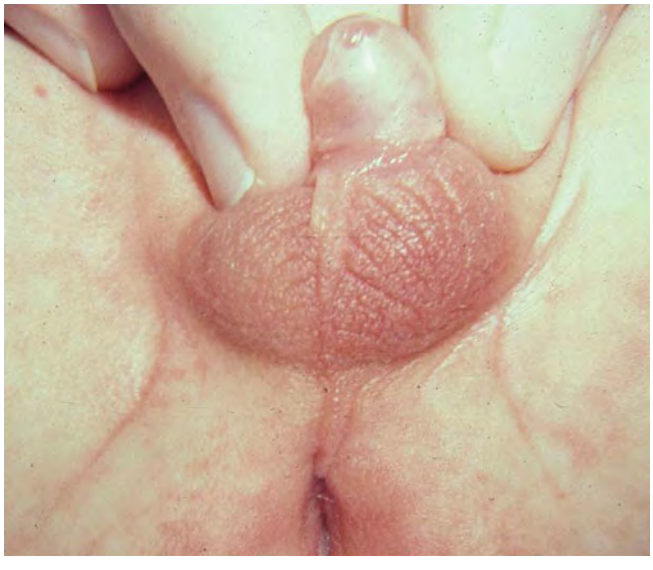

FIGURE 4-19 Female pseudohermaphroditism caused by congenital adrenal hyperplasia. Infant was 46,XX and has severe virilization with scrotal formation without a testis and has a penile urethra. (Used with permission from Dr. Lisa Halvorson.)

Congenital Adrenal Hyperplasia. This is the most common cause of androgenic excess in fetuses with female pseudohermaphroditism. The hyperplastic glands synthesize defective enzymes that cause impaired cortisol synthesis. This leads to excessive pituitary ACTH stimulation of the fetal adrenal glands with secretion of large amounts of cortisol precursors, including androgenic prehormones. These prehormones, for example, androstenedione, are converted to testosterone in fetal extra-adrenal tissues.

Mutations may involve any of several enzymes, but the most common are steroid 21-hydroxylase, 11β-hydroxylase, and 3β-hydroxysteroid dehydrogenase. Deficiency of the last prevents synthesis of virtually all steroid hormones. Deficiency of either 17β- or 11β-hydroxylase results in increased deoxycorticosterone production to cause hypertension and hypokalemic acidosis. These forms of congenital adrenal hyperplasia thus constitute medical emergencies in the newborn (Speroff and colleagues, 1994). Currently, 21-hydroxylase deficiency can be diagnosed in utero through molecular fetal DNA analysis. Prenatal maternal dexamethasone administration has shown to safely reduce fetal genital virilization (Nimkarn and New, 2009).

Excessive Androgen from Maternal Sources. Another cause of androgen excess in the female embryofetus is the transfer of androgen from the maternal compartment. This may arise from the ovaries with hyperreaction luteinalis or theca-lutein cysts or from tumors such as Leydig cell tumors and Sertoli-Leydig cell tumors (see Chap. 3, p. 71, and Chap. 40, p. 905). In most of these conditions, the female fetus does not become virilized. This is because during most of pregnancy, the fetus is protected from excess maternal androgen by the extraordinary capacity of the syncytiotrophoblast to convert most C_{19}-steroids, including testosterone, to estradiol-17β. The only exception to this generalization is fetal aromatase deficiency, which produces both maternal and fetal virilization (see Chap. 3, p. 71). Some drugs also can cause female fetal androgen excess. Most commonly, the drugs implicated are synthetic progestins or anabolic steroids (see Chap. 14, p. 321).

Importantly, except those with aromatase deficiency, all with female pseudohermaphroditism can be normal, fertile women if the proper diagnosis is made and appropriate and timely treatment initiated.

Category 2. Male Pseudohermaphroditism

This is characterized by incomplete and variable androgenic exposure of a fetus predestined to be male. The karyotype is 46,XY, and there are either testes or no gonads. In some cases, incomplete masculinization follows inadequate production of testosterone by the fetal testis. It also may arise from diminished responsiveness of the genital anlagen to normal quantities of androgen—including failure of the in situ formation of 5α-DHT in androgen-responsive tissue. Because testes were present for at least some time in embryonic life, müllerian-inhibiting substance is produced. Thus, the uterus, fallopian tubes, and upper vagina do not develop.

Fetal testicular testosterone production may fail if there is an enzymatic defect of steroidogenesis that involves any one of four enzymes in the biosynthetic pathway for testosterone synthesis. Impaired fetal testicular steroidogenesis can also be

caused by an abnormality in the LH-hCG receptor and by Leydig cell hypoplasia.

With embryonic testicular regression, the testes regress during embryonic or fetal life, and there is no testosterone production thereafter (Edman and associates, 1977). This results in a spectrum of phenotypes that varies from a normal female with absent uterus, fallopian tubes, and upper vagina, to a normal male phenotype with anorchia.

Androgen resistance or deficiencies in androgen responsiveness are caused by an abnormal or absent androgen receptor protein or by enzymatic failure of conversion of testosterone to 5α-DHT in appropriate tissues (Wilson and MacDonald, 1978).

Androgen Insensitivity Syndrome. Formerly called *testicular feminization,* this is the most extreme form of the androgen resistance syndrome, and there is no tissue responsiveness to androgen. There is a female phenotype with a short, blind-ending vagina, no uterus or fallopian tubes, and no wolffian duct structures. At the expected time of puberty, testosterone levels in affected women increase to values for normal men. Nonetheless, virilization does not occur, and even pubic and axillary hair do not develop because of end-organ resistance. Presumably, because of androgen resistance at the level of the brain and pituitary, LH levels also are elevated. In response to high concentrations of LH, there is increased testicular secretion of estradiol-17β compared with that in normal men (MacDonald and colleagues, 1979). Increased estrogen secretion and absence of androgen responsiveness act in concert to cause feminization in the form of breast development.

Individuals with *incomplete androgen insensitivity* are slightly responsive to androgen. They usually have modest clitoral hypertrophy at birth (**Fig. 4-20**). And at the expected time of puberty, pubic and axillary hair develop but virilization does not occur. These women also develop feminine breasts, presumably through the same endocrine mechanisms as in women with the complete form of the disorder (Madden and co-workers, 1975).

FIGURE 4-20 Male pseudohermaphroditism caused by incomplete androgen insensitivity syndrome. Infant is 46,XY with external genitalia demonstrating clitoral hypertrophy. (Used with permission from Dr. Lisa Halvorson.)

Another group has been referred to as *familial male pseudohermaphroditism, type I* (Walsh and colleagues, 1974). Also commonly referred to as *Reifenstein syndrome,* it constitutes a spectrum of incomplete genital virilization. Phenotypes can vary from a phenotype similar to that of women with incomplete androgen insensitivity to that of a male phenotype with only a bifid scrotum, infertility, and gynecomastia.

The gene encoding the androgen-receptor protein is located on the X chromosome. More than 100 different mutations have been demonstrated. This accounts for the wide variability in androgen responsiveness among persons in whom the androgen-receptor protein is absent or abnormal, and for the many different mutations associated with one disorder (McPhaul and associates, 1991; Patterson and co-workers, 1994).

An alternate form of androgen resistance is caused by 5α-reductase deficiency in androgen-responsive tissues. Because androgen action in the external genitalia anlagen is mediated by 5α-DHT, persons with this enzyme deficiency have external genitalia that are female but with modest clitoral hypertrophy. But because androgen action in the wolffian duct is mediated directly by testosterone, there are well-developed epididymides, seminal vesicles, and vas deferens, and the male ejaculatory ducts empty into the vagina (Walsh and associates, 1974).

Category 3: Dysgenetic Gonads

In affected individuals, karyotype varies and is commonly abnormal. As the name describes, most have abnormally developed gonads, and streak gonads are typically found. As a result, müllerian-inhibiting substance is not produced and fetal androgen exposure is variable. The uterus, fallopian tubes, and upper vagina are present.

The most common form of gonadal dysgenesis is *Turner syndrome (46X).* The phenotype is female, but secondary gender characteristics do not develop at the time of expected puberty, and genital infantilism persists. In some persons with dysgenetic gonads, the genitalia are ambiguous, a finding indicating that an abnormal gonad produced androgen, albeit in small amounts, during embryonic-fetal life. Generally, there is mixed gonadal dysgenesis—one example is a dysgenetic gonad on one side and an abnormal testis or dysontogenetic tumor on the other.

Category 4: True Hermaphroditism

In most cases, the guidelines for category 3 are met. External genitalia of such a case are shown in **Figure 4-21**. In addition, true hermaphrodites have both ovarian and testicular tissues with germ cells for both ova and sperm in the abnormal gonads.

Preliminary Diagnosis of the Cause of Genital Ambiguity

A preliminary diagnosis of genital ambiguity can be made at the birth of an affected child. By history, during physical and sonographic examination of the newborn, an experienced examiner

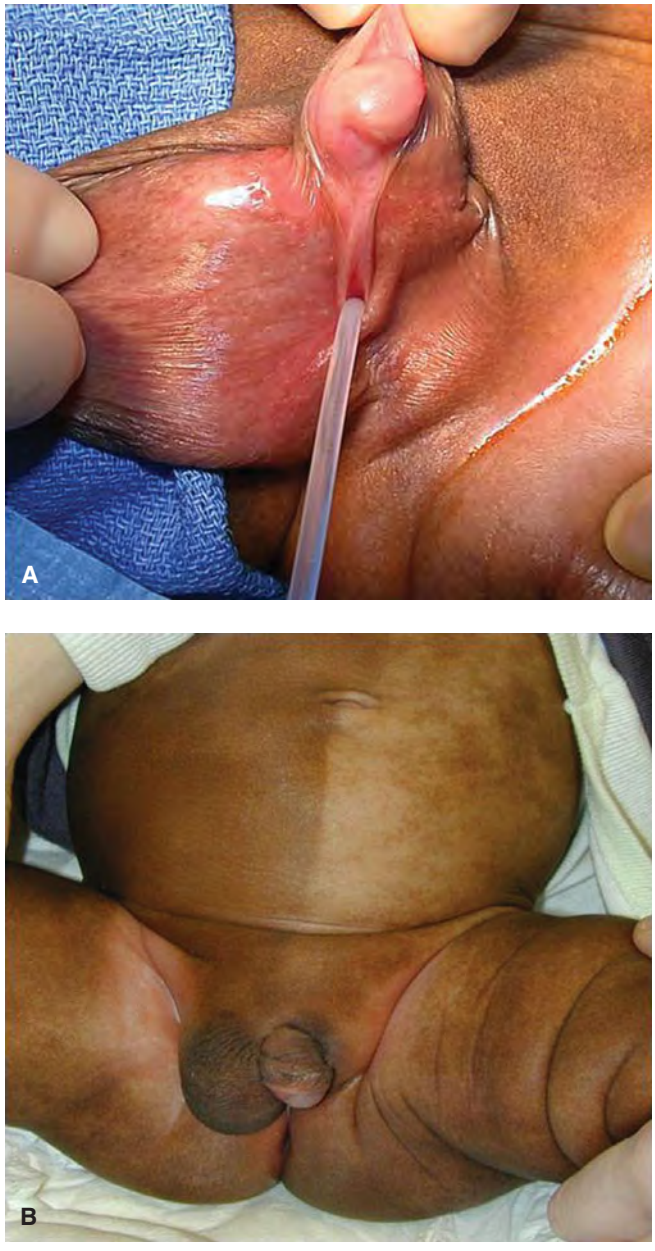

FIGURE 4-21 True hermaphroditism in infants with 46,XX/46,XY. **A.** The clitoris and hood are apparent, and the probe is in the urogenital sinus. **B.** A hemiscrotum is seen, and this infant shows different skin tones on each side. (Used with permission from Dr. Lisa Halvorson.)

can ascertain a number of important findings—whether gonads are palpable, and if so, where they are; phallus length and diameter; position of the urethral meatus; degree of labioscrotal fold fusion; and whether there is a vagina, vaginal pouch, or urogenital sinus (Speroff and associates, 1994). If the uterus is present, the diagnosis must be female pseudohermaphroditism, testicular or gonadal dysgenesis, or true hermaphroditism. A family history of congenital adrenal hyperplasia is helpful. If the uterus is not present, the diagnosis is male pseudohermaphroditism. Androgen resistance and enzymatic defects in testicular testosterone biosynthesis are often familial.

The anatomical, physiological, and biochemical adaptations to pregnancy are profound. Many of these remarkable changes begin soon after fertilization and continue throughout gestation, and most occur in response to physiological stimuli provided by the fetus and placenta. Equally astounding is that the woman who was pregnant is returned almost completely to her prepregnancy state after delivery and lactation.

Many of these physiological adaptations could be perceived as abnormal in the nonpregnant woman. For example, cardiovascular changes during pregnancy normally include substantive increases in blood volume and cardiac output, which may mimic thyrotoxicosis. On the other hand, these same adaptations may lead to ventricular failure if there is underlying heart disease. Thus, physiological adaptations of normal pregnancy can be misinterpreted as pathological but can also unmask or worsen preexisting disease.

During normal pregnancy, virtually every organ system undergoes anatomical and functional changes that can alter appreciably criteria for diagnosis and treatment of diseases. Thus, the understanding of these adaptations to pregnancy remains a major goal of obstetrics, and without such knowledge, it is almost impossible to understand the disease processes that can threaten women during pregnancy.

REPRODUCTIVE TRACT

Uterus

In the nonpregnant woman, the uterus is an almost-solid structure weighing about 70 g and with a cavity of 10 mL or less. During pregnancy, the uterus is transformed into a relatively thin-walled muscular organ of sufficient capacity to accommodate the fetus, placenta, and amnionic fluid. The total volume of the contents at term averages about 5 L but may be 20 L or more. By the end of pregnancy, the uterus has achieved a capacity that is 500 to 1000 times greater than in the nonpregnant state. The corresponding increase in uterine weight is such that, by term, the organ weighs approximately 1100 g.

During pregnancy, uterine enlargement involves stretching and marked hypertrophy of muscle cells, whereas the production of new myocytes is limited. Accompanying the increase in the muscle cell size is an accumulation of fibrous tissue, particularly in the external muscle layer, together with a considerable increase in elastic tissue. The network that is formed adds strength to the uterine wall.

Although the walls of the corpus become considerably thicker during the first few months of pregnancy, they actually thin gradually as gestation advances. By term, they are only 1 to 2 cm or even less in thickness. In these later months, the uterus is changed into a muscular sac with thin, soft, readily indentable walls through which the fetus usually can be palpated.

Uterine hypertrophy early in pregnancy probably is stimulated by the action of estrogen and perhaps that of progesterone. It is

apparent that hypertrophy of early pregnancy does not occur entirely in response to mechanical distention by the products of conception, because similar uterine changes are observed with ectopic pregnancy (see Chap. 10, p. 242). But after approximately 12 weeks, the increase in uterine size is related predominantly to pressure exerted by the expanding products of conception.

Uterine enlargement is most marked in the fundus. In the early months of pregnancy, the fallopian tubes and the ovarian and round ligaments attach only slightly below the apex of the fundus. In later months, they are located slightly above the middle of the uterus (see Fig. 2-11, p. 23). The position of the placenta also influences the extent of uterine hypertrophy, because the portion of the uterus surrounding the placental site enlarges more rapidly than does the rest.

Arrangement of the Muscle Cells

The uterine musculature during pregnancy is arranged in three strata:

1. An outer hoodlike layer, which arches over the fundus and extends into the various ligaments.
2. A middle layer, composed of a dense network of muscle fibers perforated in all directions by blood vessels.
3. An internal layer, with sphincter-like fibers around the fallopian tube orifices and internal os of the cervix.

The main portion of the uterine wall is formed by the middle layer. Each cell in this layer has a double curve so that the interlacing of any two gives approximately the form of a figure eight. This arrangement is crucial because when the cells contract after delivery, they constrict the penetrating blood vessels and thus act as ligatures (see Fig. 2-14, p. 25).

Uterine Size, Shape, and Position

For the first few weeks, the uterus maintains its original pear shape, but as pregnancy advances, the corpus and fundus assume a more globular form, becoming almost spherical by 12 weeks. Subsequently, the organ increases more rapidly in length than in width and assumes an ovoid shape. By the end of 12 weeks, the uterus has become too large to remain entirely within the pelvis. As the uterus continues to enlarge, it contacts the anterior abdominal wall, displaces the intestines laterally and superiorly, and continues to rise, ultimately reaching almost to the liver. With ascent of the uterus from the pelvis, it usually undergoes rotation to the right. This *dextrorotation* likely is caused by the rectosigmoid on the left side of the pelvis. As the uterus rises, tension is exerted on the broad and round ligaments.

With the pregnant woman standing, the longitudinal axis of the uterus corresponds to an extension of the axis of the pelvic inlet. The abdominal wall supports the uterus and unless it is quite relaxed, maintains this relation between the long axis of the uterus and the axis of the pelvic inlet. When the pregnant woman is supine, the uterus falls back to rest on the vertebral column and the adjacent great vessels, especially the inferior vena cava and aorta.

Contractility

Beginning in early pregnancy, the uterus undergoes irregular contractions that are normally painless. During the second trimester, these contractions may be detected by bimanual examination. Because attention was first called to this phenomenon in 1872 by J. Braxton Hicks, the contractions have been known by his name. Such contractions appear unpredictably and sporadically and are usually nonrhythmic. Their intensity varies between approximately 5 and 25 mm Hg (Alvarez and Caldeyro-Barcia, 1950). Until the last several weeks of pregnancy, these *Braxton Hicks contractions* are infrequent, but they increase during the last week or two. At this time, the contractions may occur as often as every 10 to 20 minutes and also may assume some degree of rhythmicity. Correspondingly, studies of uterine electrical activity have shown low and uncoordinated patterns early in gestation, which become progressively more intense and synchronized by term (Garfield and associates, 2005). Late in pregnancy, these contractions may cause some discomfort and account for so-called *false labor* (see Chap. 17, p. 390). One clinical implication recently shown is that 75 percent of women with 12 or more of these contractions per hour were diagnosed with active labor within 24 hours (Pates and colleagues, 2007).

Uteroplacental Blood Flow

The delivery of most substances essential for growth and metabolism of the fetus and placenta, as well as removal of most metabolic wastes, is dependent on adequate perfusion of the placental intervillous space (see Chap. 3, p. 55). Placental perfusion is dependent on total uterine blood flow, which is principally from the uterine and ovarian arteries. Uteroplacental blood flow increases progressively during pregnancy, with estimates ranging from 450 to 650 mL/min near term (Edman and associates, 1981; Kauppila and co-workers, 1980).

The results of studies conducted in rats by Page and coworkers (2002) show that the uterine veins also undergo significant adaptations during pregnancy. Specifically, their remodeling includes reduced elastin content and adrenergic nerve density, which results in increased venous caliber and distensibility. Logically, such changes are necessary to accommodate massively increased uteroplacental blood flow.

Assali and co-workers (1968), using electromagnetic flow probes placed directly on a uterine artery, studied the effects of labor on uteroplacental blood flow in sheep and dogs at term. They found that uterine contractions, either spontaneous or induced, caused a decrease in uterine blood flow that was approximately proportional to the intensity of the contraction. They also showed that a tetanic contraction caused a precipitous fall in uterine blood flow. Harbert and associates (1969) made a similar observation in gravid monkeys. Uterine contractions appear to affect fetal circulation much less, and Brar and colleagues (1988) reported no adverse effects on umbilical artery flow.

Regulation of Uteroplacental Blood Flow. The progressive increase in maternal-placental blood flow during gestation occurs principally by means of vasodilation, whereas fetal-placental blood flow is increased by a continuing growth of placental vessels. Palmer and colleagues (1992) showed that uterine artery diameter doubled by 20 weeks and concomitant mean Doppler velocimetry was increased eightfold. It appears likely that

vasodilation at this stage of pregnancy is at least in part the consequence of estrogen stimulation. For example, Naden and Rosenfeld (1985) found that 17β-estradiol administration to nonpregnant sheep induced cardiovascular changes similar to those observed in pregnant animals. Using measurements of the uterine artery resistance index, Jauniaux and associates (1994) found that both estradiol and progesterone contributed to the downstream fall in vascular resistance in women with advancing gestational age (see Chap. 16, p. 364).

Other mediators, in addition to estradiol and progesterone, modify vascular resistance during pregnancy, including within the uteroplacental circulation. For example, significant decreases in uterine blood flow and placental perfusion have been demonstrated in sheep following *nicotine* and *catecholamine* infusions (Rosenfeld and co-workers, 1976; Rosenfeld and West, 1977; Xiao and associates, 2007). The latter is likely the consequence of greater sensitivity of the uteroplacental vascular bed to epinephrine and norepinephrine compared with that of the systemic vasculature. In contrast, normal pregnancy is characterized by vascular refractoriness to the pressor effects of infused *angiotensin II* (see p. 120). This insensitivity serves to increase uteroplacental blood flow (Rosenfeld and Gant, 1981; Rosenfeld, 2001). More recently, Rosenfeld and associates (2005) have discovered that large-conductance potassium channels expressed in uterine vascular smooth muscle also contribute to uteroplacental blood flow regulation through several mediators, including estrogen and nitric oxide.

Cervix

As early as 1 month after conception, the cervix begins to undergo pronounced softening and cyanosis. These changes result from increased vascularity and edema of the entire cervix, together with hypertrophy and hyperplasia of the cervical glands (Straach and associates, 2005). Although the cervix contains a small amount of smooth muscle, its major component is connective tissue. Rearrangement of this collagen-rich connective tissue is necessary to permit functions as diverse as maintenance of a pregnancy to term, dilatation to aid delivery, and repair following parturition so that a successful pregnancy can be repeated (see Fig. 6-3, p. 139) (Timmons and Mahendroo, 2007; Word and associates, 2007).

As shown in **Figure 5-1**, the cervical glands undergo such marked proliferation that by the end of pregnancy they occupy approximately half of the entire cervical mass, rather than a small fraction as in the nonpregnant state. These normal pregnancy-induced changes represent an extension, or *eversion*, of the proliferating columnar endocervical glands. This tissue tends to be red and velvety and bleeds even with minor trauma, such as with Pap smear sampling.

The endocervical mucosal cells produce copious amounts of a tenacious mucus that obstruct the cervical canal soon after conception. As discussed on page 116, this mucus is rich in immunoglobulins and cytokines and may act as an immunological barrier to protect the uterine contents against infection from the vagina (Hein and colleagues, 2005). At the onset of labor, if not before, this *mucus plug* is expelled, resulting in a *bloody show.* Moreover, the consistency of the cervical mucus

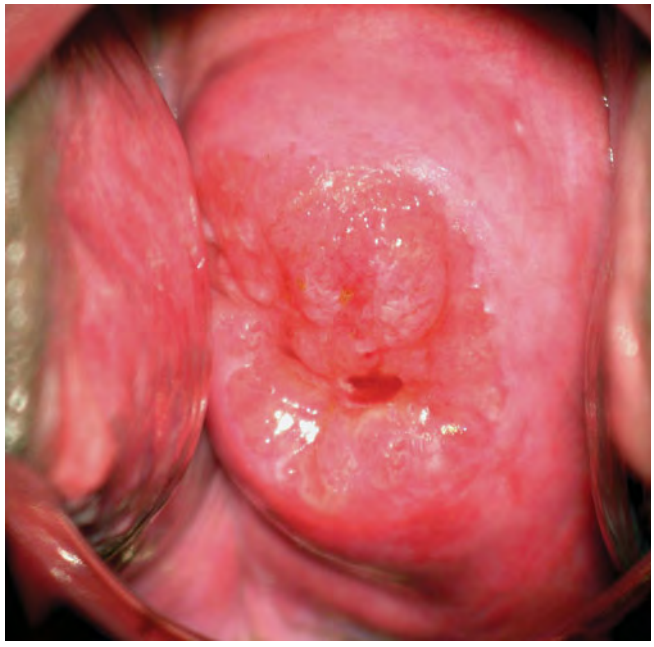

FIGURE 5-1 Cervical eversion of pregnancy as viewed through a colposcope. The eversion represents columnar epithelium on the portio of the cervix. (Used with permission from Dr. Claudia Werner.)

changes during pregnancy. In most pregnant women, when cervical mucus is spread and dried on a glass slide, it is characterized by crystallization, or *beading,* as a result of progesterone. In some women, arborization of the crystals, or *fernning,* is observed as a result of amnionic fluid leakage (see Figs. 8-3 and 8-4, p. 192).

During pregnancy, basal cells near the squamocolumnar junction are likely to be prominent in size, shape, and staining qualities. These changes are considered to be estrogen induced. In addition, pregnancy is associated with both endocervical gland hyperplasia and hypersecretory appearance—the *Arias-Stella reaction*—which makes the identification of atypical glandular cells on Pap smear particularly difficult (Connolly and Evans, 2005).

Ovaries

Ovulation ceases during pregnancy, and the maturation of new follicles is suspended. Ordinarily, only a single corpus luteum can be found in pregnant women. This functions maximally during the first 6 to 7 weeks of pregnancy—4 to 5 weeks postovulation—and thereafter contributes relatively little to progesterone production. These observations have been confirmed by surgical removal of the corpus luteum before 7 weeks—5 weeks postovulation—which results in a rapid fall in maternal serum progesterone and spontaneous abortion (Csapo and co-workers, 1973). After this time, however, corpus luteum removal ordinarily does not cause abortion. Indeed, even bilateral oophorectomy at 16 weeks has been reported to result in an otherwise uneventful pregnancy (Villaseca and associates, 2005). Interestingly in such cases, FSH levels do not reach perimenopausal levels until approximately 5 weeks postpartum.

A *decidual reaction* on and beneath the surface of the ovaries, similar to that found in the endometrial stroma, is common in pregnancy and is usually observed at cesarean delivery. These elevated patches of tissue bleed easily and may, on first glance, resemble freshly torn adhesions. Similar decidual reactions are seen on the uterine serosa and other pelvic, or even extrapelvic, abdominal organs. Although the development of such decidual reactions is incompletely understood, Taussig (1906) and others have deduced that these findings likely represent cellular detritus from the endometrium that has passed through the fallopian tubes.

The enormous caliber of the ovarian veins viewed at cesarean delivery is startling. Hodgkinson (1953) found that the diameter of the ovarian vascular pedicle increased during pregnancy from 0.9 cm to approximately 2.6 cm at term—recall that Poiseuille's law is that flow in a tubular structure is dependent on the product of its radius to the fourth power!

Relaxin

As discussed in Chapter 3 (p. 65), this protein hormone is secreted by the corpus luteum, decidua, and placenta in a pattern similar to that of human chorionic gonadotropin (hCG). It is also expressed in a variety of nonreproductive tissues, including brain, heart, and kidney. It is mentioned here because one of its major biological actions appears to be remodeling of reproductive tract connective tissue to accommodate pregnancy parturition (Park and colleagues, 2005). Relaxin also appears to be an important factor in the initiation of augmented renal hemodynamics (p. 123) and decreased osmolality (p. 112) associated with pregnancy (Smith and associates, 2006). Despite its name, serum relaxin levels do not correlate with increasing peripheral joint laxity during pregnancy (Marnach and co-workers, 2003).

Pregnancy Luteoma

In 1963, Sternberg described a solid ovarian tumor that developed during pregnancy and was composed of large acidophilic luteinized cells, which represented an exaggerated luteinization reaction of the normal ovary. These so-called *luteomas of pregnancy* are variable in size, ranging from microscopic to over 20 cm in diameter (**Fig. 5-2**). Typical sonographic characteristics include a solid, complex-appearing unilateral or bilateral mass with cystic features that correspond to areas of hemorrhage. It is usually not possible to differentiate luteomas from other solid ovarian neoplasms, such as luteinized thecoma, granulosa cell tumor, or Leydig cell tumor, by sonographic characteristics alone (Choi and associates, 2000).

FIGURE 5-2 Large luteoma of pregnancy removed at laparotomy postpartum.

Pregnancy luteomas may result in maternal virilization, but usually the female fetus is not affected. This is presumably because of the protective role of the trophoblast with its high capacity to convert androgens and androgen-like steroids to estrogens (Edman and co-workers, 1979). Occasionally, however, a female fetus can become virilized (Spitzer and co-workers, 2007). Although luteomas regress after delivery, they may recur in subsequent pregnancies (Shortle and associates, 1987).

Theca-Lutein Cysts

These benign ovarian lesions result from exaggerated physiological follicle stimulation—termed *hyperreactio luteinalis.* Although the cellular pattern of hyperreactio luteinalis is similar to that of a luteoma, these usually bilateral cystic ovaries are moderately to massively enlarged. The reaction is associated with markedly elevated serum levels of hCG. And not surprisingly, theca-lutein cysts are found frequently with gestational trophoblastic disease (see Chap. 11, p. 259). They are also more likely to be found with a large placenta such as with diabetes, D-isoimmunization, and multiple fetuses (Tanaka and colleagues, 2001). Theca-lutein cysts have also been reported in chronic renal failure as a result of reduced hCG clearance, and in hyperthyroidism as a result of the structural homology between hCG and thyroid-stimulating hormone (Coccia and colleagues, 2003; Gherman and co-workers, 2003). But they also are encountered in women with otherwise uncomplicated pregnancies and are thought to result from an exaggerated response of the ovaries to normal levels of circulating hCG (Langer and Coleman, 2007).

Although usually asymptomatic, hemorrhage into the cysts may cause abdominal pain. Maternal virilization may be seen in up to 25 percent of women (Foulk and associates, 1997). Changes including temporal balding, hirsutism, and clitoromegaly are associated with massively elevated levels of androstenedione and testosterone. The diagnosis typically is based on sonographic findings of bilateral enlarged ovaries containing multiple cysts in the appropriate clinical settings. The condition is self-limited, and resolution follows delivery. In some women, increased ovarian responsiveness to gonadotropin can be confirmed by several weeks postpartum (Bradshaw and co-workers, 1986; Sherer and associates, 2006). Their management is discussed further in Chapter 40 (p. 904).

Fallopian Tubes

The musculature of the fallopian tubes undergoes little hypertrophy during pregnancy. The epithelium of the tubal mucosa, however, becomes somewhat flattened. Decidual cells may develop in the stroma of the endosalpinx, but a continuous decidual membrane is not formed. Very rarely, the increasing size of the gravid uterus, especially in the presence of paratubal or ovarian cysts, may result in fallopian tube torsion (Batukan and co-workers, 2007).

Vagina and Perineum

During pregnancy, increased vascularity and hyperemia develop in the skin and muscles of the perineum and vulva, with softening of the underlying abundant connective tissue. Increased vascularity prominently affects the vagina and results in the violet color characteristic of *Chadwick sign.* The vaginal walls undergo striking changes in preparation for the distention that accompanies labor and delivery. These changes include a considerable increase in mucosal thickness, loosening of the connective tissue, and hypertrophy of smooth muscle cells. The papillae of the vaginal epithelium undergo hypertrophy to create a fine, hobnailed appearance.

The considerably increased volume of cervical secretions within the vagina during pregnancy consists of a somewhat thick, white discharge. The pH is acidic, varying from 3.5 to 6. This results from increased production of lactic acid from glycogen in the vaginal epithelium by the action of *Lactobacillus acidophilus.*

SKIN

Blood Flow in Skin

Increased cutaneous blood flow in pregnancy serves to dissipate excess heat generated by increased metabolism (see Chap. 56, p. 1187).

Abdominal Wall

Beginning after midpregnancy, reddish, slightly depressed streaks commonly develop in the abdominal skin and sometimes in the skin over the breasts and thighs. These are called *striae gravidarum* or *stretch marks.* In multiparous women, in addition to the reddish striae of the present pregnancy, glistening, silvery lines that represent the cicatrices of previous striae frequently are seen. In a study of 110 primiparous patients, Osman and colleagues (2007) reported that 48 percent developed striae gravidarum on their abdomen; 25 percent, on their breasts; and 25 percent, on their thighs. The strongest associated risk factors were weight gain during pregnancy, younger maternal age, and family history.

Occasionally, the muscles of the abdominal walls do not withstand the tension to which they are subjected. As a result, rectus muscles separate in the midline, creating a *diastasis recti* of varying extent. If severe, a considerable portion of the anterior uterine wall is covered by only a layer of skin, attenuated fascia, and peritoneum. True fascial defects lead to ventral hernia, which uncommonly require antepartum surgical correction.

Hyperpigmentation

This develops in up to 90 percent of women. It is usually more accentuated in those with a darker complexion (Muallem and Rubeiz, 2006). The midline of the abdominal skin—*linea alba*—becomes especially pigmented, assuming a brownish-black color to form the *linea nigra.* Occasionally, irregular brownish patches of varying size appear on the face and neck, giving rise to *chloasma* or *melasma gravidarum*—the so-called *mask of pregnancy.* Pigmentation of the areolae and genital skin may also be accentuated. These pigmentary changes usually disappear, or at least regress considerably, after delivery. Oral contraceptives may cause similar pigmentation.

Very little is known of the nature of these pigmentary changes, although melanocyte-stimulating hormone, a polypeptide similar to corticotropin, has been shown to be elevated remarkably from the end of the second month of pregnancy until term. Estrogen and progesterone also are reported to have melanocyte-stimulating effects. These conditions are considered in greater detail in Chapter 56 (p. 1185).

Vascular Changes

Angiomas, called *vascular spiders,* develop in about two thirds of white women and approximately 10 percent of black women. These are minute, red elevations on the skin, particularly common on the face, neck, upper chest, and arms, with radicles branching out from a central lesion. The condition is often designated as nevus, angioma, or telangiectasis. *Palmar erythema* is encountered during pregnancy in about two thirds of white women and one third of black women. The two conditions are of no clinical significance and disappear in most women shortly after pregnancy. They are most likely the consequence of hyperestrogenemia.

BREASTS

In the early weeks of pregnancy, women often experience breast tenderness and paresthesias. After the second month, the breasts increase in size, and delicate veins become visible just beneath the skin. The nipples become considerably larger, more deeply pigmented, and more erectile. After the first few months, a thick, yellowish fluid—*colostrum*—can often be expressed from the nipples by gentle massage. During the same months, the areolae become broader and more deeply pigmented. Scattered through the areolae are a number of small elevations, the *glands of Montgomery,* which are hypertrophic sebaceous glands. If the increase in breast size is extensive, striations similar to those observed in the abdomen may develop. Rarely, breast enlargement may become so pathologically extensive—referred to as *gigantomastia*—that it requires surgical intervention (Pasrija and Sharma, 2006; Vidaeff and associates, 2003). Interestingly, prepregnancy breast size and volume of milk production do not correlate (Hytten, 1995). Histological and functional changes of the breasts induced by pregnancy and lactation are further discussed in Chapter 30 (p. 649).

METABOLIC CHANGES

In response to the increased demands of the rapidly growing fetus and placenta, the pregnant woman undergoes metabolic changes that are numerous and intense. Certainly no other physiological event in postnatal life induces such profound

TABLE 5-1. Analysis of Weight Gain Based on Physiological Events During Pregnancy

	Cumulative Increase in Weight (g)			
Tissues and Fluids	10 Weeks	20 Weeks	30 Weeks	40 Weeks
Fetus	5	300	1500	3400
Placenta	20	170	430	650
Amnionic fluid	30	350	750	800
Uterus	140	320	600	970
Breasts	45	180	360	405
Blood	100	600	1300	1450
Extravascular fluid	0	30	80	1480
Maternal stores (fat)	310	2050	3480	3345
Total	650	4000	8500	12,500

Modified from Hytten (1991).

metabolic alterations. By the third trimester, maternal basal metabolic rate is increased by 10 to 20 percent compared with that of the nonpregnant state. This is increased by an additional 10 percent in women with twin gestations (Shinagawa and associates, 2005). Viewed another way, additional total pregnancy energy demands are estimated to be as high as 80,000 kcal or about 300 kcal/day (Hytten and Chamberlain, 1991).

Weight Gain

Most of the normal increase in weight during pregnancy is attributable to the uterus and its contents, the breasts, and increases in blood volume and extravascular extracellular fluid. A smaller fraction of the increased weight is the result of metabolic alterations that result in an increase in cellular water and deposition of new fat and protein—so-called *maternal reserves.* Hytten (1991) reported that the average weight gain during pregnancy is approximately 12.5 kg or 27.5 lb (Table 5-1). Maternal aspects of weight gain are considered in greater detail in Chapter 8 (p. 200).

Water Metabolism

Increased water retention is a normal physiological alteration of pregnancy. It is mediated, at least in part, by a fall in plasma osmolality of approximately 10 mOsm/kg induced by a resetting of osmotic thresholds for thirst and vasopressin secretion (Heenan and colleagues, 2003; Lindheimer and Davison, 1995). As shown in Figure 5-3, this phenomenon is functioning by early pregnancy.

At term, the water content of the fetus, placenta, and amnionic fluid approximates 3.5 L. Another 3.0 L accumulates as a result of increases in the maternal blood volume and in the size of the uterus and breasts. Thus, the minimum amount of extra water that the average woman accrues during normal pregnancy is approximately 6.5 L. Clearly demonstrable pitting edema of the ankles and legs is seen in most pregnant women, especially at the end of the day. This accumulation of fluid, which may amount to a liter or so, is caused by increased venous pressure below the level of the uterus as a consequence of partial vena cava occlusion. A decrease in interstitial colloid osmotic pressure induced by normal pregnancy also favors edema late in pregnancy (Øian and co-workers, 1985).

Longitudinal studies of body composition have shown a progressive increase in total body water and fat mass during pregnancy. Both initial maternal weight and weight gained during pregnancy are highly associated with birthweight. It is unclear, however, what role maternal fat or water have in fetal growth. Studies in well-nourished women suggest that maternal body water, rather than fat, contributes more significantly to infant birthweight (Lederman and co-workers, 1999; Mardones-Santander and associates, 1998).

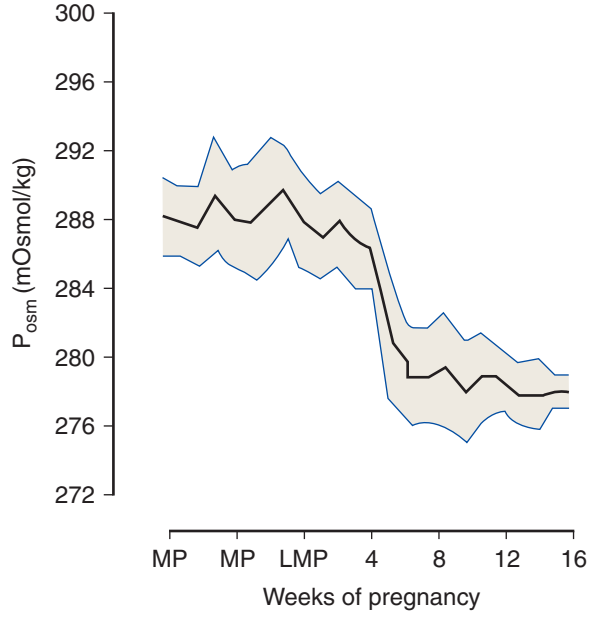

FIGURE 5-3 Mean values (*black line*) ± standard deviations (*blue lines*) for plasma osmolality (P_{osm}) measured at weekly intervals in nine women from preconception to 16 weeks. (LMP = last menstrual period; MP = menstrual period.) (From Davison and colleagues, 1981, with permission.)

Protein Metabolism

The products of conception, the uterus, and maternal blood are relatively rich in protein rather than fat or carbohydrate. At term, the fetus and placenta together weigh about 4 kg and contain approximately 500 g of protein, or about half of the total pregnancy increase (Hytten and Leitch, 1971). The remaining 500 g is added to the uterus as contractile protein, to the breasts primarily in the glands, and to the maternal blood as hemoglobin and plasma proteins.

Amino acid concentrations are higher in the fetal than in the maternal compartment (Cetin and co-workers, 2005; van den Akker and associates, 2009). This increased concentration is largely regulated by the placenta, which not only concentrates amino acids into the fetal circulation, but also is involved in protein synthesis, oxidation, and transamination of some nonessential amino acids (Galan and colleagues, 2009).

Mojtahedi and associates (2002) measured *nitrogen balance* across pregnancy in 12 healthy women. It increased with gestation and thus suggested a more efficient use of dietary protein. They also found that urinary excretion of 3-methylhistidine did not change, indicating that breakdown of maternal muscle is not required to meet metabolic demands. Further support that pregnancy is associated with nitrogen conservation comes from Kalhan and colleagues (2003), who found that the turnover rate of nonessential serine decreases across gestation. The daily requirements for dietary protein intake during pregnancy are discussed in Chapter 8 (p. 202).

Carbohydrate Metabolism

Normal pregnancy is characterized by mild fasting hypoglycemia, postprandial hyperglycemia, and hyperinsulinemia (Fig. 5-4). This increased basal level of plasma insulin in normal pregnancy is associated with several unique responses to glucose ingestion. For example, after an oral glucose meal, gravid women demonstrate both prolonged hyperglycemia and hyperinsulinemia as well as a greater suppression of glucagon (Phelps and associates, 1981). This cannot be explained by a decreased metabolism of insulin because its half-life during pregnancy is not changed (Lind and associates, 1977). Instead, this response is consistent with a pregnancy-induced state of peripheral insulin resistance, the purpose of which is likely to ensure a sustained postprandial supply of glucose to the fetus. Indeed, insulin sensitivity in late normal pregnancy is 45 to 70 percent lower than that of nonpregnant women (Butte, 2000; Freemark, 2006).

The mechanism(s) responsible for insulin resistance is not completely understood. Progesterone and estrogen may act, directly or indirectly, to mediate this resistance. Plasma levels of placental lactogen increase with gestation, and this protein hormone is characterized by growth hormone–like action that may result in increased lipolysis with liberation of free fatty acids (Freinkel, 1980). The increased concentration of circulating free fatty acids also may aid increased tissue resistance to insulin (Freemark, 2006).

The pregnant woman changes rapidly from a postprandial state characterized by elevated and sustained glucose levels to a fasting state characterized by decreased plasma glucose and some amino acids. Simultaneously, plasma concentrations of free fatty acids, triglycerides, and cholesterol are higher. Freinkel and colleagues (1985) have referred to this pregnancy-induced switch in fuels from glucose to lipids as *accelerated starvation.* Certainly, when fasting is prolonged in the pregnant woman, these alterations are exaggerated and ketonemia rapidly appears.

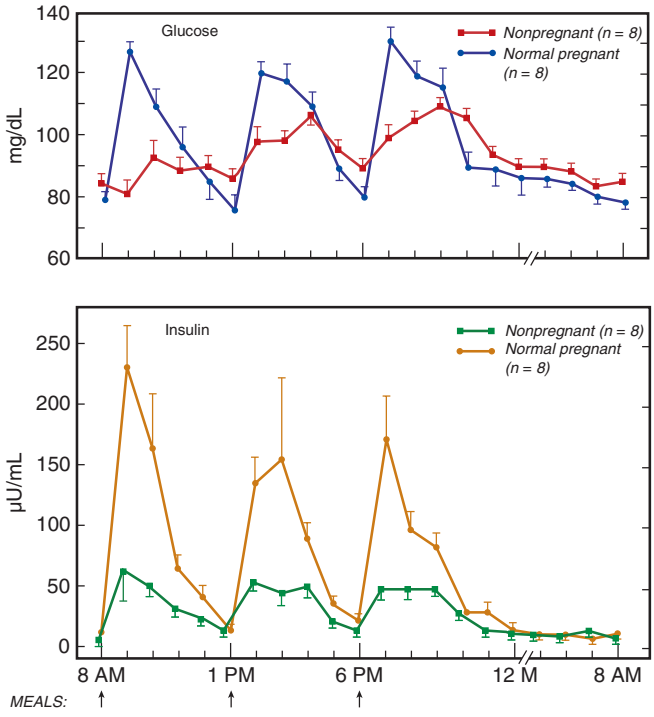

FIGURE 5-4 Diurnal changes in plasma glucose and insulin in normal late pregnancy. (This figure was redrawn from *American Journal of Obstetrics & Gynecology,* Vol. 140, No. 7, RL Phelps, BE Metzger, and N Freinkel, Carbohydrate metabolism in pregnancy. XVII. Diurnal profiles of plasma glucose, insulin, free fatty acids, triglycerides, cholesterol, and individual amino acids in late normal pregnancy, pp. 730–736, Copyright Elsevier 1981, with permission.)

Fat Metabolism

The concentrations of lipids, lipoproteins, and apolipoproteins in plasma increase appreciably during pregnancy. The storage of fat occurs primarily during midpregnancy (Hytten and Thomson, 1968; Pipe and co-workers, 1979). This fat is deposited mostly in central rather than peripheral sites. It becomes available for placental transfer during the last trimester when fetal growth rate is maximal along with essential fatty acids requirements (Herrera and colleagues, 2006; Innis, 2005). It may be that progesterone acts to reset a lipostat in the hypothalamus, and at the end of pregnancy, the lipostat returns to its previous nonpregnant level, and the added fat is lost (Hytten and Thomson, 1968). Such a mechanism for energy storage, theoretically at least, might protect the mother and fetus during prolonged starvation or hard physical exertion.

Maternal hyperlipidemia is one of the most consistent and striking changes to take place in lipid metabolism during late pregnancy. Triacylglycerol and cholesterol levels in very-low-density lipoprotein (VLDL), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs) are increased during the third

trimester compared with those in nonpregnant women. The mechanisms responsible for these changes include increased lipolytic and decreased lipoprotein lipase activities in adipose tissue (Herrera and colleagues, 2006). The hepatic effects of estradiol and progesterone also play an important role (Desoye and associates, 1987).

During the third trimester, average total serum cholesterol, LDL-C, HDL-C, and triglyceride levels are approximately 267 ± 30 mg/dL, 136 ± 33 mg/dL, 81 ± 17 mg/dL, and 245 ± 73 mg/dL, respectively (Lippi and associates, 2007). After delivery, the concentrations of these lipids, as well as lipoproteins and apolipoproteins decrease. Lactation speeds the change in levels of many of these (Darmady and Postle, 1982).

Hyperlipidemia is of some concern because it is associated with endothelial dysfunction. From their studies, however, Saarelainen and associates (2006) found that endothelium-dependent vasodilation responses actually improved across pregnancy. This was partly because increased concentrations of HDL-cholesterol likely inhibit oxidation of low-density lipoprotein and thus protect the endothelium. Their findings suggest that the increased risk of cardiovascular disease in multiparous women may be related to factors other than maternal hypercholesterolemia.

Leptin

In nonpregnant humans, this peptide hormone is primarily secreted by adipose tissue. It has a key role in the regulation of body fat and energy expenditure. Maternal serum leptin levels increase and peak during the second trimester and plateau until term in concentrations two to four times higher than those in nonpregnant women. This increase is only partially due to pregnancy weight gain, because leptin also is produced in significant amounts by the placenta. Indeed, placental weight is significantly correlated with leptin levels measured in umbilical cord blood (Pighetti and co-workers, 2003). Hauguel-de Mouzon and associates (2006) have hypothesized that increased leptin production may be critical for the regulation of increased maternal energy demands. Leptin may also help to regulate fetal growth and play a role in fetal macrosomia as well as growth restriction (Gohlke, 2006; Grisaru-Granovsky, 2008; Henson, 2006, Lepercq, 2003, and all their associates). This topic is discussed further in Chapter 38 (p. 842).

Ghrelin

This is another hormone secreted by adipose tissue that likely has a role in fetal growth and cell proliferation. It is also expressed in placental tissue, and this hormone regulates growth hormone secretion. Maternal serum levels of ghrelin increase and peak at midpregnancy and then decrease until term (Fuglsang, 2008). This is explicable in that ghrelin levels are known to be decreased in other insulin-resistant states such as metabolic syndrome (Riedl and associates, 2007).

Electrolyte and Mineral Metabolism

During normal pregnancy, nearly 1000 mEq of *sodium* and 300 mEq of *potassium* are retained (Lindheimer and colleagues, 1987). Although the glomerular filtration of sodium and potassium is increased, the excretion of these electrolytes is unchanged during pregnancy as a result of enhanced tubular resorption (Brown and colleagues, 1986, 1988). And although there are increased total accumulations of sodium and potassium, their serum concentrations are decreased slightly because of expanded plasma volume (see Appendix). Still, they remain very near the range of normal for nonpregnant women (Kametas and colleagues, 2003b).

Total serum *calcium* levels decline during pregnancy, the reduction reflecting lowered plasma albumin concentration and, in turn, the consequent decrease in the amount bound to protein. Levels of serum ionized calcium, however, remain unchanged (Power and associates, 1999). The developing fetus imposes a significant demand on maternal calcium homeostasis. For example, the fetal skeleton accretes approximately 30 g of calcium by term, 80 percent of which is deposited during the third trimester. This demand is largely met by a doubling of maternal intestinal calcium absorption mediated, in part, by 1,25-dihydroxyvitamin D_3 (Kovacs and Fuleihan, 2006). In addition, dietary intake of sufficient calcium is necessary to prevent excess depletion from the mother (see Table 8-7, p. 201). This is especially important in pregnant adolescents, in whom bones are still developing (Repke, 1994).

Serum *magnesium* levels also decline during pregnancy. Bardicef and colleagues (1995) concluded that pregnancy is actually a state of extracellular magnesium depletion. Compared with nonpregnant women, they found that both total and ionized magnesium were significantly lower during normal pregnancy. Serum *phosphate* levels are within the nonpregnant range (Kametas and colleagues, 2003b). The renal threshold for inorganic phosphate excretion is elevated in pregnancy due to increased calcitonin (Weiss and colleagues, 1998).

With respect to most other minerals, pregnancy induces little change in their metabolism other than their retention in amounts equivalent to those needed for growth (see Chap. 4, p. 88, and Chap. 8, p. 202). An important exception is the considerably increased requirement for *iron,* which is discussed subsequently.

HEMATOLOGICAL CHANGES

Blood Volume

The well-known hypervolemia associated with normal pregnancy averages 40 to 45 percent above the nonpregnant blood volume after 32 to 34 weeks (Pritchard, 1965; Whittaker and associates, 1996). In individual women, expansion varies considerably. In some there is only a modest increase, whereas in others the blood volume nearly doubles. A fetus is not essential for this because increased blood volume develops in some women with hydatidiform mole (Pritchard, 1965).

Pregnancy-induced hypervolemia has important functions:

1. To meet the metabolic demands of the enlarged uterus with its greatly hypertrophied vascular system.
2. To provide an abundance of nutrients and elements to support the rapidly growing placenta and fetus.
3. To protect the mother and in turn the fetus, against the deleterious effects of impaired venous return in the supine and erect positions.
4. To safeguard the mother against the adverse effects of blood loss associated with parturition.

Maternal blood volume begins to increase during the first trimester. By 12 menstrual weeks, plasma volume expands by approximately 15 percent compared with that of prepregnancy (Bernstein and co-workers, 2001). As shown in **Figure 5-5**, maternal blood volume expands most rapidly during the second trimester. It then rises at a much slower rate during the third trimester to plateau during the last several weeks of pregnancy.

Blood volume expansion results from an increase in both plasma and erythrocytes. Although more plasma than erythrocytes is usually added to the maternal circulation, the increase in erythrocyte volume is considerable, averaging about 450 mL (Pritchard and Adams, 1960). Moderate erythroid hyperplasia is present in the bone marrow, and the reticulocyte count is elevated slightly during normal pregnancy. As discussed in Chapter 51 (p. 1079), these changes are almost certainly related to the increase in maternal plasma erythropoietin levels, which peak early during the third trimester and correspond to maximal erythrocyte production (Clapp and colleagues, 2003; Harstad and co-workers, 1992).

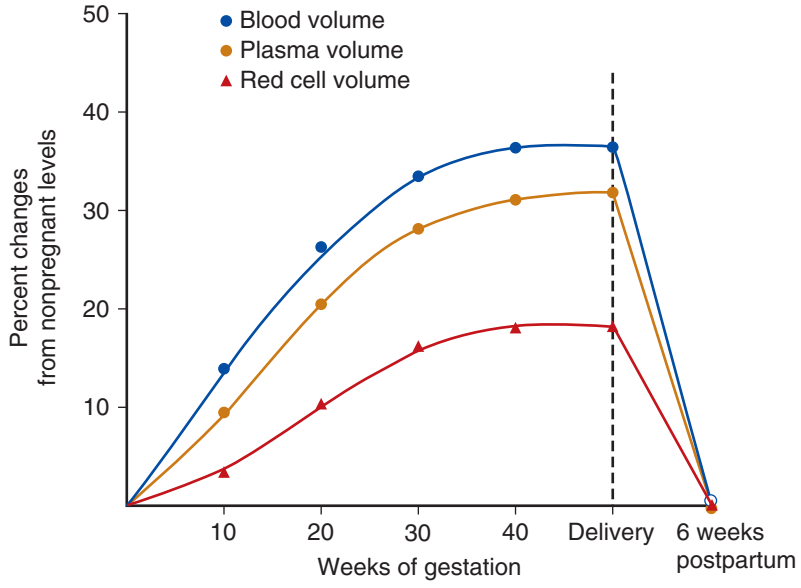

FIGURE 5-5 Changes in total blood volume and its components (plasma and red cell volumes) during pregnancy and postpartum. (From Peck and Arias, 1979, with permission.)

Hemoglobin Concentration and Hematocrit

Because of great plasma augmentation, hemoglobin concentration and hematocrit decrease slightly during pregnancy (see Appendix). As a result, whole blood viscosity decreases (Huisman and colleagues, 1987). Hemoglobin concentration at term averages 12.5 g/dL, and in approximately 5 percent of women, it is below 11.0 g/dL (Table 51-1, p. 1080). Thus, a hemoglobin concentration below 11.0 g/dL, especially late in pregnancy, should be considered abnormal and usually due to iron deficiency rather than due to hypervolemia of pregnancy.

Iron Metabolism

Storage Iron

The total iron content of normal adult women ranges from 2.0 to 2.5 g or about half the amount found normally in men. Importantly, the iron stores of normal young women are only approximately 300 mg (Pritchard and Mason, 1964).

Iron Requirements

Of the approximate 1000 mg of iron required for normal pregnancy, about 300 mg are actively transferred to the fetus and placenta, and another 200 mg are lost through various normal routes of excretion, primarily the gastrointestinal tract. These are obligatory losses and occur even when the mother is iron deficient. The average increase in the total volume of circulating erythrocytes—about 450 mL—requires another 500 mg because 1 mL of erythrocytes contains 1.1 mg of iron. Because most iron is used during the latter half of pregnancy, the iron requirement becomes large after midpregnancy and averages 6 to 7 mg/day (Pritchard and Scott, 1970). This amount is usually not available from storage iron in most women, and the optimal increase in maternal erythrocyte volume will not develop without supplemental iron. Without supplementation, the hemoglobin concentration and hematocrit fall appreciably as the blood volume increases. At the same time, fetal red cell production is not impaired because the placenta transfers iron even when the mother has severe iron deficiency anemia. In severe cases, we have documented hemoglobin values of 3 g/dL and hematocrits of 10 percent.

It follows that the amount of dietary iron, together with that mobilized from stores, will be insufficient to meet the average demands imposed by pregnancy. As shown in **Figure 5-6**, if the

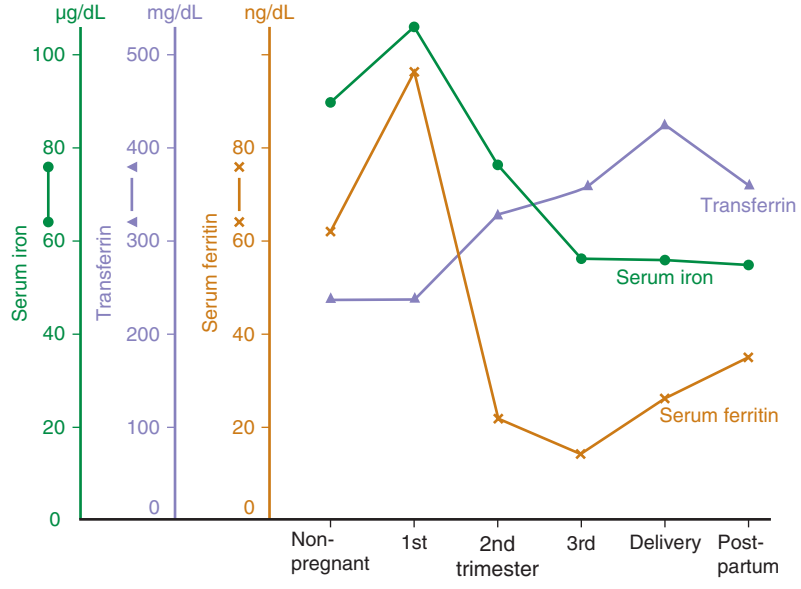

FIGURE 5-6 Indices of iron turnover during pregnancy in women without overt anemia but who were not given iron supplementation. (From Kaneshige, 1981, with permission.)

nonanemic pregnant woman is not given supplemental iron, which is discussed in Chapter 8, then serum iron and ferritin concentrations decline after midpregnancy. The early pregnancy increases in serum iron and ferritin are likely due to minimal iron demands early on combined with the positive iron balance from amenorrhea (see Fig. 5-6).

The Puerperium

Generally, not all the maternal iron added in the form of hemoglobin is lost with normal delivery. At the time of vaginal delivery, and through the next few days, only approximately half of the added erythrocytes are lost from most women. These normal losses are from the placental implantation site, episiotomy or lacerations, and lochia. On average, maternal erythrocytes corresponding to approximately 500 to 600 mL of predelivery whole blood are lost with vaginal delivery of a single fetus (Pritchard, 1965; Ueland, 1976). The average blood loss associated with cesarean delivery or with the vaginal delivery of twins is about 1000 mL (see Fig. 35-2, p. 760).

Immunological Functions

Pregnancy is thought to be associated with suppression of a variety of humoral and cell-mediated immunological functions to accommodate the "foreign" semiallogeneic fetal graft (Thellin and Heinen, 2003). This is discussed further in Chapter 3 (p. 58). One mechanism appears to involve suppression of T-helper (Th) 1 and T-cytotoxic (Tc) 1 cells, which decreases secretion of interleukin-2(IL-2), interferon-γ, and tumor necrosis factor-β (TNF-β). There is also evidence that a suppressed Th1 response is requisite for pregnancy continuation. It also may explain pregnancy-related remission of some autoimmune disorders. Examples include rheumatoid arthritis, multiple sclerosis, and autoimmune thyroiditis—which are Th1-mediated diseases (Kumru and colleagues, 2005). As discussed in Chapter 34 (p. 711), failure of Th1 immune suppression may be related to development of preeclampsia (Jonsson and co-workers, 2006).

Not all aspects of immunological function are depressed. For example, there is upregulation of Th2 cells to increase secretion of IL-4, IL-6, and IL-13 (Michimata and colleagues, 2003). In cervical mucus, peak levels of immunoglobulins A and G (IgA and IgG) are significantly higher during pregnancy. Similarly, the amount of interleukin-1β found in cervical mucus during pregnancy is approximately 10-fold greater than in nonpregnant women. Because oral contraceptives have been shown to induce similar changes, Kutteh and Franklin (2001) hypothesized that changes in the cervical mucus may be a result of estrogen and progesterone. Although these changes may be important for fetal protection, their actual clinical significance is unclear.

Leukocytes

Some polymorphonuclear leukocyte chemotaxis and adherence functions are depressed beginning in the second trimester and continuing throughout pregnancy (Krause and associates, 1987). Although incompletely understood, this may be partly related to the finding that relaxin (see p. 110) impairs neutrophil activation (Masini and co-workers, 2004). It is possible that these depressed leukocyte functions of pregnant women also account in part for the improvement of some autoimmune disorders and possible increased susceptibility to certain infections.

Although the leukocyte count varies considerably during pregnancy, usually it ranges from 5000 to 12,000/μL. During labor and the early puerperium, it may become markedly elevated, attaining levels of 25,000/μL or even more, however, it averages 14,000 to 16,000/μL (Taylor and co-workers, 1981). The cause for the marked increase is not known, but the same response occurs during and after strenuous exercise. It probably represents the reappearance of leukocytes previously shunted out of active circulation. Interestingly, increasing numbers of immune cells are also found in the uterine wall during normal pregnancy. Garfield and co-workers (2006) have found that these cells, especially mast cells, may play an important role in mediating uterine contractility.

In addition to normal variations in the leukocyte count, the distribution of cell types is altered significantly during pregnancy. Specifically, during the third trimester, the percentages of granulocytes and CD8 T lymphocytes are significantly increased along with a concomitant reduction in the percentages of CD4 T lymphocytes and monocytes. Moreover, circulating leukocytes undergo significant phenotypic changes including, for example, the upregulation of certain adhesion molecules (Luppi and associates, 2002).

Inflammatory Markers

Many tests performed to diagnose inflammation cannot be used reliably during pregnancy. For example, *leukocyte alkaline phosphatase* levels are used to evaluate myeloproliferative disorders and are increased beginning early in pregnancy. The concentration of *C-reactive protein,* an acute-phase serum reactant, rises rapidly to 1000-fold in response to tissue trauma or inflammation. Watts and colleagues (1991) measured C-reactive protein levels across pregnancy and found that median values were higher than for nonpregnant women. Levels were elevated further in labor. In women not in labor, 95 percent had levels of 1.5 mg/dL or less, and gestational age did not affect serum levels. Another marker of inflammation, the *erythrocyte sedimentation rate (ESR),* is increased in normal pregnancy because of elevated plasma globulins and fibrinogen (Hytten and Leitch, 1971). Lastly, *complement factors C3* and *C4* also are significantly elevated during the second and third trimesters (Gallery and colleagues, 1981; Richani and associates, 2005).

Coagulation and Fibrinolysis

During normal pregnancy, both coagulation and fibrinolysis are augmented but remain balanced to maintain hemostasis. They are even more enhanced in multifetal gestation (Morikawa and colleagues, 2006). Evidence of activation includes increased concentrations of all clotting factors, except factors XI and XIII, and increased levels of high-molecular-weight fibrinogen complexes (Table 5-2). The clotting time of whole blood, however, does not differ significantly in normal pregnant women. Considering the substantive physiological increase in plasma volume in normal pregnancy, such increased concentrations represent a markedly augmented production of these procoagulants. For example, plasma fibrinogen (factor I) in normal nonpregnant women averages about 300 mg/dL and ranges from 200 to 400 mg/dL.

TABLE 5-2. Changes in Measures of Hemostasis During Normal Pregnancy

Parameter	Nonpregnant	Pregnant (35–40 weeks)
Activated PTT (sec)	31.6 ± 4.9	31.9 ± 2.9
Thrombin time (sec)	18.9 ± 2.0	22.4 ± 4.1[a]
Fibrinogen (mg/dL)	256 ± 58	473 ± 72[a]
Factor VII (%)	99.3 ± 19.4	181.4 ± 48.0[a]
Factor X (%)	97.7 ± 15.4	144.5 ± 20.1[a]
Plasminogen (%)	105.5 ± 14.1	136.2 ± 19.5[a]
tPA (ng/mL)	5.7 ± 3.6	5.0 ± 1.5
Antithrombin III (%)	98.9 ± 13.2	97.5 ± 33.3
Protein C (%)	77.2 ± 12.0	62.9 ± 20.5[a]
Total Protein S (%)	75.6 ± 14.0	49.9 ± 10.2[a]

[a]Statistically significant difference.

During normal pregnancy, fibrinogen concentration increases approximately 50 percent. It averages 450 mg/dL late in pregnancy, with a range from 300 to 600 mg/dL. The percentage of high-molecular-weight fibrinogen is unchanged (Manten and colleagues, 2004). This contributes greatly to the striking increase in the *erythrocyte sedimentation rate* as discussed previously. Some of the pregnancy-induced changes in the levels of coagulation factors can be duplicated by the administration of estrogen plus progestin contraceptive tablets to nonpregnant women.

The end product of the coagulation cascade is fibrin formation, and the main function of the fibrinolytic system is to remove excess fibrin. Tissue plasminogen activator (tPA) converts plasminogen into plasmin, which causes fibrinolysis and produces fibrin degradation products such as D-dimers. Studies of the fibrinolytic system in pregnancy have produced conflicting results, although most evidence suggests that fibrinolytic activity is actually reduced in normal pregnancy. For example, tPA activity gradually decreases over the course of normal pregnancy. Moreover, plasminogen activator inhibitor type 1 (PAI-2) and type 2 (PAI-2), which inhibit tPA and regulate fibrin degradation by plasmin, increase during normal pregnancy (Robb and co-workers, 2009). As reviewed by Holmes and Wallace (2005), these changes—which may indicate that the fibrinolytic system is impaired—are countered by increased levels of plasminogen and decreased levels of another plasmin inhibitor, α_2 antiplasmin. Such changes serve to ensure hemostatic balance during normal pregnancy.

Platelets

Normal pregnancy also involves changes in platelets (Baker and Cunningham, 1999). In a study of almost 7000 healthy women at term, Boehlen and associates (2000) found that the average platelet count was decreased slightly during pregnancy to 213,000/μL compared with 250,000/μL in nonpregnant control women. They defined thrombocytopenia as below the 2.5th percentile, which corresponded to a platelet count of 116,000/mL. Decreased platelet concentrations are partially due to the effects of hemodilution. However, they also likely represent increased platelet consumption, leading to a greater proportion of younger, and therefore, larger platelets (Tygart and co-workers, 1986). Further supporting this concept, Hayashi and associates (2002) found that beginning in midpregnancy, production of thromboxane A_2, which induces platelet aggregation, progressively increases.

Regulatory Proteins

There are a number of natural inhibitors of coagulation, including proteins C, S, and Z and antithrombin. Inherited or acquired deficiencies of these and other natural regulatory proteins—collectively referred to as thrombophilias—account for many thromboembolic episodes during pregnancy. They are discussed in detail in Chapter 47.

Activated protein C, along with the co-factors protein S and factor V, functions as an anticoagulant by neutralizing the procoagulants factor Va and factor VIIIa (see Fig. 47-1, p. 1016). At the same time, resistance to activated protein C increases progressively and is related to a concomitant decrease in free protein S and increase in factor VIII. Between the first and third trimesters, levels of activated protein C decrease from about 2.4 to 1.9 U/mL, and free protein S decreases from 0.4 to 0.16 U/mL (Walker and colleagues, 1997). Oral contraceptives also decrease free protein S levels. *Protein Z* is a vitamin-K dependent glycoprotein that inhibits activation of factor X. Quack Loetscher and co-workers (2005) reported a 20-percent increase across pregnancy. Effraimidou and associates (2009) have speculated that low protein Z levels may prove to be a risk factor for otherwise unexplained recurrent early pregnancy loss. Levels of *antithrombin* remain relatively constant throughout gestation and the early puerperium (Delorme and associates, 1992).

Spleen

By the end of normal pregnancy, the splenic area enlarges by up to 50 percent compared with the first trimester. The echogenic

appearance of the spleen remains homogeneous throughout gestation (Maymon and co-workers, 2007).

CARDIOVASCULAR SYSTEM

During pregnancy and the puerperium, the heart and circulation undergo remarkable physiological adaptations. Changes in cardiac function become apparent during the first 8 weeks of pregnancy (McLaughlin and Roberts, 1999). Cardiac output is increased as early as the fifth week and reflects a reduced systemic vascular resistance and an increased heart rate. The resting pulse rate increases about 10 beats/min during pregnancy (Stein and co-workers, 1999). Between weeks 10 and 20, plasma volume expansion begins and preload is increased. Ventricular performance during pregnancy is influenced by both the decrease in systemic vascular resistance and changes in pulsatile arterial flow. As discussed subsequently, multiple factors contribute to these changes in overall hemodynamic function and allow the cardiovascular system to adjust to the physiological demands of the fetus while maintaining maternal cardiovascular integrity. These changes during the last half of pregnancy are graphically summarized in Figure 5-7, which also shows the important effects of maternal posture on hemodynamic events during pregnancy.

Heart

As the diaphragm becomes progressively elevated, the heart is displaced to the left and upward and rotated somewhat on its long axis. As a result, the apex is moved somewhat laterally from its usual position, causing a larger cardiac silhouette on chest radiograph (Fig. 5-8). Furthermore, pregnant women normally have some degree of benign pericardial effusion, which may increase the cardiac silhouette (Enein and colleagues, 1987). Variability of these factors makes it difficult to precisely identify moderate degrees of cardiomegaly by simple radiographic studies. Normal pregnancy induces no characteristic electrocardiographic changes other than slight left-axis deviation as a result of the altered heart position.

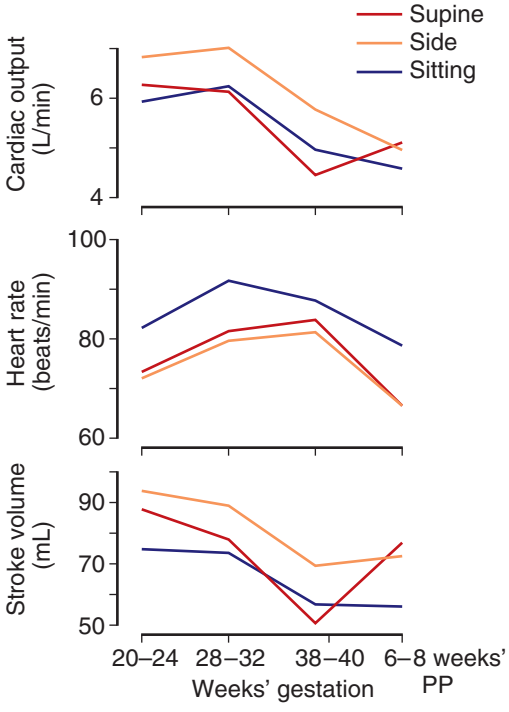

FIGURE 5-7 Effect of maternal posture on hemodynamics. PP = postpartum. (From Ueland and Metcalfe, 1975, with permission.)

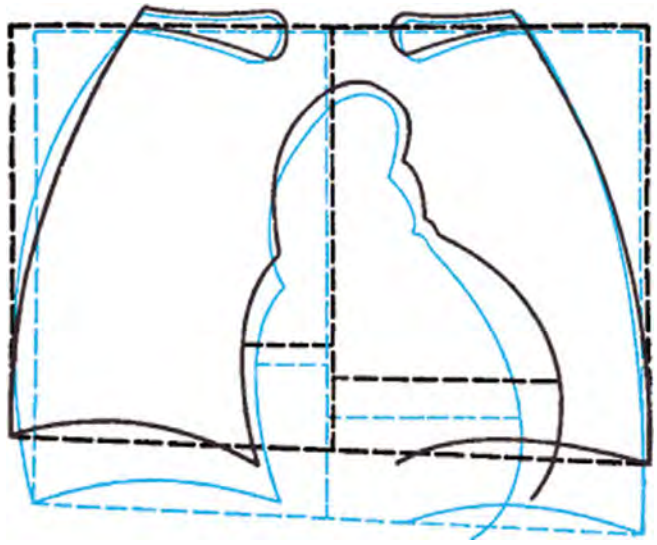

FIGURE 5-8 Change in cardiac outline that occurs in pregnancy. The blue lines represent the relations between the heart and thorax in the nonpregnant woman, and the black lines represent the conditions existing in pregnancy. These findings are based on radiographic findings in 33 women. (Redrawn from Klafen and Palugyay, 1927, with permission.)

Many of the normal *cardiac sounds* are altered during pregnancy. Cutforth and MacDonald (1966) used phonocardiography and documented: (1) an exaggerated splitting of the first heart sound with increased loudness of both components; (2) no definite changes in the aortic and pulmonary elements of the second sound; and (3) a loud, easily heard third sound (Fig. 44-1, p. 960). They heard a systolic murmur in 90 percent of pregnant women that was intensified during inspiration in some or expiration in others, and disappeared shortly after delivery. A soft diastolic murmur was noted transiently in 20 percent, and continuous murmurs arising from the breast vasculature in 10 percent.

The increased plasma volume during normal pregnancy, which was discussed previously (p. 115), leads to several reversible morphological and functional adaptations. There is no doubt that the heart is capable of remodeling in response to stimuli such as hypertension and exercise. Cardiac *plasticity* likely is a continuum that encompasses physiological growth, such as that in exercise, as well as pathological hypertrophy—such as with hypertension (Hill and Olson, 2008). And although it is widely held that there is physiological hypertrophy of cardiac myocytes as a result of pregnancy, this has never been absolutely proven. For example, in one study, Schannwell and associates (2002) performed serial echocardiographic examinations across pregnancy and postpartum in 46 healthy women and found a 34-percent greater left ventricular muscle mass index during late versus early pregnancy. These and earlier studies with similar findings were derived with echocardiography but have not been verified with the more precise techniques of magnetic resonance

imaging. Hibbard and colleagues (2009) concluded that any increased mass does not meet criteria for hypertrophy.

Cardiac Output

During normal pregnancy, mean arterial pressure and vascular resistance decrease, while blood volume and basal metabolic rate increase. As a result, cardiac output *at rest,* when measured in the lateral recumbent position, increases significantly beginning in early pregnancy (Duvekot and colleagues, 1993; Mabie and co-workers, 1994). It continues to increase and remains elevated during the remainder of pregnancy (Fig. 5-9).

During late pregnancy with the woman in the supine position, the large pregnant uterus rather consistently compresses venous return from the lower body. It also may compress the aorta (Bieniarz and associates, 1968). The results are that cardiac filling may be reduced with diminished cardiac output (see Fig. 5-7). Specifically, Bamber and Dresner (2003) found cardiac output at term to increase 1.2 L/min—almost 20 percent—when a woman was moved from her back onto her left side. Moreover, in the supine gravid patient, uterine blood flow estimated by Doppler velocimetry decreases by a third (Jeffreys and associates, 2006). Of note, Simpson and James (2005) found that fetal oxygen saturation is approximately 10 percent higher when a laboring woman is in a lateral recumbent position compared with supine. Upon standing, cardiac output falls to the same degree as in the nonpregnant woman (Easterling and associates, 1988).

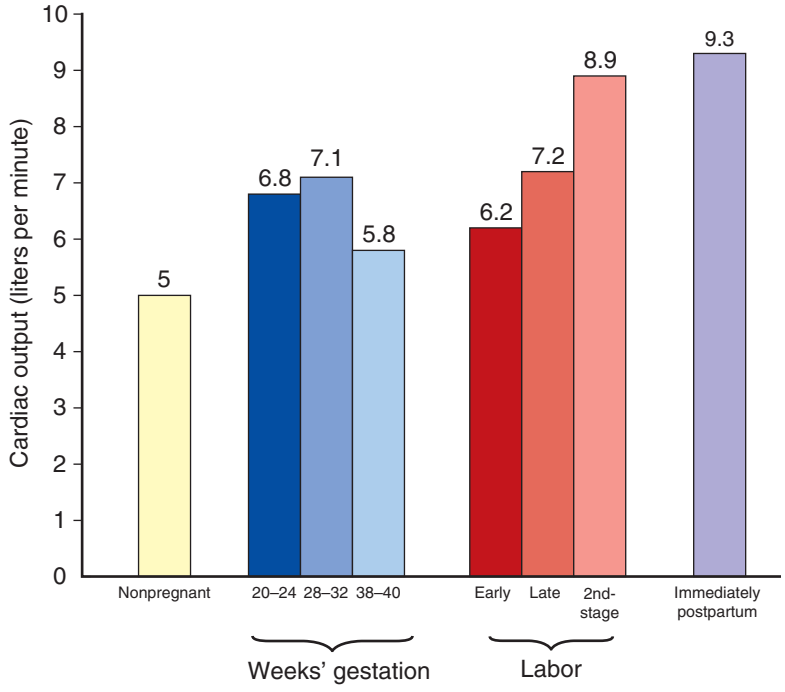

FIGURE 5-9 Cardiac output during three stages of gestation, labor, and immediately postpartum compared with values of nonpregnant women. All values were determined with women in the lateral recumbent position. (Adapted from Ueland and Metcalfe, 1975, with permission.)

In multifetal pregnancies, compared with singletons, maternal cardiac output is augmented further by another almost 20 percent because of a greater stroke volume (15 percent) and heart rate (3.5 percent). Left atrial diameter and left ventricular end-diastolic diameter are also increased due to augmented preload (Kametas and co-workers, 2003a). The increased heart rate and inotropic contractility imply that cardiovascular reserve is reduced in multifetal gestations.

During the first stage of labor, cardiac output increases moderately. During the second stage, with vigorous expulsive efforts, it is appreciably greater (see Fig. 5-9). The pregnancy-induced increase is lost after delivery, at times dependent on blood loss.

Hemodynamic Function in Late Pregnancy

To further elucidate the net changes of normal pregnancy-induced cardiovascular changes, Clark and colleagues (1989) conducted invasive studies to measure hemodynamic function late in pregnancy (Table 5-3). Right heart catheterization was performed in 10 healthy nulliparous women at 35 to 38 weeks, and again at 11 to 13 weeks postpartum. Late pregnancy was associated with the expected increases in heart rate, stroke volume, and cardiac output. Systemic vascular and pulmonary vascular resistance both decreased significantly, as did colloid osmotic pressure. Pulmonary capillary wedge pressure and central venous pressure did not change appreciably between late pregnancy and the puerperium. Thus, as shown in Figure 5-10, although cardiac output is increased, left ventricular function as measured by stroke work index remains similar to the nonpregnant normal range. Put another way, normal pregnancy is not a continuous "high-output" state.

Circulation and Blood Pressure

Changes in posture affect arterial blood pressure. Brachial artery pressure when sitting is lower than that when in the lateral recumbent supine position (Bamber and Dresner, 2003). Arterial pressure usually decreases to a nadir at 24 to 26 weeks and rises thereafter. Diastolic pressure decreases more than systolic (Fig. 5-11).

Antecubital venous pressure remains unchanged during pregnancy. However, in the supine position, femoral venous pressure rises steadily, from approximately 8 mm Hg early in pregnancy to 24 mm Hg at term. Wright and co-workers (1950) demonstrated that venous blood flow in the legs is retarded during pregnancy except when the lateral recumbent position is assumed. This tendency toward stagnation of blood in the lower extremities during the latter part of pregnancy is attributable to the occlusion of the pelvic veins and inferior vena cava by the enlarged uterus. The elevated venous pressure returns to normal when the pregnant woman lies on her side and immediately after delivery (McLennan, 1943). These alterations contribute to the dependent edema frequently experienced and to the development of varicose veins in the legs and vulva, as well as hemorrhoids. They also predispose to deep-venous thrombosis (see Chap. 47, p. 1019).

TABLE 5-3. Central Hemodynamic Changes in 10 Normal Nulliparous Women Near Term and Postpartum

	Pregnant[a] (35–38 wks)	Postpartum (11–13 wks)	Change[b]
Mean arterial pressure (mm Hg)	90 ± 6	86 ± 8	NSC
Pulmonary capillary wedge pressure (mm Hg)	8 ± 2	6 ± 2	NSC
Central venous pressure (mm Hg)	4 ± 3	4 ± 3	NSC
Heart rate (beats/min)	83 ± 10	71 ± 10	+17%
Cardiac output (L/min)	6.2 ± 1.0	4.3 ± 0.9	+43%
Systemic vascular resistance (dyne/sec/cm^{-5})	1210 ± 266	1530 ± 520	−21%
Pulmonary vascular resistance (dyne/sec/cm^{-5})	78 ± 22	119 ± 47	−34%
Serum colloid osmotic pressure (mm Hg)	18.0 ± 1.5	20.8 ± 1.0	−14%
COP-PCWP gradient (mm Hg)	10.5 ± 2.7	14.5 ± 2.5	−28%
Left ventricular stroke work index (g/m/m^2)	48 ± 6	41 ± 8	NSC

[a]Measured in lateral recumbent position.
[b]Changes significant unless NSC = no significant change.
COP = colloid osmotic pressure; PCWP = pulmonary capillary wedge pressure.

Supine Hypotension

In about 10 percent of women, supine compression of the great vessels by the uterus causes significant arterial hypotension, sometimes referred to as the *supine hypotensive syndrome* (Kinsella and Lohmann, 1994). Also when supine, uterine arterial pressure—and thus blood flow—is significantly lower than that in the brachial artery. As discussed in Chapter 18 (p. 432), this may directly affect fetal heart rate patterns (Tamás and colleagues, 2007). This also occurs with hemorrhage or with spinal analgesia (see Chap. 19, p. 452).

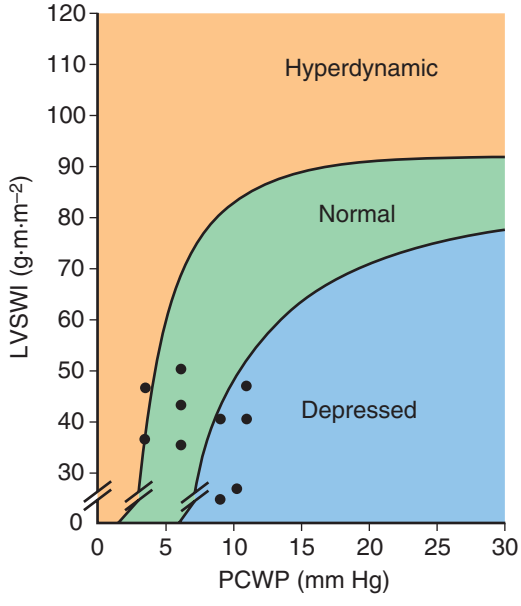

FIGURE 5-10 Relationship between left ventricular stroke work index (LVSWI) (cardiac output) and pulmonary capillary wedge pressure (PCWP) in 10 normal pregnant women in the third trimester. (Figure from Hauth and Cunningham, 1999; data from Clark and colleagues, 1989.)

Renin, Angiotensin II, and Plasma Volume

The renin-angiotensin-aldosterone axis is intimately involved in renal control of blood pressure via sodium and water balance. All components of this system are increased in normal pregnancy (Bentley-Lewis and co-workers, 2005). Renin is produced by both the maternal kidney and the placenta, and increased renin substrate (angiotensinogen) is produced by both maternal and fetal liver. This increase in angiotensinogen results, in part, from high levels of estrogen production during normal pregnancy. August and colleagues (1995) observed that stimulation of the renin-angiotensin system is important in first-trimester blood pressure maintenance.

Gant and associates (1973) studied vascular reactivity to angiotensin II throughout pregnancy. Nulliparas who remained

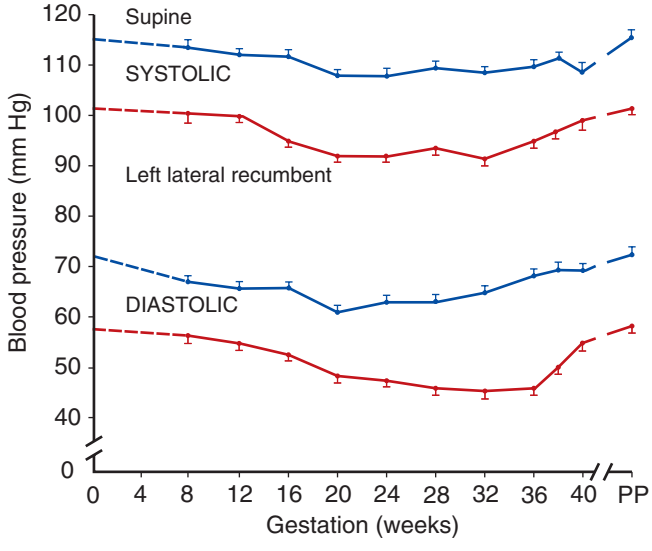

FIGURE 5-11 Sequential changes (±SEM) in blood pressure throughout pregnancy in 69 women in supine (*blue lines*) and left lateral recumbent positions (*red lines*). PP = postpartum. (Adapted from Wilson and colleagues, 1980.)

normotensive became and stayed refractory to the pressor effects of infused angiotensin II. Conversely, those who ultimately became hypertensive developed, but then lost, this refractoriness. Follow-up studies by Gant (1974) and Cunningham (1975) and their associates indicated that increased refractoriness to angiotensin II resulted from individual vessel refractoriness. Said another way, the abnormally increased sensitivity was an alteration in vessel wall refractoriness rather than the consequence of altered blood volume or renin-angiotensin secretion.

The vascular responsiveness to angiotensin II may be progesterone related. Normally, pregnant women lose their acquired vascular refractoriness to angiotensin II within 15 to 30 minutes after the placenta is delivered. Moreover, large amounts of intramuscular progesterone given during late labor delay this diminishing refractoriness. And although exogenous progesterone does not restore angiotensin II refractoriness to women with gestational hypertension, this can be done with infusion of its major metabolite—5α-dihydroprogesterone.

Cardiac Natriuretic Peptides

At least two species of these—*atrial natriuretic peptide (ANP)* and *B-type natriuretic peptide (BNP)*—are secreted by cardiomyocytes in response to chamber-wall stretching. These peptides regulate blood volume by provoking natriuresis, diuresis, and vascular smooth-muscle relaxation (Clerico and Emdin, 2004). In nonpregnant patients, levels of BNP as well as amino-terminal pro-brain natriuretic peptide—or Nt pro-BNP—may be useful in screening for depressed left ventricular systolic function and determining prognosis in chronic heart failure (Heidenreich and associates, 2004; Jarolim, 2006).

During normal pregnancy, plasma ANP levels are maintained in the nonpregnant range despite increased plasma volume (Lowe and co-workers, 1992). In one study, Resnik and co-workers (2005) found that median BNP levels are less than 20 pg/mL and are stable across normal pregnancy. However, these levels are increased in severe preeclampsia. Tihtonen and colleagues (2007) concluded that this resulted from cardiac strain caused by high afterload. It would appear that ANP-induced physiological adaptations participate in the expansion of extracellular fluid volume and the increase in plasma aldosterone concentrations characteristic of normal pregnancy.

A third species, *C-type natriuretic peptide (CNP),* is predominantly secreted by noncardiac tissues. Among its diverse biological functions, this peptide appears to be a major regulator of fetal bone growth. Walther and Stepan (2004) have provided a detailed review of its role during pregnancy.

Prostaglandins

Increased production of prostaglandins during pregnancy is thought to have a central role in control of vascular tone, blood pressure, and sodium balance (Gallery and Lindheimer, 1999). Renal medullary prostaglandin E_2 synthesis is increased markedly during late pregnancy and is presumed to be natriuretic. Prostacyclin (PGI_2), the principal prostaglandin of endothelium, also is increased during late pregnancy and regulates blood pressure and platelet function. It also has been implicated in the angiotensin resistance characteristic of normal pregnancy (Friedman, 1988). The ratio of PGI_2 to thromboxane in maternal urine and blood has been considered important in the pathogenesis of preeclampsia (see Chap. 34, p. 714).

Endothelin

There are a number of endothelins generated in pregnancy. Endothelin-1 is a potent vasoconstrictor produced in endothelial and vascular smooth muscle cells and regulates local vasomotor tone (Feletou and Vanhoutte, 2006). Its production is stimulated by angiotensin II, arginine vasopressin, and thrombin. Endothelins, in turn, stimulate secretion of ANP, aldosterone, and catecholamines. As discussed in Chapter 6 (p. 161), there are endothelin receptors in pregnant and nonpregnant myometrium. Endothelins also have been identified in the amnion, amnionic fluid, decidua, and placental tissue (Kubota and colleagues, 1992; Margarit and associates, 2005). Vascular sensitivity to endothelin-1 is not altered during normal pregnancy (Ajne and associates, 2005). These investigators postulated that vasodilating factors counterbalance the endothelin-1 vasoconstrictor effects and produce reduced peripheral vascular resistance.

Nitric Oxide

This potent vasodilator is released by endothelial cells and may have important implications for modifying vascular resistance during pregnancy (Seligman and colleagues, 1994). As discussed in Chapter 34 (p. 714), abnormal nitric oxide synthesis has been linked to the development of preeclampsia (Baksu, 2005; Savvidou, 2003; Teran, 2006, and all their colleagues).

RESPIRATORY TRACT

The diaphragm rises about 4 cm during pregnancy (see Fig. 5-8). The subcostal angle widens appreciably as the transverse diameter of the thoracic cage increases approximately 2 cm. The thoracic circumference increases about 6 cm, but not sufficiently to prevent a reduction in the residual lung volume created by the elevated diaphragm. Diaphragmatic excursion is actually greater in pregnant than in nonpregnant women.

Pulmonary Function

The respiratory rate is essentially unchanged, but *tidal volume* and *resting minute ventilation* increase significantly as pregnancy advances. In a study of 51 healthy pregnant women, Kolarzyk and co-workers, (2005) reported significantly increased mean tidal volume—0.66 to 0.8 L/min—and minute ventilation—10.7 to 14.1 L/min—compared with nonpregnant women. The increase in minute ventilation is caused by several factors including enhanced respiratory drive primarily due to the stimulatory effects of progesterone, low expiratory reserve volume, and compensated respiratory alkalosis (Wise and associates, 2006). These are discussed in more detail subsequently.

The *functional residual capacity* and the *residual volume* are decreased as a consequence of the elevated diaphragm (**Fig. 5-12**). *Peak expiratory flow rates* decline progressively as gestation advances (Harirah and associates, 2005). *Lung compliance* is unaffected by pregnancy, but *airway conductance* is increased and *total pulmonary resistance* reduced, possibly as a result of

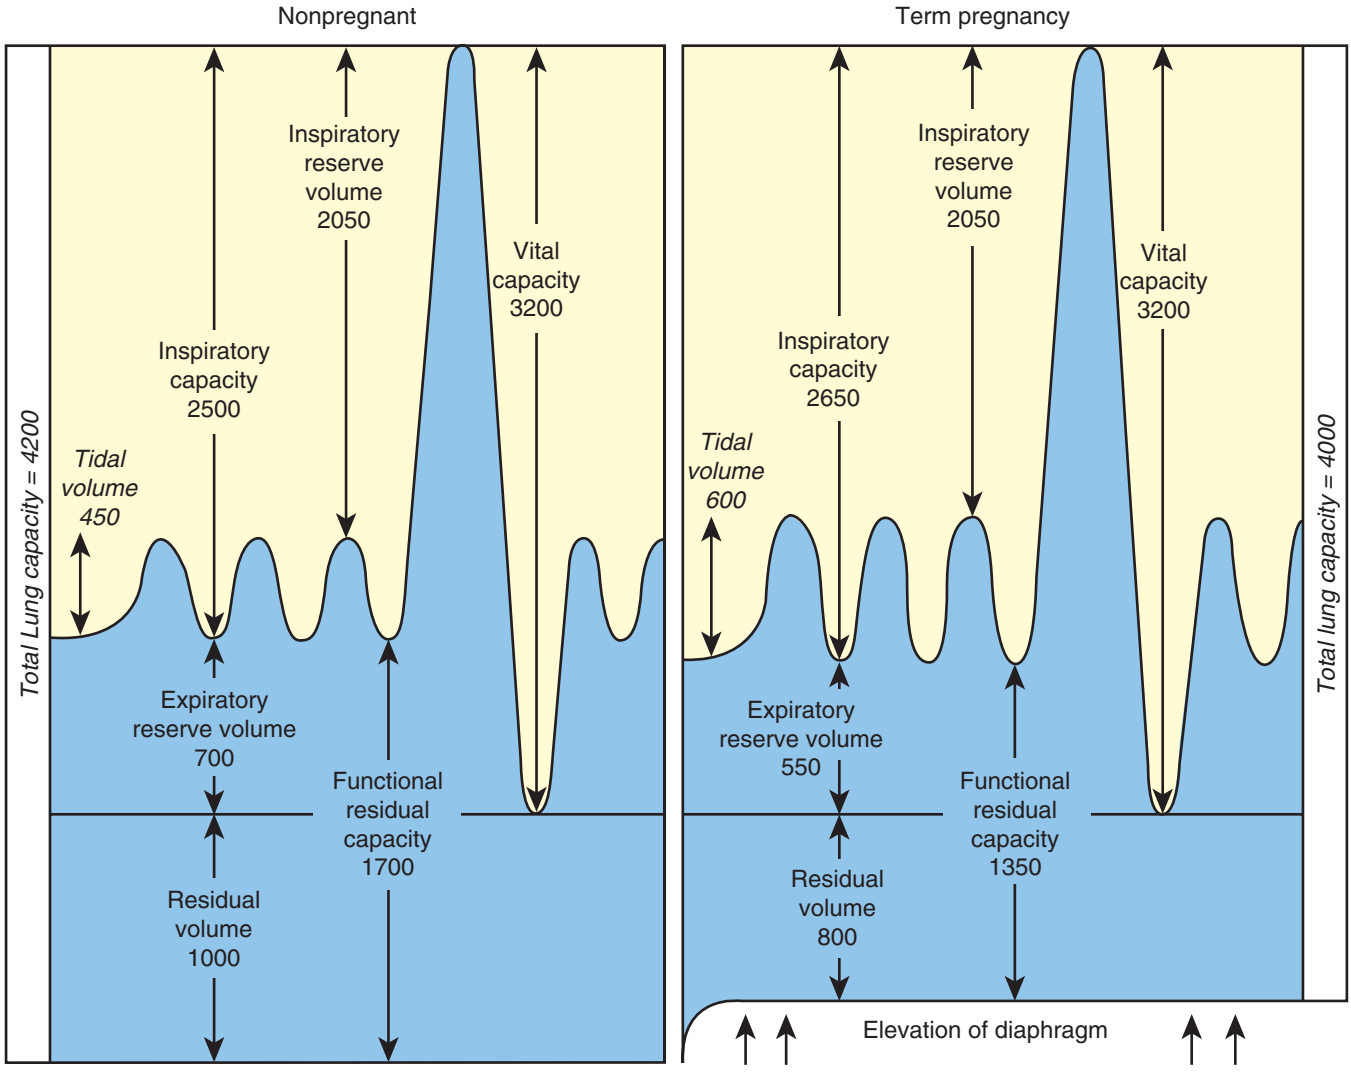

FIGURE 5-12 Changes in lung volumes during pregnancy. (Modified from Bonica, 1967, with permission.)

progesterone. The *maximum breathing capacity* and *forced* or *timed vital capacity* are not altered appreciably. It is unclear whether the critical *closing volume*—the lung volume at which airways in the dependent parts of the lung begin to close during expiration—is changed. It has been held that this is higher in pregnancy, but this is disputed (DeSwiet, 1991). The increased oxygen requirements and perhaps the increased critical closing volume imposed by pregnancy tend to make respiratory diseases more serious during gestation (see Chap. 46).

McAuliffe and associates (2002) compared pulmonary function in 140 women with a singleton pregnancy with that in 68 women with twins. They found no significant differences between the two groups.

Oxygen Delivery

The amount of oxygen delivered into the lungs by the increased tidal volume clearly exceeds oxygen requirements imposed by pregnancy. Moreover, the total hemoglobin mass, and in turn total oxygen-carrying capacity, increases appreciably during normal pregnancy, as does cardiac output. As a consequence, the *maternal arteriovenous oxygen* difference is decreased.

Acid–Base Equilibrium

An increased awareness of a desire to breathe is common even early in pregnancy (Milne and colleagues, 1978). This may be interpreted as dyspnea, which may suggest pulmonary or cardiac abnormalities when none exist. This physiological dyspnea is thought to result from increased tidal volume that lowers the blood P_{CO_2} slightly, which paradoxically causes dyspnea. The increased respiratory effort, and in turn the reduction in P_{CO_2}, during pregnancy is most likely induced in large part by progesterone and to a lesser degree by estrogen. Progesterone appears to act centrally, where it lowers the threshold and increases the sensitivity of the chemoreflex response to CO_2 (Jensen and associates, 2005).

To compensate for the resulting respiratory alkalosis, plasma bicarbonate levels decrease from 26 to approximately 22 mmol/L. Although blood pH is increased only minimally, it does shift the oxygen dissociation curve to the left. This shift increases the affinity of maternal hemoglobin for oxygen—the *Bohr effect*—thereby decreasing the oxygen-releasing capacity of maternal blood. This is offset because the slight pH increase also

stimulates an increase in 2,3-diphosphoglycerate in maternal erythrocytes. This shifts the curve back to the right (Tsai and de Leeuw, 1982). Thus, reduced P_{CO_2} from maternal hyperventilation aids carbon dioxide (waste) transfer from the fetus to the mother while also facilitating oxygen release to the fetus.

URINARY SYSTEM

Kidney

A remarkable number of changes are observed in the urinary system as a result of pregnancy (Table 5-4). *Kidney size* increases slightly. Using radiographs, Bailey and Rolleston (1971) reported that the kidney was 1.5 cm longer during the early puerperium compared with 6 months later. The *glomerular filtration rate (GFR)* and *renal plasma flow* increase early in pregnancy. The GFR increases as much as 25 percent by the second week after conception and 50 percent by the beginning of the second trimester. Renal plasma flow increases are even greater (Davison and Noble, 1981; Lindheimer and co-workers, 2001). Animal studies suggest that both relaxin and neuronal nitric oxide synthase may be important for mediating both increased glomerular filtration and plasma flow during pregnancy (Abram and colleagues, 2001; Conrad and associates, 2005). As shown in Figure 5-13, elevated glomerular filtration persists until term, even though renal plasma flow decreases during late pregnancy. Primarily as a consequence of this elevated GFR, approximately 60 percent of women report urinary frequency during pregnancy (Sanhu and associates, 2009).

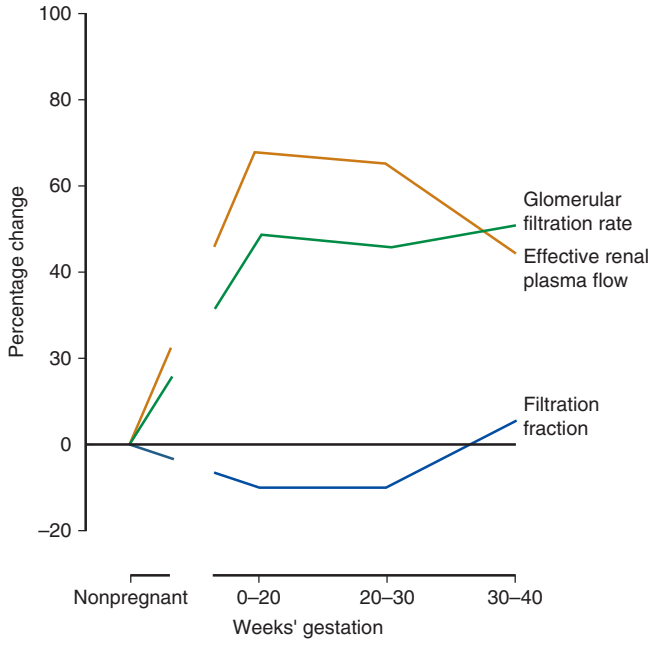

FIGURE 5-13 Relative changes in measures of glomerular filtration rate (GFR), effective renal plasma flow (ERPF), and filtration fraction during normal pregnancy. (Data from Davison and Dunlop, 1980, with permission.)

TABLE 5-4. Renal Changes in Normal Pregnancy

Alteration		Clinical Relevance
Kidney size	Approximately 1 cm longer on radiograph	Size returns to normal postpartum
Dilatation	Resembles hydronephrosis on sonogram or IVP (more marked on right)	Can be confused with obstructive uropathy; retained urine leads to collection errors; renal infections are more virulent; may be responsible for "distension syndrome"; elective pyelography should be deferred to at least 12 weeks postpartum
Renal function	Glomerular filtration rate and renal plasma flow increase ~50%	Serum creatinine decreases during normal gestation; >0.8 mg/dL (>72 μmol/L) creatinine already borderline; protein, amino acid, and glucose excretion all increase
Maintenance of acid-base	Decreased bicarbonate threshold; progesterone stimulates respiratory center	Serum bicarbonate decreased by 4–5 mEq/L; PCO_2 decreased 10 mm Hg; a PCO_2 of 40 mm Hg already represents CO_2 retention
Plasma osmolality	Osmoregulation altered: osmotic thresholds for AVP release and thirst decrease; hormonal disposal rates increase	Serum osmolality decreases 10 mOsm/L (serum Na ~5 mEq/L) during normal gestation; increased placental metabolism of AVP may cause transient diabetes insipidus during pregnancy

AVP = vasopressin; CO_2 = carbon dioxide; IVP = intravenous pyelography; PCO_2 = partial pressure carbon dioxide.
Modified from Lindheimer and colleagues (2000).

Kallikrein, a tissue protease synthesized in cells of the distal renal tubule, is increased in several conditions associated with increased glomerular perfusion in nonpregnant individuals. Platts and colleagues (2000) found increased urinary kallikrein excretion rates in women at 18 and 34 weeks, but excretion returned to nonpregnant levels by term. The significance of these fluctuations remains unknown.

As with blood pressure, maternal posture may have a considerable influence on several aspects of renal function. Late in pregnancy, for instance, urinary flow and sodium excretion average less than half the excretion rate in the supine position compared with that in the lateral recumbent position. The impact of posture on glomerular filtration and renal plasma flow is much more variable.

Loss of Nutrients

One unusual feature of the pregnancy-induced changes in renal excretion is the remarkably increased amounts of various nutrients lost in the urine. Amino acids and water-soluble vitamins are lost in the urine in much greater amounts in pregnancy (Hytten, 1973; Powers and associates, 2004).

Tests of Renal Function

The physiological changes in renal hemodynamics induced during normal pregnancy have several implications for the interpretation of tests of renal function (see Appendix). *Serum creatinine* levels decrease during normal pregnancy from a mean of 0.7 to 0.5 mg/dL. **Values of 0.9 mg/dL suggest underlying renal disease and should prompt further evaluation** (Lindheimer and associates, 2000). *Creatinine clearance* in pregnancy averages about 30 percent higher than the 100 to 115 mL/min in nonpregnant women (Lindheimer and associates, 2000).

Creatinine clearance is a useful test to estimate renal function provided that complete urine collection is made during an accurately timed period. If either is done incorrectly, results are misleading (Davison and colleagues, 1981). During the day, pregnant women tend to accumulate water as dependent edema, and at night, while recumbent, they mobilize this fluid with diuresis. This reversal of the usual nonpregnant diurnal pattern of urinary flow causes nocturia, and the urine is more dilute than in nonpregnant women. Failure of a pregnant woman to excrete concentrated urine after withholding fluids for approximately 18 hours does not necessarily signify renal damage. In fact, the kidney in these circumstances functions perfectly normally by excreting mobilized extracellular fluid of relatively low osmolality.

Urinalysis

Glucosuria during pregnancy may not be abnormal. The appreciable increase in glomerular filtration, together with impaired tubular reabsorptive capacity for filtered glucose, accounts in most cases for glucosuria (Davison and Hytten, 1974). For these reasons alone, Chesley (1963) calculated that about a sixth of pregnant women should spill glucose in the urine. That said, although common during pregnancy, the possibility of diabetes mellitus should not be ignored when glucosuria is identified.

Proteinuria normally is not evident during pregnancy except occasionally in slight amounts during or soon after vigorous labor. Higby and associates (1994) measured protein excretion in 270 normal women throughout pregnancy. Their mean 24-hour excretion was 115 mg, and the upper 95-percent confidence limit was 260 mg/day without significant differences by trimester (Fig. 5-14). These investigators also showed that albumin excretion is minimal and ranges from 5 to 30 mg/day. Nomograms for urinary microalbumin and creatinine ratios during uncomplicated pregnancies have been developed by Waugh and co-workers (2003).

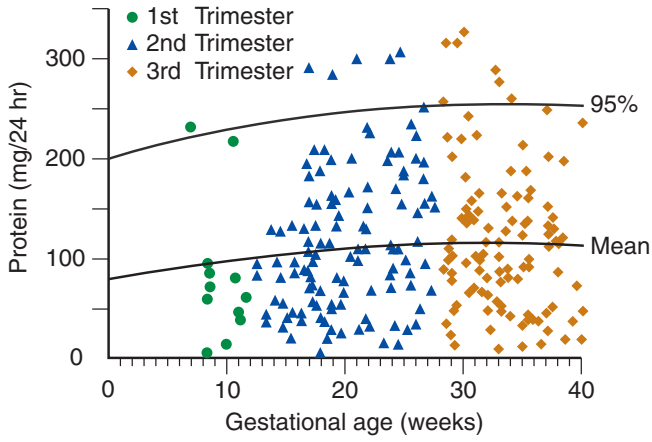

FIGURE 5-14 Scatter plot of all patients showing 24-hour urinary total protein excretion by gestational age. Mean and 95-percent confidence limits are outlined. (Data from Higby and colleagues, 1994, with permission.)

Hematuria is often the result of contamination during collection. If not, it most often suggests urinary tract disease as discussed in Chapter 48 (p. 1033). Hematuria is common after difficult labor and delivery because of trauma to the bladder and urethra.

Ureters

After the uterus rises completely out of the pelvis, it rests upon the ureters, laterally displacing and compressing them at the pelvic brim. This results in increased intraureteral tonus above this level (Rubi and Sala, 1968). Ureteral dilatation is impressive, and Schulman and Herlinger (1975) found it to be greater on the right side in 86 percent of women (Fig. 5-15). Unequal dilatation may result from a cushioning provided the left ureter by the sigmoid colon and perhaps from greater compression of the right ureter as the consequence of dextrorotation of the uterus. The right ovarian vein complex, which is remarkably dilated during pregnancy, lies obliquely over the right ureter and may contribute significantly to right ureteral dilatation.

Progesterone likely has some effect. Van Wagenen and Jenkins (1939) described continued ureteral dilatation after removal of the monkey fetus but with the placenta left in situ. However, the relatively abrupt onset of dilatation in women at midpregnancy seems more consistent with ureteral compression.

Ureteral elongation accompanies distention, and the ureter is frequently thrown into curves of varying size, the smaller of which may be sharply angulated. These so-called kinks are poorly named, because the term connotes obstruction. They are usually single or double curves, which when viewed in the radiograph taken in the same plane as the curve, may appear as acute angulations. Another exposure at right angles nearly always identifies them to be more gentle curves. Despite these anatomical changes, Semins and associates (2009) concluded, based upon their review of the literature, that complication

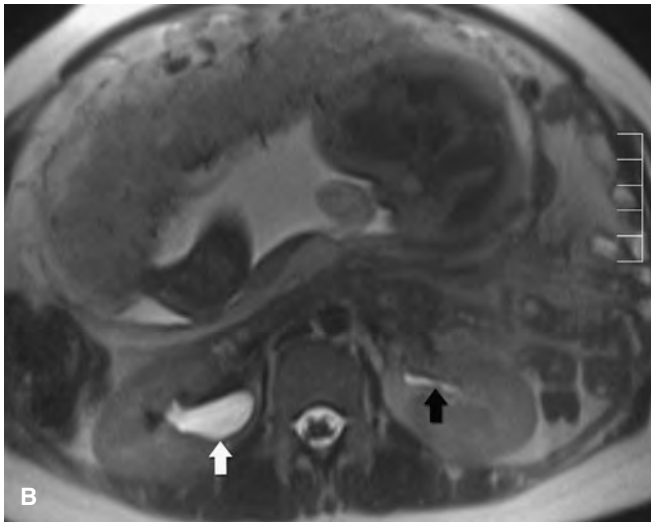

FIGURE 5-15 Hydronephrosis. **A.** Plain film from the 15-minute image of an intravenous pyelogram (IVP). Moderate hydronephrosis on the right (*arrows*) and mild hydronephrosis on the left (*arrowheads*) are both normal for this 35-week gestation. **B.** Axial MR image from a study performed for a fetal indication. Moderate hydronephrosis on the right (*white arrow*) and mild on the left (*black arrow*) are incidental findings.

rates associated with ureteroscopy in pregnant and nonpregnant patients do not differ significantly.

Bladder

There are few significant anatomical changes in the bladder before 12 weeks. From that time onward, however, increased uterine size, the hyperemia that affects all pelvic organs, and the hyperplasia of the bladder's muscle and connective tissues elevates the bladder trigone and causes thickening of its posterior, or intraureteric, margin. Continuation of this process to the end of pregnancy produces marked deepening and widening of the trigone. There are no mucosal changes other than an increase in the size and tortuosity of its blood vessels.

Using urethrocystometry, Iosif and colleagues (1980) reported that bladder pressure in primigravidas increased from 8 cm H_2O early in pregnancy to 20 cm H_2O at term. To compensate for reduced bladder capacity, absolute and functional urethral lengths increased by 6.7 and 4.8 mm, respectively. At the same time, maximal intraurethral pressure increased from 70 to 93 cm H_2O, and thus continence is maintained. Still, at least half of women experience some degree of urinary incontinence by the third trimester (van Brummen and colleagues, 2006; Wesnes and co-workers, 2009). Indeed, this is always considered in the differential diagnosis of ruptured membranes.

Toward the end of pregnancy, particularly in nulliparas in whom the presenting part often engages before labor, the entire base of the bladder is pushed forward and upward, converting the normal convex surface into a concavity. As a result, difficulties in diagnostic and therapeutic procedures are greatly increased. In addition, the pressure of the presenting part impairs the drainage of blood and lymph from the bladder base, often rendering the area edematous, easily traumatized, and probably more susceptible to infection.

GASTROINTESTINAL TRACT

As pregnancy progresses, the stomach and intestines are displaced by the enlarging uterus. Consequently, the physical findings in certain diseases are altered. The appendix, for instance, is usually displaced upward and somewhat laterally as the uterus enlarges. At times, it may reach the right flank.

Gastric emptying time, studied using acetaminophen absorption techniques, appears to be unchanged during each trimester and during comparison with nonpregnant women (Macfie and colleagues, 1991; Wong and associates, 2002, 2007). During labor, however, and especially after administration of analgesic agents, gastric emptying time may be prolonged appreciably. As a result, a major danger of general anesthesia for delivery is regurgitation and aspiration of either food-laden or highly acidic gastric contents (see Chap. 19, p. 459).

Pyrosis (heartburn) is common during pregnancy and is most likely caused by reflux of acidic secretions into the lower esophagus (see Chap. 49, p. 1052). Although the altered position of the stomach probably contributes to its frequent occurrence, lower esophageal sphincter tone also is decreased. In addition, intraesophageal pressures are lower and intragastric pressures higher in pregnant women. At the same time, esophageal peristalsis has lower wave speed and lower amplitude (Ulmsten and Sundström, 1978).

The gums may become hyperemic and softened during pregnancy and may bleed when mildly traumatized, as with a toothbrush. A focal, highly vascular swelling of the gums, the so-called *epulis* of pregnancy, develops occasionally but typically regresses spontaneously after delivery. Most evidence indicates that pregnancy does not incite tooth decay.

Hemorrhoids are fairly common during pregnancy. They are caused in large measure by constipation and elevated pressure in veins below the level of the enlarged uterus (see Fig. 2-7, p. 21).

Liver

Unlike in some animals, there is no increase in liver size during human pregnancy (Combes and Adams, 1971). Hepatic blood flow, however, increases substantively as does the diameter of the portal vein (Clapp and colleagues, 2000). Histological evaluation of liver biopsies, including examination with the electron microscope, has shown no distinct morphological changes in normal pregnant women (Ingerslev and Teilum, 1946).

Some laboratory test results of hepatic function are altered during normal pregnancy, and some would be considered abnormal for nonpregnant patients. Total *alkaline phosphatase* activity almost doubles, but much of the increase is attributable to heat-stable placental alkaline phosphatase isozymes. Serum aspartate transaminase (AST), alanine transaminase (ALT), γ-glutamyl transferase (GGT), and bilirubin levels are slightly lower compared with nonpregnant values (Girling and colleagues, 1997; Ruiz-Extremera and associates, 2005).

The concentration of serum albumin decreases during pregnancy. By late pregnancy, albumin concentrations may be near 3.0 g/dL compared with approximately 4.3 g/dL in nonpregnant women (Mendenhall, 1970). Total albumin is increased, however, because of a greater volume of distribution from plasma volume increase. There is also a slight increase in serum globulin levels.

Leucine aminopeptidase is a proteolytic liver enzyme whose serum levels may be increased with liver disease. Its activity is markedly elevated in pregnant women. The increase, however, results from the appearance of a pregnancy-specific enzyme(s) with distinct substrate specificities (Song and Kappas, 1968). Pregnancy-induced aminopeptidase has oxytocinase and vasopressinase activity which occasionally causes transient diabetes insipidus (see Chap. 53, p. 1139).

Gallbladder

During normal pregnancy, the contractility of the gallbladder is reduced, leading to an increased residual volume (Braverman and co-workers, 1980). This may be because progesterone impairs gallbladder contraction by inhibiting cholecystokinin-mediated smooth muscle stimulation, which is the primary regulator of gallbladder contraction. Impaired emptying leads to stasis, which associated with increased bile cholesterol saturation of pregnancy, contributes to the increased prevalence of cholesterol gallstones in multiparous women.

The effects of pregnancy on maternal bile acid serum concentrations have been incompletely characterized despite the long-acknowledged propensity for pregnancy to cause intrahepatic cholestasis and pruritus gravidarum from retained bile salts. Intrahepatic cholestasis has been linked to high circulating levels of estrogen, which inhibit intraductal transport of bile acids (Simon and colleagues, 1996). In addition, increased progesterone and genetic factors have been implicated in the pathogenesis (Lammert and associates, 2000). Cholestasis of pregnancy is described in greater detail in Chapter 50 (p. 1073).

ENDOCRINE SYSTEM

Some of the most important endocrine changes of pregnancy are discussed elsewhere, especially in Chapter 3.

Pituitary Gland

During normal pregnancy, the pituitary gland enlarges by approximately 135 percent (Gonzalez and colleagues, 1988). Although it has been suggested that the increase may be sufficient to compress the optic chiasma and reduce visual fields, impaired vision due to physiological pituitary enlargement during normal pregnancy is rare (Inoue and associates, 2007). Scheithauer and colleagues (1990) have provided evidence that the incidence of pituitary prolactinomas is not increased during pregnancy. When these tumors are large before pregnancy—a macroadenoma is 10 mm or greater—then enlargement during pregnancy is more likely (see Chap. 53, p. 1139).

The maternal pituitary gland is not essential for maintenance of pregnancy. Many women have undergone hypophysectomy, completed pregnancy successfully, and undergone spontaneous labor while receiving glucocorticoids along with thyroid hormone and vasopressin.

Growth Hormone

During the first trimester, growth hormone is secreted predominantly from the maternal pituitary gland, and concentrations in serum and amnionic fluid are within nonpregnant values of 0.5 to 7.5 ng/mL (Kletzky and associates, 1985). As early as 8 weeks, growth hormone secreted from the placenta becomes detectable (Lønberg and co-workers, 2003). By approximately 17 weeks, the placenta is the principal source of growth hormone secretion (Obuobie and co-workers, 2001). Maternal serum values increase slowly from approximately 3.5 ng/mL at 10 weeks to plateau after 28 weeks at approximately 14 ng/mL. Growth hormone in amnionic fluid peaks at 14 to 15 weeks and slowly declines thereafter to reach baseline values after 36 weeks.

Placental growth hormone—which differs from pituitary growth hormone by 13 amino acid residues—is secreted by syncytiotrophoblasts in a nonpulsatile fashion (Fuglsang and coworkers, 2006). The regulation and physiological effects of placental growth hormone are incompletely understood, but it appears to have some influence on fetal growth as well as the development of preeclampsia (Mittal and co-workers, 2007). For example, placental growth hormone is a major determinant of maternal insulin resistance after midpregnancy. And maternal serum levels correlate positively with birthweight, and negatively with fetal-growth restriction and uterine artery resistance (Chellakooty and colleagues, 2004; Schiessl and associates, 2007). That said, fetal growth still progresses in the complete absence of placental growth hormone. Freemark (2006) concluded that the hormone, although not absolutely essential, may act in concert with human placental lactogen and other somatolactogens to regulate fetal growth.

Prolactin

Maternal plasma levels of prolactin increase markedly during normal pregnancy and concentrations are usually 10-fold greater at

term—about 150 ng/mL—compared with nonpregnant women. Paradoxically, plasma concentrations decrease after delivery even in women who are breast feeding. During early lactation, there are pulsatile bursts of prolactin secretion in response to suckling.

The physiological basis of the marked increase in prolactin prior to parturition is still unclear. What is known is that estrogen stimulation increases the number of anterior pituitary lactotrophs and may stimulate their release of prolactin (Andersen, 1982). Thyroid-releasing hormone also acts to cause an increased prolactin level in pregnant compared with nonpregnant women, but the response decreases as pregnancy advances (Miyamoto, 1984). Serotonin also is believed to increase prolactin, and dopamine—previously known as prolactin-inhibiting factor—inhibits its secretion.

The principal function of maternal prolactin is to ensure lactation. Early in pregnancy, prolactin acts to initiate DNA synthesis and mitosis of glandular epithelial cells and presecretory alveolar cells of the breast. Prolactin also increases the number of estrogen and prolactin receptors in these cells. Finally, prolactin promotes mammary alveolar cell RNA synthesis, galactopoiesis, and production of casein, lactalbumin, lactose, and lipids (Andersen, 1982). A woman with isolated prolactin deficiency described by Kauppila and co-workers (1987) failed to lactate after two pregnancies, thus establishing prolactin as a requisite for lactation but not for pregnancy.

Prolactin is present in amnionic fluid in high concentrations. Levels of up to 10,000 ng/mL are found at 20 to 26 weeks. Thereafter, levels decrease and reach a nadir after 34 weeks. There is convincing evidence that the uterine decidua is the site of prolactin synthesis found in amnionic fluid (see Chap. 3, p. 46). Although the exact function of amnionic fluid prolactin is not known, it has been suggested that this prolactin impairs water transfer from the fetus into the maternal compartment, thus preventing fetal dehydration.

Thyroid Gland

Physiological changes of pregnancy cause the thyroid gland to increase production of thyroid hormones by 40 to 100 percent to meet maternal and fetal needs (Smallridge and associates, 2005). To accomplish this, there are a number of pregnancy-induced changes that are documented.

Anatomically, the thyroid gland undergoes moderate enlargement during pregnancy caused by glandular hyperplasia and increased vascularity. Glinoer and colleagues (1990) reported that mean thyroid volume increased from 12 mL in the first trimester to 15 mL at delivery. Total volume was inversely proportional to serum thyrotropin concentrations. Such enlargement is not pathological, but normal pregnancy does not typically cause significant thyromegaly. Thus, any goiter should be investigated.

A number of alterations in thyroid physiology and function during pregnancy are detailed in **Figure 5-16**. Beginning early in the first trimester, levels of the principal carrier protein—*thyroxine-binding globulin*—increases, reaches its zenith at about 20 weeks, and stabilizes at approximately double baseline values for the remainder of pregnancy. *Total serum thyroxine (T_4)* increases sharply beginning between 6 and 9 weeks and reaches a plateau at 18 weeks. *Free serum T_4* levels rise slightly

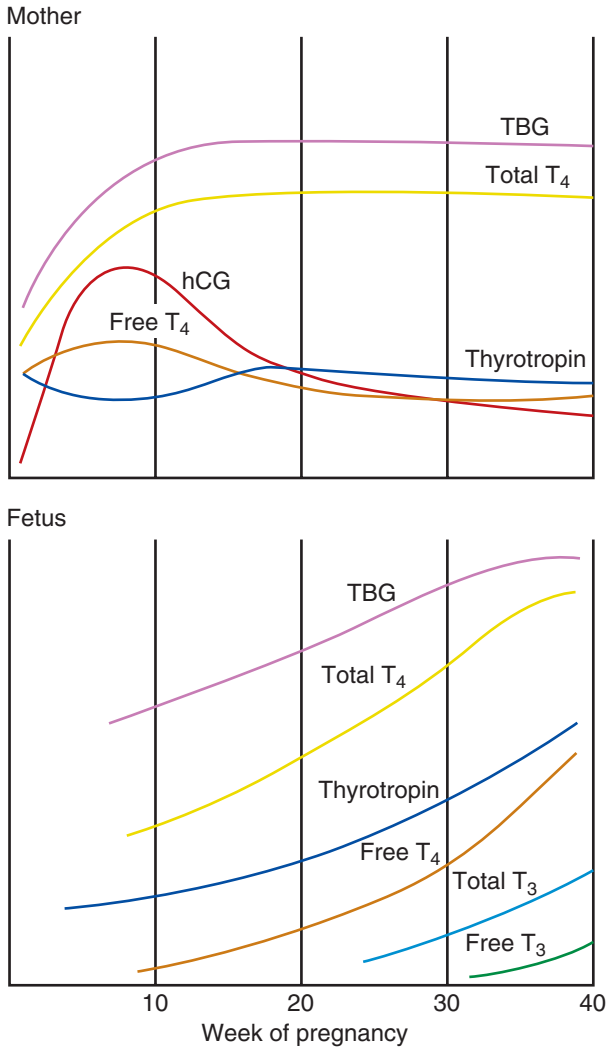

FIGURE 5-16 Relative changes in maternal thyroid function during pregnancy. Maternal changes include a marked and early increase in hepatic production of thyroxine-binding globulin (TBG) and placental production of chorionic gonadotropin (hCG). Increased thyroxine-binding globulin increases serum thyroxine (T_4) concentrations, and chorionic gonadotropin has thyrotropin-like activity and stimulates maternal T_4 secretion. The transient hCG-induced increase in serum T_4 levels inhibits maternal secretion of thyrotropin. Except for minimally increased free T_4 levels when hCG peaks, these levels are essentially unchanged. (T_3 = triiodothyronine.) (Modified from Burrow and colleagues, 1994.)

and peak along with hCG levels, and then they return to normal. The rise in *total triiodothyronine (T_3)* is more pronounced up to 18 weeks, and thereafter, it plateaus. *Thyroid-releasing hormone (TRH)* levels are not increased during normal pregnancy, but this neurotransmitter does cross the placenta and may serve to stimulate the fetal pituitary to secrete thyrotropin (Thorpe-Beeston and associates, 1991).

Interestingly, the secretion of T_4 and T_3 is not similar for all pregnant women (Glinoer and associates, 1990). Approximately a third of women experience relative hypothyroxinemia, preferential T_3 secretion, and higher, albeit normal, serum thyrotropin levels. Thus, there may be considerable variability in thyroidal adjustments during normal pregnancy.

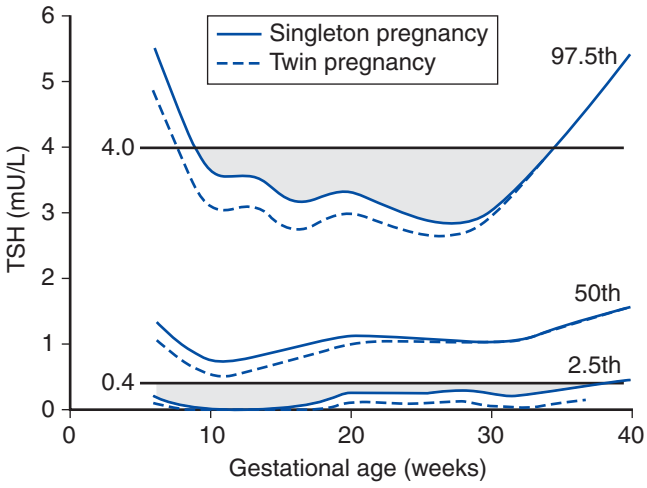

FIGURE 5-17 Gestational age-specific TSH nomogram derived from 13,599 singleton and 132 twin pregnancies. Singleton pregnancies are represented with solid blue lines and twin pregnancies with dashed lines. The nonpregnant reference values of 4.0 and 0.4 mU/L are represented as solid black lines. Upper shaded area represents the 28 percent of singleton pregnancies with TSH values above the 97.5th percentile threshold that would not have been identified as abnormal based on the assay reference value of 4.0 mU/L. Lower shaded area represents singleton pregnancies that would have been (falsely) identified as having TSH suppression based on the assay reference value of 0.4 mU/L. (From Dashe and colleagues, 2005, with permission.)

The modifications in serum *thyrotropin*—known also as thyroid-stimulating hormone (TSH)—and chorionic gonadotropin (hCG) as a function of gestational age also are shown in Figure 5-16. As discussed in Chapter 3 (p. 63), the α-subunits of the two glycoproteins are identical, whereas the β-subunits, although similar, differ in their amino acid sequence. As a result of this structural similarity, hCG has intrinsic thyrotropic activity, and thus, high serum levels cause thyroid stimulation. Indeed, thyrotropin levels decrease in more than 80 percent of pregnant women, whereas they remain in the normal range for nonpregnant women (see p. 1126).

As shown in **Figure 5-17**, normal suppression of TSH during pregnancy may lead to a misdiagnosis of subclinical hyperthyroidism. Of greater concern is the potential failure to identify women with early hypothyroidism because of suppressed TSH concentrations. To mitigate the likelihood of such misdiagnoses, Dashe and co-workers (2005) conducted a population-based study at Parkland Hospital to develop gestational-age-specific TSH nomograms for both singleton and twin pregnancies.

These complex alterations of thyroid regulation do not appear to alter maternal thyroid status as measured by metabolic studies. Although basal metabolic rate increases progressively during normal pregnancy by as much as 25 percent, most of this increase in oxygen consumption can be attributed to fetal metabolic activity. If fetal body surface area is considered along with that of the mother, the predicted and observed basal metabolic rates are similar to those in nonpregnant women. Fetal thyroid physiology is discussed in Chapter 4 (p. 97).

Parathyroid Glands

The regulation of calcium concentration is closely interrelated to magnesium, phosphate, parathyroid hormone, vitamin D, and calcitonin physiology. Any alteration of one of these factors is likely to change the others. In a longitudinal investigation of 20 women, More and associates (2003) found that all markers of bone turnover increased during normal pregnancy and failed to reach baseline level by 12 months postpartum. They concluded that the calcium needed for fetal growth and lactation may be drawn at least in part from the maternal skeleton.

Parathyroid Hormone and Calcium

Acute or chronic decreases in plasma calcium or acute decreases in magnesium stimulate the release of parathyroid hormone, whereas increases in calcium and magnesium suppress parathyroid hormone levels. The action of this hormone on bone resorption, intestinal absorption, and kidney reabsorption is to increase extracellular fluid calcium and decrease phosphate.

Parathyroid hormone plasma concentrations decrease during the first trimester and then increase progressively throughout the remainder of pregnancy (Pitkin and associates, 1979). Increased levels likely result from the lower calcium concentration in the pregnant woman. As discussed earlier, this is the result of increased plasma volume, increased glomerular filtration rate, and maternal-fetal transfer of calcium. Ionized calcium is decreased only slightly, and Reitz and co-workers (1977) suggest that during pregnancy a new "set point" is established for ionized calcium and parathyroid hormone. Estrogens also appear to block the action of parathyroid hormone on bone resorption, resulting in another mechanism to increase parathyroid hormone during pregnancy. The net result of these actions is a *physiological hyperparathyroidism* of pregnancy, likely to supply the fetus with adequate calcium.

Calcitonin and Calcium

The calcitonin-secreting C cells are derived embryologically from the neural crest and are located predominantly in the perifollicular areas of the thyroid gland. Calcium and magnesium increase the biosynthesis and secretion of calcitonin. Various gastric hormones—gastrin, pentagastrin, glucagon, and pancreozymin—and food ingestion also increase calcitonin plasma levels.

The known actions of calcitonin generally are considered to oppose those of parathyroid hormone and vitamin D to protect skeletal calcification during times of calcium stress. Pregnancy and lactation cause profound calcium stress, and during these times, calcitonin levels are appreciably higher than those in nonpregnant women (Weiss and co-workers, 1998).

Vitamin D and Calcium

After its ingestion or synthesis in the skin, vitamin D is converted by the liver into 25-hydroxyvitamin D_3. This form then is converted in the kidney, decidua, and placenta to 1,25-dihydroxyvitamin D_3, serum levels of which are increased during normal pregnancy (Weisman and co-workers, 1979; Whitehead and associates, 1981). Most likely this form is the biologically active compound, and it stimulates resorption of calcium from bone and absorption from the intestines. Although its control is unclear, the conversion of 25-hydroxyvitamin D_3 to 1,25-dihydroxyvitamin D_3 is

facilitated by parathyroid hormone and by low calcium and phosphate plasma levels and is opposed by calcitonin.

Adrenal Glands

In normal pregnancy, the maternal adrenal glands undergo little, if any, morphological change.

Cortisol

The serum concentration of circulating cortisol is increased, but much of it is bound by *transcortin*, the cortisol-binding globulin. The rate of adrenal cortisol secretion is not increased, and probably it is decreased compared with that of the nonpregnant state. The metabolic clearance rate of cortisol, however, is lower during pregnancy because its half-life is nearly doubled over that for nonpregnant women (Migeon and associates, 1957). Administration of estrogen, including most oral contraceptives, causes changes in serum cortisol levels and transcortin similar to those of pregnancy.

During early pregnancy, the levels of circulating corticotropin (ACTH) are reduced strikingly. As pregnancy progresses, the levels of ACTH and free cortisol rise (Fig. 5-18). This apparent paradox is not understood completely. Nolten and Rueckert (1981) have presented evidence that the higher free cortisol levels observed in pregnancy are the result of a "resetting" of the maternal feedback mechanism to higher levels. They further propose that this might result from *tissue refractoriness* to cortisol. Keller-Wood and Wood (2001) later suggested that these incongruities may result from an antagonistic action of progesterone on mineralocorticoids. Thus, in response to elevated progesterone levels during pregnancy, an elevated free cortisol is needed to maintain homeostasis. Indeed, experiments in pregnant ewes demonstrate that elevated maternal cortisol and aldosterone secretion are necessary to maintain the normal increase in plasma volume during late pregnancy (Jensen and associates, 2002).

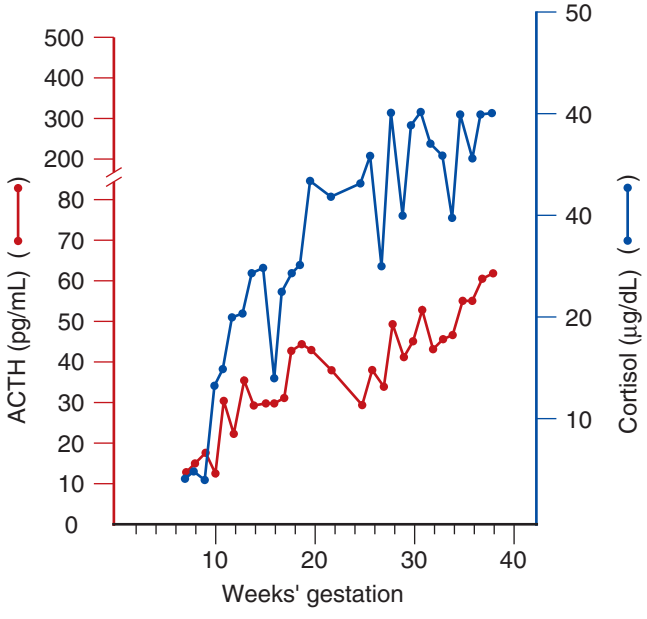

FIGURE 5-18 Serial increases in serum cortisol (*blue line*) and ACTH (*red line*) during pregnancy in normal controls throughout pregnancy. (From Carr and co-workers, 1981, with permission.)

Aldosterone

As early as 15 weeks, the maternal adrenal glands secrete considerably increased amounts of aldosterone. By the third trimester, about 1 mg/day is secreted. If sodium intake is restricted, aldosterone secretion is elevated even further (Watanabe and co-workers, 1963). At the same time, levels of renin and angiotensin II substrate normally are increased, especially during the latter half of pregnancy. This scenario gives rise to increased plasma levels of angiotensin II, which by acting on the zona glomerulosa of the maternal adrenal glands, accounts for the markedly elevated aldosterone secretion. It has been suggested that the increased aldosterone secretion during normal pregnancy affords protection against the natriuretic effect of progesterone and atrial natriuretic peptide.

Deoxycorticosterone

Maternal plasma levels of this potent mineralocorticosteroid progressively increase during pregnancy. Indeed, plasma levels of deoxycorticosterone rise to near 1500 pg/mL by term, a more than 15-fold increase (Parker and associates, 1980). This marked elevation is not derived from adrenal secretion but instead represents increased kidney production resulting from estrogen stimulation. The levels of deoxycorticosterone and its sulfate in fetal blood are appreciably higher than those in maternal blood, which suggests transfer of fetal deoxycorticosterone into the maternal compartment.

Dehydroepiandrosterone Sulfate

Maternal serum and urine levels of *dehydroepiandrosterone sulfate* are decreased during normal pregnancy. As discussed in Chapter 3 (p. 68), this is a consequence of increased metabolic clearance through extensive maternal hepatic 16α-hydroxylation and placental conversion to estrogen.

Androstenedione and Testosterone

Maternal plasma levels of both of these androgens are increased during pregnancy. This finding is not totally explained by alterations in their metabolic clearance. Maternal plasma androstenedione and testosterone are converted to estradiol in the placenta, which increases their clearance rates. Conversely, increased plasma sex hormone-binding globulin in pregnant women retards testosterone clearance. Thus, the production rates of maternal testosterone and androstenedione during human pregnancy are increased. The source of this increased C_{19}-steroid production is unknown, but it likely originates in the ovary. Interestingly, little or no testosterone in maternal plasma enters the fetal circulation as testosterone. Even when massive testosterone levels are found in the circulation of pregnant women, as with androgen-secreting tumors, testosterone levels in umbilical cord blood are likely to be undetectable and are the result of the near complete trophoblastic conversion of testosterone to 17β-estradiol (Edman and associates, 1979).

OTHER SYSTEMS

Musculoskeletal System

Progressive lordosis is a characteristic feature of normal pregnancy. Compensating for the anterior position of the enlarging

uterus, the lordosis shifts the center of gravity back over the lower extremities. In a recent and interesting anthropological study, Whitcome and colleagues (2007) demonstrated that this curvature and reinforcement of the lumbar vertebrae have evolved in humans to permit bipedal posture and locomotion despite up to a 31-percent increase in the maternal abdominal mass by term.

The sacroiliac, sacrococcygeal, and pubic joints have increased mobility during pregnancy. As discussed earlier (p. 110), the increase in joint laxity during pregnancy does not correlate with increased maternal serum levels of estradiol, progesterone, or relaxin (Marnach and co-workers, 2003). Joint mobility may contribute to the alteration of maternal posture and in turn may cause discomfort in the lower back. This is especially bothersome late in pregnancy, during which time aching, numbness, and weakness also occasionally are experienced in the upper extremities. This may result from the marked lordosis with anterior neck flexion and slumping of the shoulder girdle, which in turn produce traction on the ulnar and median nerves (Crisp and DeFrancesco, 1964).

The bones and ligaments of the pelvis undergo remarkable adaptation during pregnancy. In 1934, Abramson and colleagues described the normal relaxation of the pelvic joints, and particularly the symphysis pubis, that occurs during pregnancy (**Fig. 5-19**). They reported that most relaxation takes place in the first half of pregnancy. However, pelvic dimensions measured by magnetic resonance imaging are not significantly different before compared with up to 3 months after delivery (Huerta-Enochian and associates, 2006).

Although some symphyseal separation likely accompanies many deliveries, those greater than 1 cm may cause significant pain (Jain and Sternberg, 2005). Regression begins immediately following delivery, and it is usually complete within 3 to 5 months.

Eyes

Intraocular pressure decreases during pregnancy, attributed in part to increased vitreous outflow (Sunness, 1988). Corneal sensitivity is decreased, and the greatest changes are late in gestation. Most pregnant women demonstrate a measurable but slight increase in corneal thickness, thought to be due to edema. Consequently, they may have difficulty with previously comfortable contact lenses. Brownish-red opacities on the posterior surface of the cornea—*Krukenberg spindles*—have also been observed with a higher than expected frequency during pregnancy. Hormonal effects similar to those observed for skin lesions are postulated to cause this increased pigmentation. Other than transient loss of accommodation reported with both pregnancy and lactation, visual function is unaffected by pregnancy. These changes during pregnancy, as well as pathological eye aberrations, were reviewed by Dinn and colleagues (2003).

Central Nervous System

Women often report problems with attention, concentration, and memory throughout pregnancy and the early postpartum period. Systematic studies of memory in pregnancy, however, are limited and often anecdotal. Keenan and colleagues (1998) longitudinally investigated memory in pregnant women as well as a matched control group. They found pregnancy-related memory decline, which was limited to the third trimester. This decline was not attributable to depression, anxiety, sleep deprivation, or other physical changes associated with pregnancy. It was transient and quickly resolved following delivery. Interestingly, Rana and associates (2006) found that attention and memory were improved in women with preeclampsia receiving magnesium sulfate compared with normal pregnant women.

Zeeman and co-workers (2003) used magnetic resonance imaging to measure cerebral blood flow across pregnancy in 10 healthy women. They found that mean blood flow in the middle and posterior cerebral arteries decreased progressively from 147 and 56 mL/min when nonpregnant to 118 and 44 mL/min late in the third trimester, respectively. The mechanism and clinical significance of this decrease is unknown. Pregnancy does not appear to impact cerebrovascular autoregulation (Bergersen and co-workers, 2006).

Sleep

Beginning as early as about 12 weeks and extending through the first 2 months postpartum, women have difficulty going to sleep, frequent awakenings, fewer hours of night sleep, and reduced sleep efficiency (Lee and colleagues, 2000; Swain and colleagues, 1997). The frequency and duration of sleep apnea episodes were reported to be decreased significantly in pregnant women compared with those postpartum (Trakada and coworkers, 2003). In the supine position, however, average PaO_2 levels were lower. The greatest disruption of sleep is encountered postpartum and may contribute to *postpartum blues* or to frank depression (see Chap. 55, p. 1176).

CHAPTER 6

Parturition

PHASES OF PARTURITION 136
PHYSIOLOGICAL AND BIOCHEMICAL PROCESSES REGULATING PARTURITION 147
PHYSIOLOGY AND BIOCHEMISTRY OF PRETERM LABOR 162

The last few hours of human pregnancy are characterized by uterine contractions that effect cervical dilatation and cause the fetus to descend through the birth canal. Long before these forceful, painful contractions, there are extensive preparations in both the uterus and cervix, and these progress throughout gestation. During the first 36 to 38 weeks of normal gestation, the myometrium is in a preparatory yet unresponsive state. Concurrently, the cervix begins an early stage of remodeling termed *softening*, yet maintains structural integrity. Following this prolonged uterine quiescence, there is a transitional phase during which myometrial unresponsiveness is suspended, and the cervix undergoes ripening, effacement, and loss of structural integrity.

The physiological processes that regulate parturition and the onset of labor continue to be defined. It is clear, however, that labor onset represents the culmination of a series of biochemical changes in the uterus and cervix. These result from endocrine and paracrine signals emanating from both mother and fetus. Their relative contributions vary between species, and it is these differences that complicate elucidation of the exact factors that regulate human parturition. When parturition is abnormal, preterm labor, dystocia, or postterm pregnancy may result. Of these, preterm labor remains the major contributor to neonatal mortality and morbidity in developed countries (see Chap. 36, p. 804).

PHASES OF PARTURITION

Parturition, the bringing forth of young, requires multiple transformations in both uterine and cervical function. As shown in **Figure 6-1**, parturition can be arbitrarily divided into four overlapping phases that correspond to the major physiological transitions of the myometrium and cervix during pregnancy (Casey and MacDonald, 1993, 1997; Challis and associates, 2000; Word and colleagues, 2007). These phases of parturition include: (1) a prelude to—first phase; (2) the preparation for—second phase; (3) the process of—third phase; and (4) recovery from—fourth phase. Importantly, the *phases of parturition* should not be confused with the *clinical stages of labor,* that is, the first, second, and third stages—which comprise the third phase of parturition (**Fig. 6-2**).

Phase 1 of Parturition: Uterine Quiescence and Cervical Softening

Uterine Quiescence

Beginning even before implantation, a remarkably effective period of myometrial quiescence is imposed. This phase normally comprises 95 percent of pregnancy and is characterized by uterine smooth muscle tranquility with maintenance of cervical structural integrity. The inherent propensity of the myometrium to contract is held in abeyance, and uterine muscle is rendered unresponsive to natural stimuli. Concurrently, the uterus must initiate extensive changes in its size and vascularity to accommodate the pregnancy and prepare for uterine contractions in phase 3 of parturition. The myometrial unresponsiveness of phase 1 continues until near the end of pregnancy.

Although some myometrial contractions are noted during the quiescent phase, they do not normally cause cervical dilatation. They are characterized by their unpredictability, low intensity, and brief duration. Any discomfort that they produce usually is

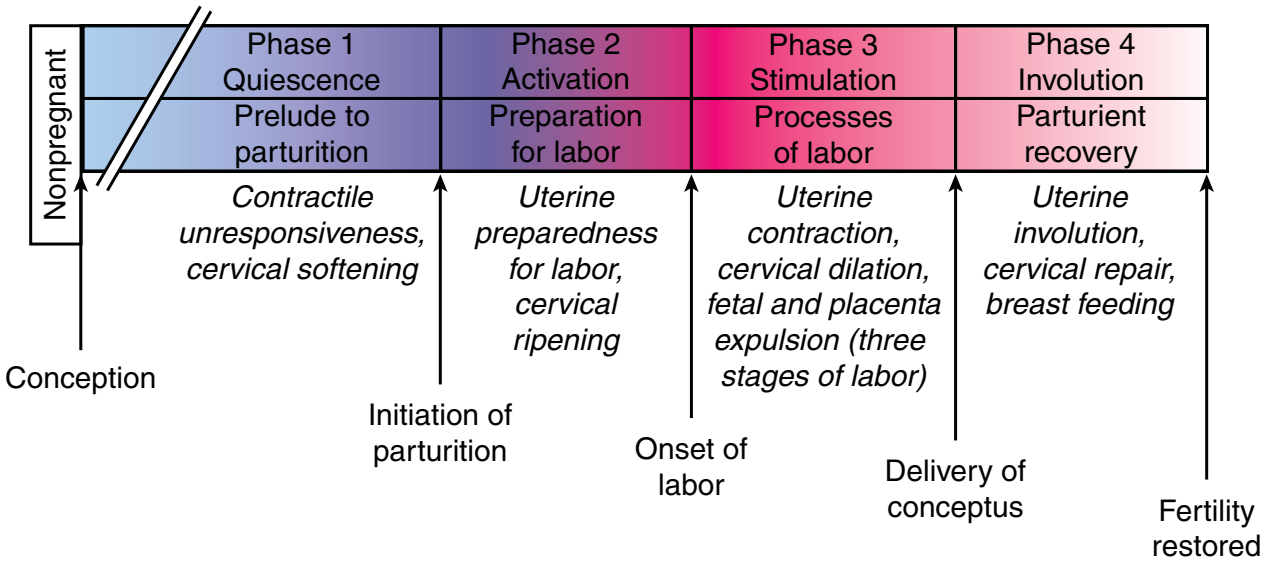

FIGURE 6-1 The phases of parturition.

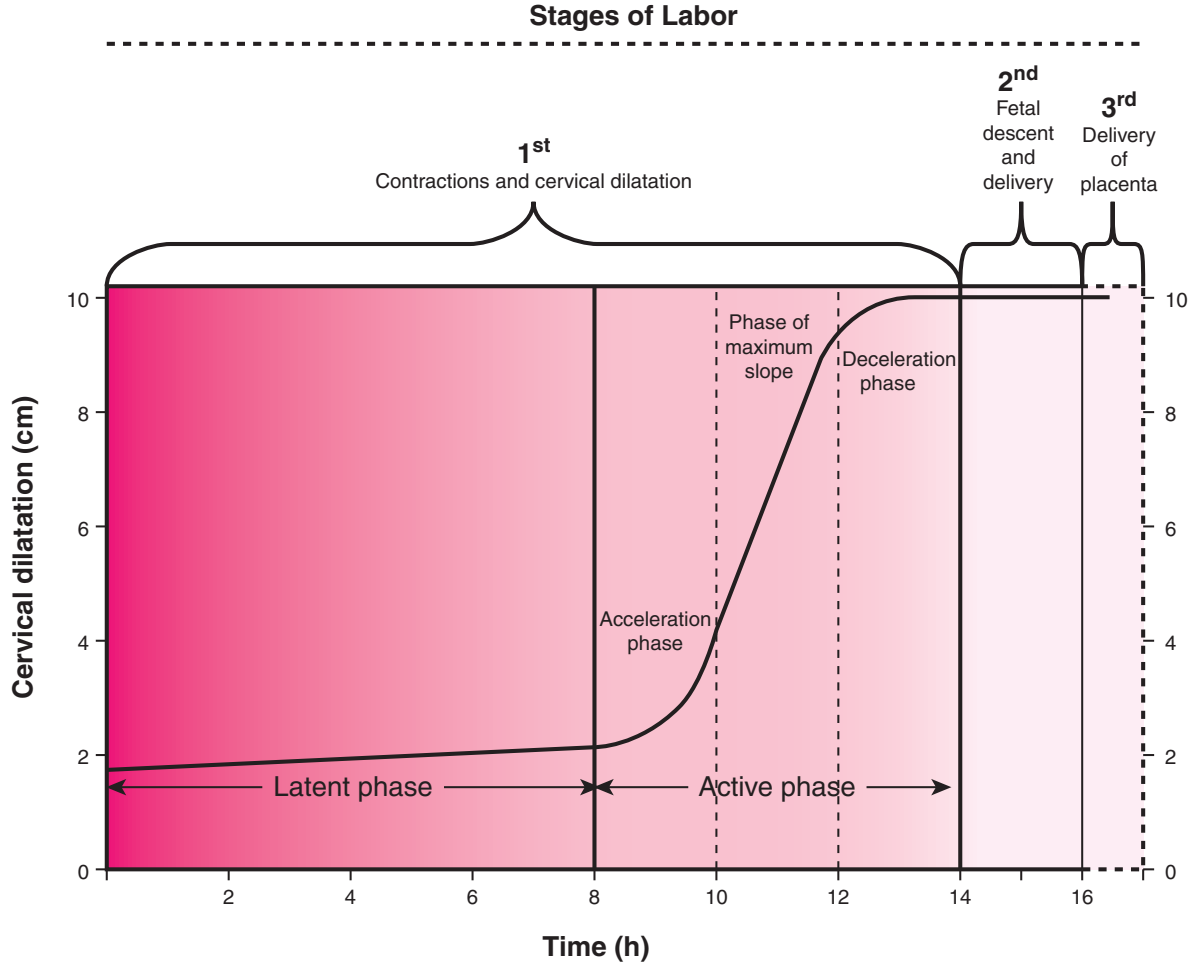

FIGURE 6-2 Composite of the average dilatation curve for labor in nulliparous women. The curve is based on analysis of data derived from a large, nearly consecutive series of women. The first stage is divided into a relatively flat latent phase and a rapidly progressive active phase. In the active phase, there are three identifiable component parts: an acceleration phase, a linear phase of maximum slope, and a deceleration phase. (Redrawn from Friedman, 1978.)

confined to the lower abdomen and groin. Near the end of pregnancy, contractions of this type become more common, especially in multiparous women. They are sometimes referred to as *Braxton Hicks contractions* or *false labor* (see Chap. 17, p. 390).

Cervical Softening

The cervix has multiple functions during pregnancy that include: (1) maintenance of barrier function to protect the reproductive tract from infection, (2) maintenance of cervical competence despite the increasing gravitational forces imposed by the expanding uterus, and (3) orchestrating extracellular matrix changes that allow progressive increases in tissue compliance in preparation for birth.

In nonpregnant women, the cervix is closed and firm, and its consistency is similar to nasal cartilage. By the end of pregnancy, the cervix is easily distensible, and its consistency is similar to the lips of the oral cavity. Thus, the first stage of this remodeling—termed *softening*—is characterized by an increase in tissue compliance, yet the cervix remains firm and unyielding. Hegar (1895) first described palpable softening of the lower uterine segment at 4 to 6 weeks' gestation, and this sign was once used to diagnose pregnancy.

Clinically, the maintenance of cervical anatomical and structural integrity is essential for continuation of pregnancy to term. Preterm cervical dilatation, structural incompetence, or both may forecast an unfavorable pregnancy outcome that ends most often in preterm delivery (see Chap. 36, p. 814). Indeed, cervical shortening between 16 and 24 weeks has been associated with an increased risk of preterm delivery (Hibbard and associates, 2000; Iams and colleagues, 1996).

Structural Changes with Softening. Cervical softening results from increased vascularity, stromal hypertrophy, glandular hypertrophy and hyperplasia, and compositional or structural changes of the extracellular matrix (Danforth and colleagues, 1974; Leppert, 1995; Liggins, 1978 ; Word and associates, 2007). Specifically, during phase 1 of parturition, the cervix begins a slow, progressive increase in turnover of matrix components. For example, in mouse models with deficiency of the extracellular matrix protein, thrombospondin 2, collagen fibril morphology is altered and there is premature cervical softening (Kokenyesi and co-workers, 2004).

Another change found in animal models is that physiological softening is preceded by an increase in collagen solubility (Read and associates, 2007). This reflects a change in collagen processing or a change in the number or type of covalent cross-links between collagen triple helices which are normally required for stable collagen fibril formation (**Fig. 6-3**) (Canty and Kadler, 2005). A reduction in cross-linking of newly synthesized collagen may aid cervical softening because decreased transcripts and activity of the cross-linking enzyme, lysyl oxidase, have been reported in the mouse cervix during pregnancy (Drewes and associates, 2007; Ozasa and colleagues, 1981).

In humans, the clinical importance of these matrix changes is shown by the greater prevalence of cervical incompetence in women with inherited defects in collagen and elastin synthesis or assembly—for example, Ehlers-Danlos and Marfan syndromes (Anum, 2009; Hermanns-Lê, 2005; Paternoster, 1998; Rahman, 2003; Wang, 2006, and all their colleagues).

Phase 2 of Parturition: Preparation for Labor

To prepare for labor, the myometrial tranquility of phase 1 of parturition must be suspended through what has been called *uterine awakening* or *activation*. This process constitutes phase 2 and represents a progression of uterine changes during the last 6 to 8 weeks of pregnancy. Importantly, shifting events associated with phase 2 can cause either preterm or delayed labor. Thus, understanding myometrial and cervical modifications during phase 2 provides a better understanding of events leading to normal and abnormal labor.

Myometrial Changes During Phase 2

Most myometrial changes during phase 2 prepare it for labor contractions. This shift probably results from alterations in the expression of key proteins that control contractility. These *contraction-associated proteins* (*CAPs)* include the oxytocin receptor, prostaglandin F receptor, and connexin 43 (Smith, 2007). Thus, myometrial oxytocin receptors markedly increase along with increased numbers and surface areas of gap junction proteins such as connexin 43. Together these lead to increased uterine irritability and responsiveness to *uterotonins*—agents that stimulate contractions.

Another critical change in phase 2 is formation of the lower uterine segment from the isthmus. With this development, the fetal head often descends to or even through the pelvic inlet—so-called *lightening*. The abdomen commonly undergoes a change in shape, sometimes described as "the baby dropped." It is also likely that the lower segment myometrium is unique from that in the upper uterine segment, resulting in distinct roles for each during labor. This is supported by baboon studies that demonstrate differential expression of prostaglandin receptors within myometrial regions. There are also human studies that report an expression gradient of oxytocin receptors, with higher expression in fundal myometrial cells (Fuchs, 1984; Havelock, 2005; Smith, 2001, and all their colleagues).

Cervical Ripening During Phase 2

Prior to the initiation of contractions, the cervix must undergo more extensive remodeling. This eventually results in cervical yielding and dilatation upon initiation of forceful uterine contractions in the third phase of parturition. Cervical modifications during this second phase principally involve connective tissue changes—so-called *cervical ripening*. The transition from the softening to the ripening phase begins weeks or days before onset of contractions. During this transformation, the total amount and composition of proteoglycans and glycosaminoglycans within the matrix are altered. Many of the processes that aid cervical remodeling are controlled by the same hormones regulating uterine function. That said, the molecular events of each are varied because of differences in cellular composition and physiological requirements. The uterine corpus is predominantly smooth muscle, whereas the cervix is primarily connective tissue. Cellular components of the cervix include smooth muscle, fibroblasts, and epithelia.

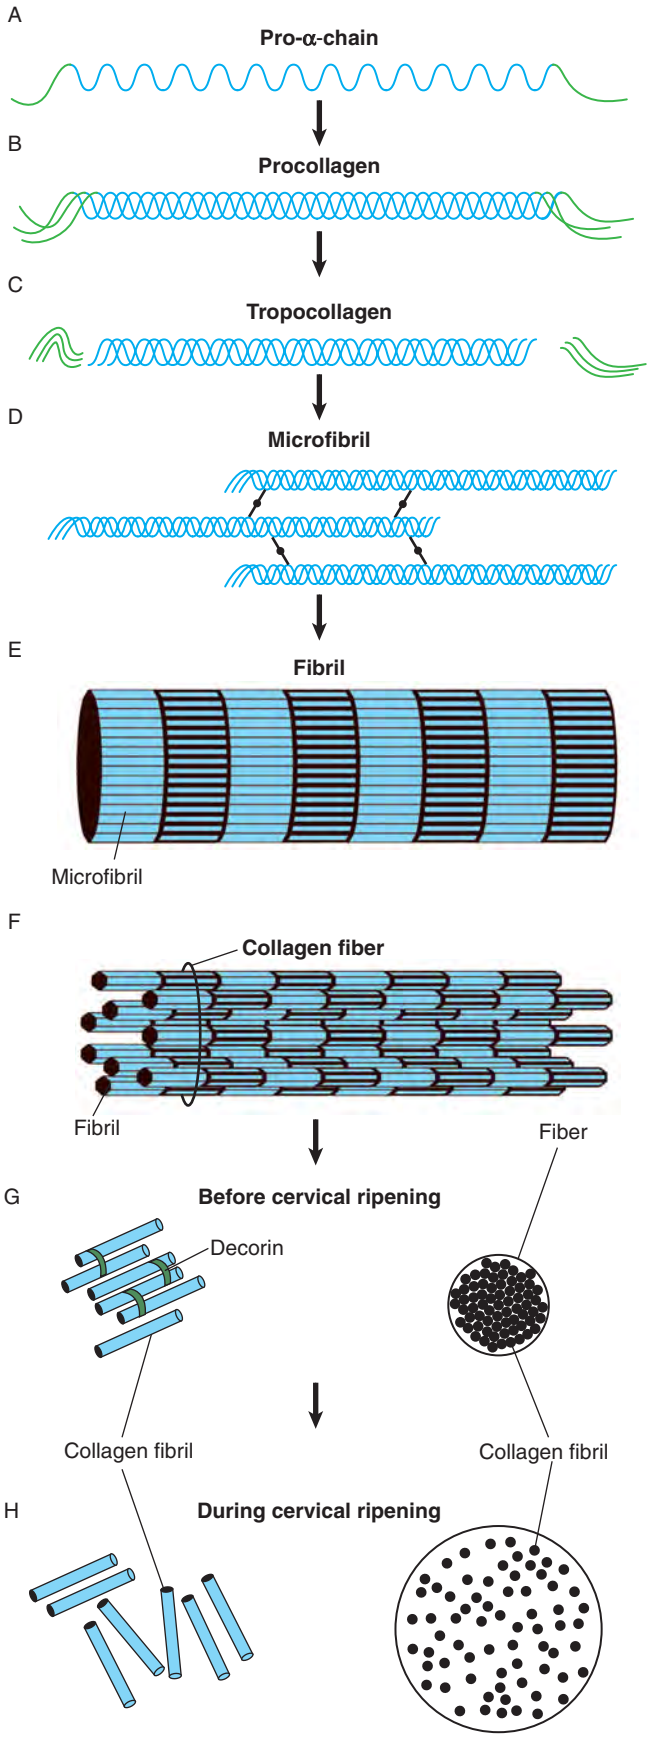

FIGURE 6-3 Fibrillar collagen synthesis and organization. Three α chains **(A)** are synthesized to form procollagen. **B.** Amino terminal and carboxy terminal propeptide (indicated in green) are cleaved from procollagen by specific proteases outside the cell. **C.** Tropocollagen results from this cleavage. **D.** Removal of these propeptides results in a decline in solubility of collagen and self-assembly of collagen α chains into fibrils. The enzyme lysyl oxidase catalyzes the formation of nonreducible cross-links between two triple helical regions to make stable collagen fibrils **(E). F.** Fibrils, in turn, are assembled into collagen fibers. **G.** Fibril size and packing are regulated in part by small proteoglycans that bind collagen such as decorin. Before cervical ripening, fibril size is uniform, and fibrils are well-packed and organized. **H.** During cervical ripening, fibril size is less uniform, and spacing between collagen fibrils and fibers is increased and disorganized.

Endocervical Epithelia. During pregnancy, endocervical epithelial cells proliferate such that endocervical glands occupy a significant percentage of cervical mass by the end of pregnancy. The endocervical canal is lined with mucus-secreting columnar and stratified squamous epithelia, which protect against microbial invasion. Mucosal epithelia function as sentinels that recognize antigens, respond in ways that lead to bacterial and viral killing, and signal to underlying immune cells when pathogenic challenge exceeds their protective capacity (Wira and co-workers, 2005). Recent studies in mice suggest that cervical epithelia may also aid cervical remodeling by regulating tissue hydration and maintenance of barrier function. Hydration may be regulated by expression of *aquaporins*—water channel proteins, whereas paracellular transport of ion and solutes and maintenance of barrier function is regulated by tight junction proteins, such as claudins 1 and 2 (Anderson and colleagues, 2006; Timmons and Mahendroo, 2007).

Cervical Connective Tissue. The cervix is made up of only 10 to 15 percent smooth muscle with the remaining tissue comprised primarily of extracellular connective tissue. Constituents of the latter include type I, III, and IV collagen, glycosaminoglycans, proteoglycans, and elastin.

Collagen. This material is the major component of the cervix and it is largely responsible for its structural disposition. Collagen is the most abundant mammalian protein, and it has a complex biosynthesis pathway including at least six enzymes and chaperones to accomplish maturation (see Fig. 6-3). Each collagen molecule is composed of three alpha chains, which wind around each other to form procollagen. Multiple collagen triple-helical molecules are cross-linked to one another by the actions of lysyl oxidase to form long fibrils. Collagen fibrils interact with small proteoglycans such as decorin or biglycan, as well as matricellular proteins such as thrombospondin 2. These interactions determine fibril size, packing, and organization so collagen fibrils are of uniform diameter and are packed together in a regular and highly organized pattern (Canty and associates, 2005). During cervical ripening, collagen fibrils are disorganized, and there is increased spacing between fibrils.

Matrix metalloproteases (MMPs) are proteases capable of degrading extracellular matrix proteins. Of these, collagenase members of the MMP family degrade collagen. Some studies support a role of MMPs in cervical ripening, whereas others suggest that the biomechanical changes are not consistent solely with collagenase activation and loss of collagen. For example, Buhimschi and colleagues (2004) performed tissue biomechanical studies in the rat and suggest that ripening correlates with changes in collagen's three-dimensional structure rather than its degradation by collagenases. Moreover, mouse and human studies document no changes in collagen content between nonpregnancy and term pregnancy (Myers and associates, 2008; Read and co-workers, 2007).

Collagen solubility—a marker of less mature collagen—is increased early in the cervical softening phase in mice and continues for the remainder of pregnancy (Read and colleagues, 2007). Increased solubility may result in part from a decline in expression of the cross-linking enzyme, lysyl oxidase, during pregnancy (Drewes and associates, 2007; Ozasa and co-workers, 1981). Although collagen solubility has not been determined during cervical softening in early human pregnancy, increased solubility of collagen during cervical ripening has been noted (Granström and colleagues, 1989; Myers and associates, 2008).

Thus, it is possible that dynamic changes in collagen structure rather than collagen content may regulate remodeling. Specifically, ultrastructure analysis by electron microscopy in the rat cervix suggests that collagen dispersion predominates rather than degradation during ripening (Yu and colleagues, 1995). Dispersion of collagen fibrils leads to a loss of tissue integrity and increased tissue compliance. In further support, polymorphisms or mutations in genes required for collagen assembly are associated with an increased incidence of cervical insufficiency (Anum, 2009; Paternoster, 1998; Rahman, 2003; Warren, 2007; and all their colleagues).

Glycosaminoglycans (GAGs). These are high-molecular-weight polysaccharides that contain amino sugars and can form complexes with proteins to form proteoglycans. One glycosaminoglycan is hyaluronan (HA), a carbohydrate polymer whose synthesis is carried out by hyaluronan synthase isoenzymes. In both women and mice, hyaluronan content and hyaluronan synthase 2 expression is increased in the cervix during ripening (Osmers and associates, 1993; Straach and co-workers, 2005).

Hyaluronans' functions are dependent on size, and the breakdown of large-molecular-weight HA to small-molecular-weight products is carried out by a family of enzymes termed hyaluronidases. Large-molecular-weight HA, which in the mouse cervix predominates during cervical ripening, has a dynamic role in creating and filling space to increase viscoelasticity and matrix disorganization. Low-molecular-weight HA has proinflammatory properties, and studies in mice reveal increases in low-molecular-weight HA during labor and the puerperium (Ruscheinsky and colleagues, 2008). The importance of regulated changes in HA size during cervical ripening and dilatation is supported by a study reporting administration of hyaluronidase to the cervix of term pregnant women. Administration resulted in a reduction in labor duration and a reduced incidence of cesarean delivery due to cervical malfunction (Spallacci and co-workers, 2007). Activation of intracellular signaling cascades and other biological functions requires interactions with cell-associated HA-binding proteins. There are several in the cervix and include the proteoglycan, *versican*, and the cell surface receptor, CD44 (Ruscheinsky and colleagues, 2008).

Proteoglycans. These glycoproteins are found in abundance in the cervix, and changes in proteoglycan composition within the cervical matrix also accompany cervical ripening. At least two small leucine-rich proteoglycans are expressed in the cervix—*decorin* and *biglycan*. Although mRNA content of these two does not change during cervical ripening, changes in proteoglycan content are reported during ripening in support of posttranslational regulation (Westergren-Thorsson and colleagues, 1998). Decorin and other family members interact with collagen and influence the packing and order of collagen fibrils (Ameye and co-workers, 2002). The net result of their decreased expression is a rearrangement of collagen such that collagen fibers are weakened, shortened, and disorganized. Mice

deficient in decorin have loose, fragile skin due to the inability of collagen fibrils to form uniform, packed structures. (Danielson and associates, 1997).

Inflammatory Changes. The marked changes within the extracellular matrix during cervical ripening in Phase 2 are accompanied by stromal invasion with inflammatory cells. This has led to a model in which cervical ripening is considered an inflammatory process such that cervical chemoattractants attract inflammatory cells, which in turn release proteases that may aid degradation of collagen and other matrix components. In phase 3 or 4 of parturition, there is increased cervical expression of chemokines and collagenase/protease activity. It was assumed that processes regulating phases 3 and 4 of dilation and postpartum recovery of the cervix were similar to those in phase 2 of cervical ripening (Osman, 2003; Bokström, 1997; Sennström, 2000; Young, 2002, and all their colleagues). This, however, may not be the case. Recent observations from both human and animal studies have challenged the importance of inflammation in initiation of cervical ripening. For example, Sakamoto and associates (2004, 2005) found no correlation between the degree of clinical cervical ripening with cervical interleukin 8 tissue (IL-8) concentrations. Interleukin 8, a cytokine that chemoattracts neutrophils, however, is present in increased levels in cervical tissue collected after vaginal delivery—phases 3 and 4.

Word and colleagues (2005) described an animal model in which parturition fails due to a small rigid cervix despite uterine contractions. Although this model has a robust recruitment of inflammatory cells to the stromal matrix, cervical ripening does not develop. In mouse models, monocyte migration, but not activation, takes place prior to labor (Timmons and Mahendroo, 2006, 2007; Timmons and associates, 2009). Furthermore, tissue depletion of neutrophils before birth has no effect on the timing or success of parturition. Finally, activation of neutrophils, proinflammatory M1 macrophages, and alternatively, activated M2 macrophages is increased within 2 hours after birth, suggesting a role for inflammatory cells in postpartum cervical remodeling.

Induction and Prevention of Cervical Ripening. The exact mechanisms that lead to cervical ripening are still being defined, and therapies to prevent premature cervical ripening remain to be identified. Therapies to promote cervical ripening for labor induction include direct application of prostaglandins E_2 (PGE_2) and $F_{2\alpha}$ ($PGF_{2\alpha}$). These modify collagen and alter relative glycosaminoglycan concentrations. This property is useful clinically to aid labor induction (see Chap. 22, p. 502).

In some nonhuman species, the cascades of events that allow cervical ripening are induced by decreasing serum progesterone concentrations. And in humans, administration of progesterone antagonists causes cervical ripening. As discussed later, humans may have developed unique mechanisms to localize decreases in progesterone action in the cervix and myometrium.

Phase 3 of Parturition: Labor

Phase 3 is synonymous with active labor, that is, uterine contractions that bring about progressive cervical dilatation and delivery. Clinically, phase 3 is customarily divided into the three stages of labor. These stages compose the commonly used labor graph shown in Figure 6-2. The clinical stages of labor may be summarized as follows:

1. The first stage begins when widely spaced uterine contractions of sufficient frequency, intensity, and duration are attained to bring about cervical thinning, termed *effacement*. This labor stage ends when the cervix is fully dilated—about 10 cm—to allow passage of the fetal head. The first stage of labor, therefore, is the *stage of cervical effacement and dilatation*
2. The second stage begins when cervical dilatation is complete, and ends with delivery. Thus, the second stage of labor is the *stage of fetal expulsion*
3. The third stage begins immediately after delivery of the fetus and ends with the delivery of the placenta. Thus, the third stage of labor is the *stage of placental separation and expulsion.*

First Stage of Labor: Clinical Onset of Labor

In some women, forceful uterine contractions that effect delivery begin suddenly. In others, the initiation of labor is heralded by spontaneous release of a small amount of blood-tinged mucus from the vagina. This extrusion of the mucus plug that had previously filled the cervical canal during pregnancy is referred to as "show" or "bloody show." There is very little blood with the mucous plug, and its passage indicates that labor is already in progress or likely will ensue in hours to days.

Uterine Labor Contractions. Unique among physiological muscular contractions, those of uterine smooth muscle during labor are painful. The pain's cause is not known definitely, but several possibilities have been suggested:

- Hypoxia of the contracted myometrium—such as that with angina pectoris
- Compression of nerve ganglia in the cervix and lower uterus by contracted interlocking muscle bundles
- Stretching of the cervix during dilatation
- Stretching of the peritoneum overlying the fundus.

Compression of nerve ganglia in the cervix and lower uterine segment by the contracting myometrium is an especially attractive hypothesis. Paracervical infiltration with a local anesthetic usually produces appreciable pain relief with contractions (see Chap. 19, p. 450). Uterine contractions are involuntary and for the most part, independent of extrauterine control. Neural blockade from epidural analgesia does not diminish their frequency or intensity. In other examples, myometrial contractions in paraplegic women and in women after bilateral lumbar sympathectomy are normal but painless.

Mechanical stretching of the cervix enhances uterine activity in several species, including humans. This phenomenon has been referred to as the *Ferguson reflex* (Ferguson, 1941). Its exact mechanism is not clear, and release of oxytocin has been suggested but not proven. Manipulation of the cervix and "stripping" the fetal membranes is associated with an increase in blood levels of prostaglandin $F_{2\alpha}$ metabolite (PGFM). As shown in **Figure 6-4**, this could also increase contractions (see also Chap. 22, p. 504).

The interval between contractions diminishes gradually from about 10 minutes at the onset of the first stage of labor to

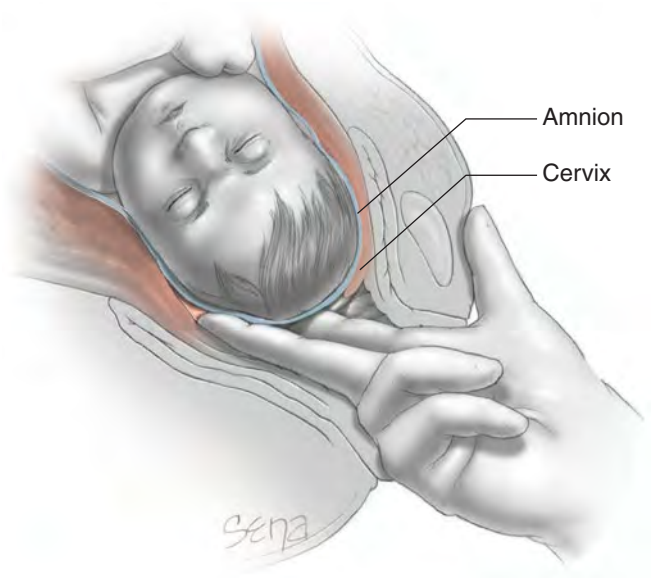

FIGURE 6-4 Clinically, membrane stripping may aid cervical ripening and in some cases, labor induction.

as little as 1 minute or less in the second stage. Periods of relaxation between contractions, however, are essential for fetal welfare. Unremitting contractions compromise uteroplacental blood flow sufficiently to cause fetal hypoxemia. In active-phase labor, the duration of each contraction ranges from 30 to 90 seconds, averaging about 1 minute. There is appreciable variability in contraction intensity during normal labor. Specifically, amnionic fluid pressures generated by contractions during spontaneous labor average approximately 40 mm Hg, but with variations from 20 to 60 mm Hg (see Chap. 18, p. 437).

Distinct Lower and Upper Uterine Segments. During active labor, the uterine divisions that were initiated in phase 2 of parturition become increasingly evident (Figs. 6-5 and 6-6). By abdominal palpation, even before rupture of the membranes, the two segments can sometimes be differentiated. The upper segment is firm during contractions, whereas the lower segment is softer, distended, and more passive. This mechanism is imperative because if the entire myometrium, including the lower uterine segment and cervix, were to contract simultaneously and with equal intensity, the net expulsive force would be decreased markedly. Thus, the upper segment contracts, retracts, and expels the fetus. In response to these contractions, the softened lower uterine segment and cervix dilate and thereby form a greatly expanded, thinned-out tube through which the fetus can pass.

The myometrium of the upper segment does not relax to its original length after contractions. Instead, it becomes relatively fixed at a shorter length. The upper active uterine segment contracts down on its diminishing contents, but myometrial tension remains constant. The net effect is to take up slack, thus maintaining the advantage gained in the expulsion of the fetus. Concurrently, the uterine musculature is kept in firm contact with the uterine contents. As the consequence of retraction, each successive contraction commences where its predecessor left off. Thus, the upper part of the uterine cavity becomes slightly smaller with each successive contraction. Because of the successive shortening of the muscular fibers, the upper active segment becomes progressively thickened throughout first- and second-stage labor (see Fig. 6-5). This process continues and results in a tremendously thickened upper uterine segment immediately after delivery.

Clinically, it is important to understand that the phenomenon of upper segment retraction is contingent upon a decrease in the volume of its contents. For this to happen, particularly early in labor when the entire uterus is virtually a closed sac with only minimal cervical dilatation, the musculature of the lower segment must stretch. This permits increasingly more of the uterine contents to occupy the lower segment. The upper segment retracts only to the extent that the lower segment distends and the cervix dilates.

Relaxation of the lower uterine segment mirrors the same gradual progression of retraction. Recall that after each contraction of the upper segment, the muscles do not return to the

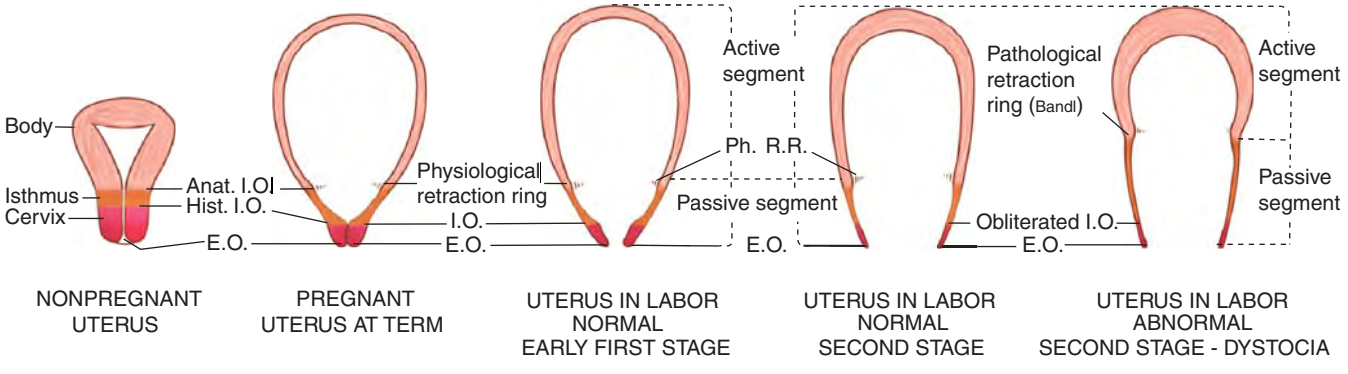

FIGURE 6-5 Sequence of development of the segments and rings in the uterus at term and in labor. Note comparison between the uterus of a nonpregnant woman, the uterus at term, and the uterus during labor. The passive lower uterine segment is derived from the isthmus, and the physiological retraction ring develops at the junction of the upper and lower uterine segments. The pathological retraction ring develops from the physiological ring. (Anat. I.O. = anatomical internal os; E.O. = external os; Hist. I.O.= histological internal os; Ph.R.R. = physiological retraction ring.)

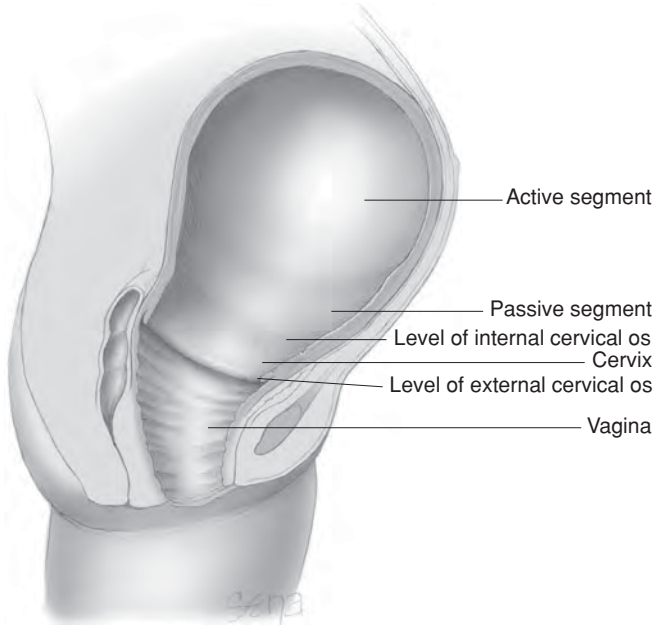

FIGURE 6-6 The uterus at the time of vaginal delivery. The active upper segment retracts around the presenting part as the fetus descends through the birth canal. In the passive lower segment, there is considerably less myometrial tone.

previous length, but tension remains essentially the same. By comparison, in the lower segment, successive lengthening of the fibers with labor is accompanied by thinning, normally to only a few millimeters in the thinnest part. As a result of the lower segment thinning and concomitant upper segment thickening, a boundary between the two is marked by a ridge on the inner uterine surface—the *physiological retraction ring*. When the thinning of the lower uterine segment is extreme, as in obstructed labor, the ring is prominent and forms a *pathological retraction ring* (see Fig. 6-5). This abnormal condition is also known as the *Bandl ring,* which is discussed further in Chapter 20 (p. 486).

Uterine Shape Changes During Labor. Each contraction produces an elongation of the ovoid uterine shape with a concomitant decrease in horizontal diameter. This change in shape has important effects on the process of labor. First, there is increased *fetal axis pressure*. The decreased horizontal diameter serves to straighten the fetal vertebral column. This presses the upper pole of the fetus firmly against the fundus, whereas the lower pole is thrust farther downward. The lengthening of the ovoid shape has been estimated at 5 and 10 cm. Second, with lengthening of the uterus, the longitudinal fibers are drawn taut. As a result, the lower segment and cervix are the only parts of the uterus that are flexible, and these are pulled upward and around the lower pole of the fetus.

Ancillary Forces in Labor. After the cervix is dilated fully, the most important force in fetal expulsion is that produced by maternal intra-abdominal pressure. Contraction of the abdominal muscles simultaneously with forced respiratory efforts with the glottis closed is referred to as *pushing*. The nature of the force is similar to that with defecation, but the intensity usually is much greater. The importance of intra-abdominal pressure is attested to by prolonged descent during labor in paraplegic women. And although increased intra-abdominal pressure is necessary to complete second-stage labor, pushing accomplishes little in the first stage. It exhausts the mother, and its associated increased intrauterine pressures may be harmful to the fetus.

Cervical Changes During First-Stage Labor

As the result of contraction forces, two fundamental changes—effacement and dilatation—take place in the already-ripened cervix. For an average-sized fetal head to pass through the cervix, its canal must dilate to a diameter of approximately 10 cm. At this time, the cervix is said to be completely or fully dilated. Although there may be no fetal descent during cervical effacement, most commonly, the presenting fetal part descends somewhat as the cervix dilates. During second-stage labor in nulliparas, the presenting part typically descends slowly and steadily. In multiparas, however, particularly those of high parity, descent may be rapid.

Cervical effacement is "obliteration" or "taking up" of the cervix. It is manifest clinically by shortening of the cervical canal from a length of about 2 cm to a mere circular orifice with almost paper-thin edges. The muscular fibers at about the level of the internal cervical os are pulled upward, or "taken up," into the lower uterine segment. The condition of the external os remains temporarily unchanged (**Fig. 6-7**).

Effacement may be compared with a funneling process in which the whole length of a narrow cylinder is converted into a very obtuse, flaring funnel with a small circular opening. Because of increased myometrial activity during uterine preparedness for labor, appreciable effacement of a softened cervix sometimes is accomplished before active labor begins. Effacement causes expulsion of the mucous plug as the cervical canal is shortened.

Because the lower segment and cervix have lesser resistance during a contraction, a centrifugal pull is exerted on the cervix leading to distension, or *cervical dilatation* (**Figs. 6-8**). As uterine contractions cause pressure on the membranes, the hydrostatic action of the amnionic sac in turn dilates the cervical canal like a wedge. In the absence of intact membranes, the pressure of the presenting part against the cervix and lower uterine segment is similarly effective. Early rupture of the membranes does not retard cervical dilatation so long as the presenting fetal part is positioned to exert pressure against the cervix and lower segment. The process of cervical effacement and dilatation causes the formation of the *forebag* of amnionic fluid, which is the leading portion of the amnionic sac and fluid located in front of the presenting part.

Referring back to Figure 6-2, recall that cervical dilatation is divided into latent and active phases. The active phase is subdivided further into the acceleration phase, the phase of maximum slope, and the deceleration phase (Friedman, 1978). The duration of the latent phase is more variable and sensitive to changes by extraneous factors. For example, sedation may prolong the latent phase, and myometrial stimulation shortens it.

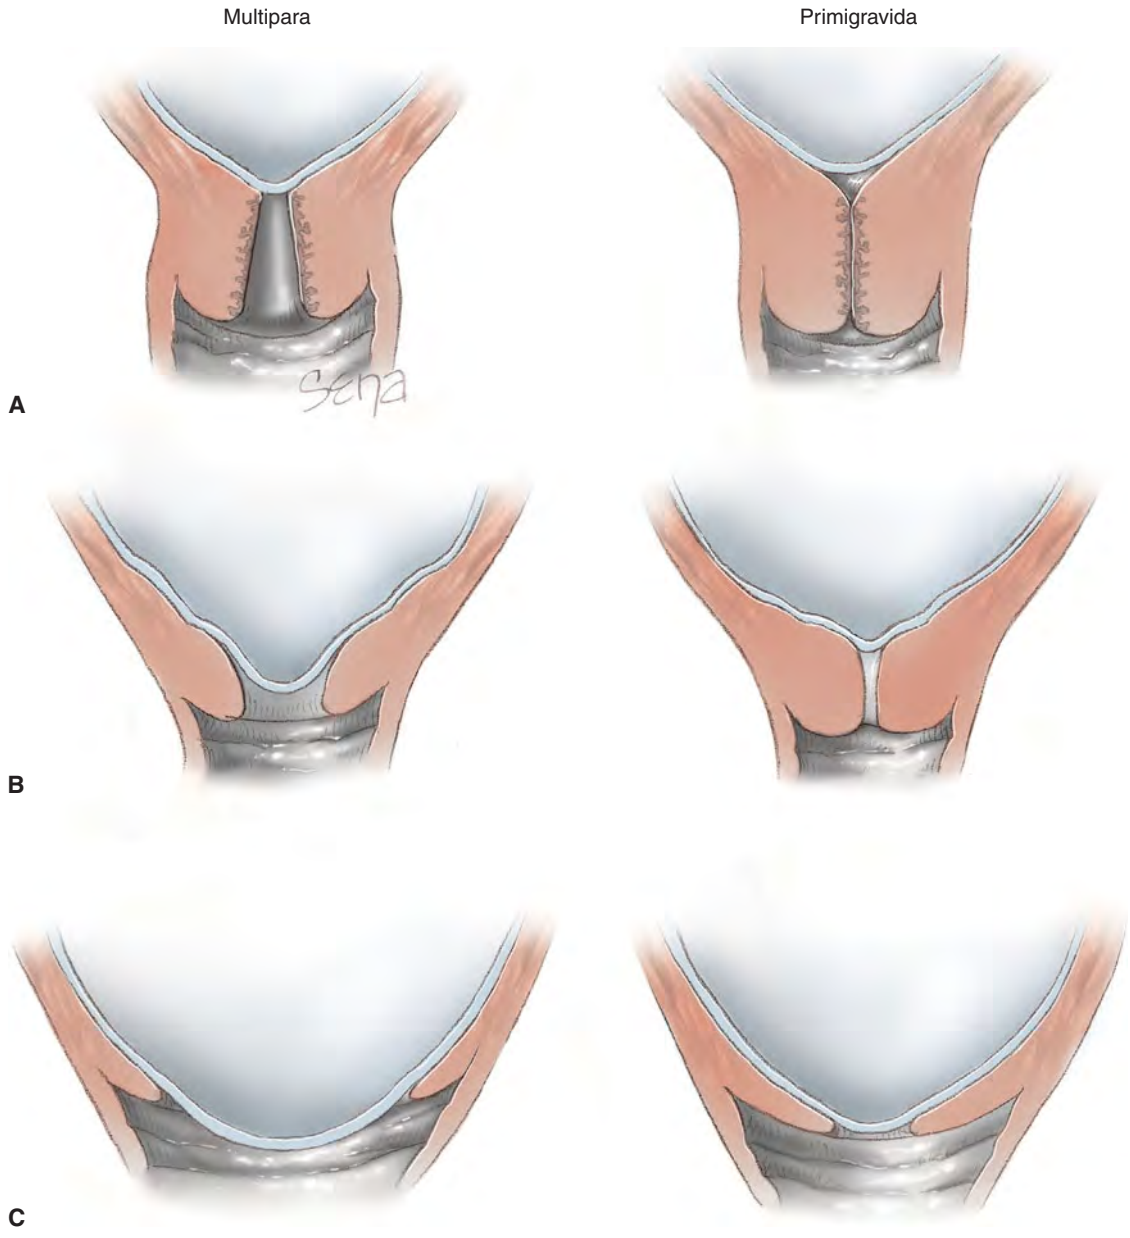

FIGURE 6-7 Schematic showing effacement and dilatation. **A.** Before labor, the primigravid cervix is long and undilated in contrast to that of the multipara, which has dilatation of the internal and external os. **B.** As effacement begins, the multiparous cervix shows dilatation and funneling of the internal os. This is less apparent in the primigravid cervix. **C.** As complete effacement is achieved in the primigravid cervix, dilation is minimal. The reverse is true in the multipara.

The latent phase duration has little bearing on the subsequent course of labor, whereas the characteristics of the accelerated phase are usually predictive of a particular labor outcome. Completion of cervical dilatation during the active phase is accomplished by cervical retraction about the presenting part. The first stage ends when cervical dilatation is complete. Once the second stage commences, only progressive descent of the presenting part will foretell further progress.

Second Stage of Labor: Fetal Descent

In many nulliparas, engagement of the head is accomplished before labor begins. That said, the head may not descend further until late in labor. In the descent pattern of normal labor, a typical hyperbolic curve is formed when the station of the fetal head is plotted as a function of labor duration. *Station* describes descent of the fetal biparietal diameter in relation to a line drawn between maternal ischial spines (Chap. 17, p. 392). Active descent usually takes place after dilatation has progressed for some time (Fig. 6-9). In nulliparas, increased rates of descent are observed ordinarily during cervical dilatation phase of maximum slope. At this time, the speed of descent is also maximal and is maintained until the presenting part reaches the perineal floor (Friedman, 1978).

Pelvic Floor Changes During Labor

The birth canal is supported and is functionally closed by several layers of tissues that together form the pelvic floor. The

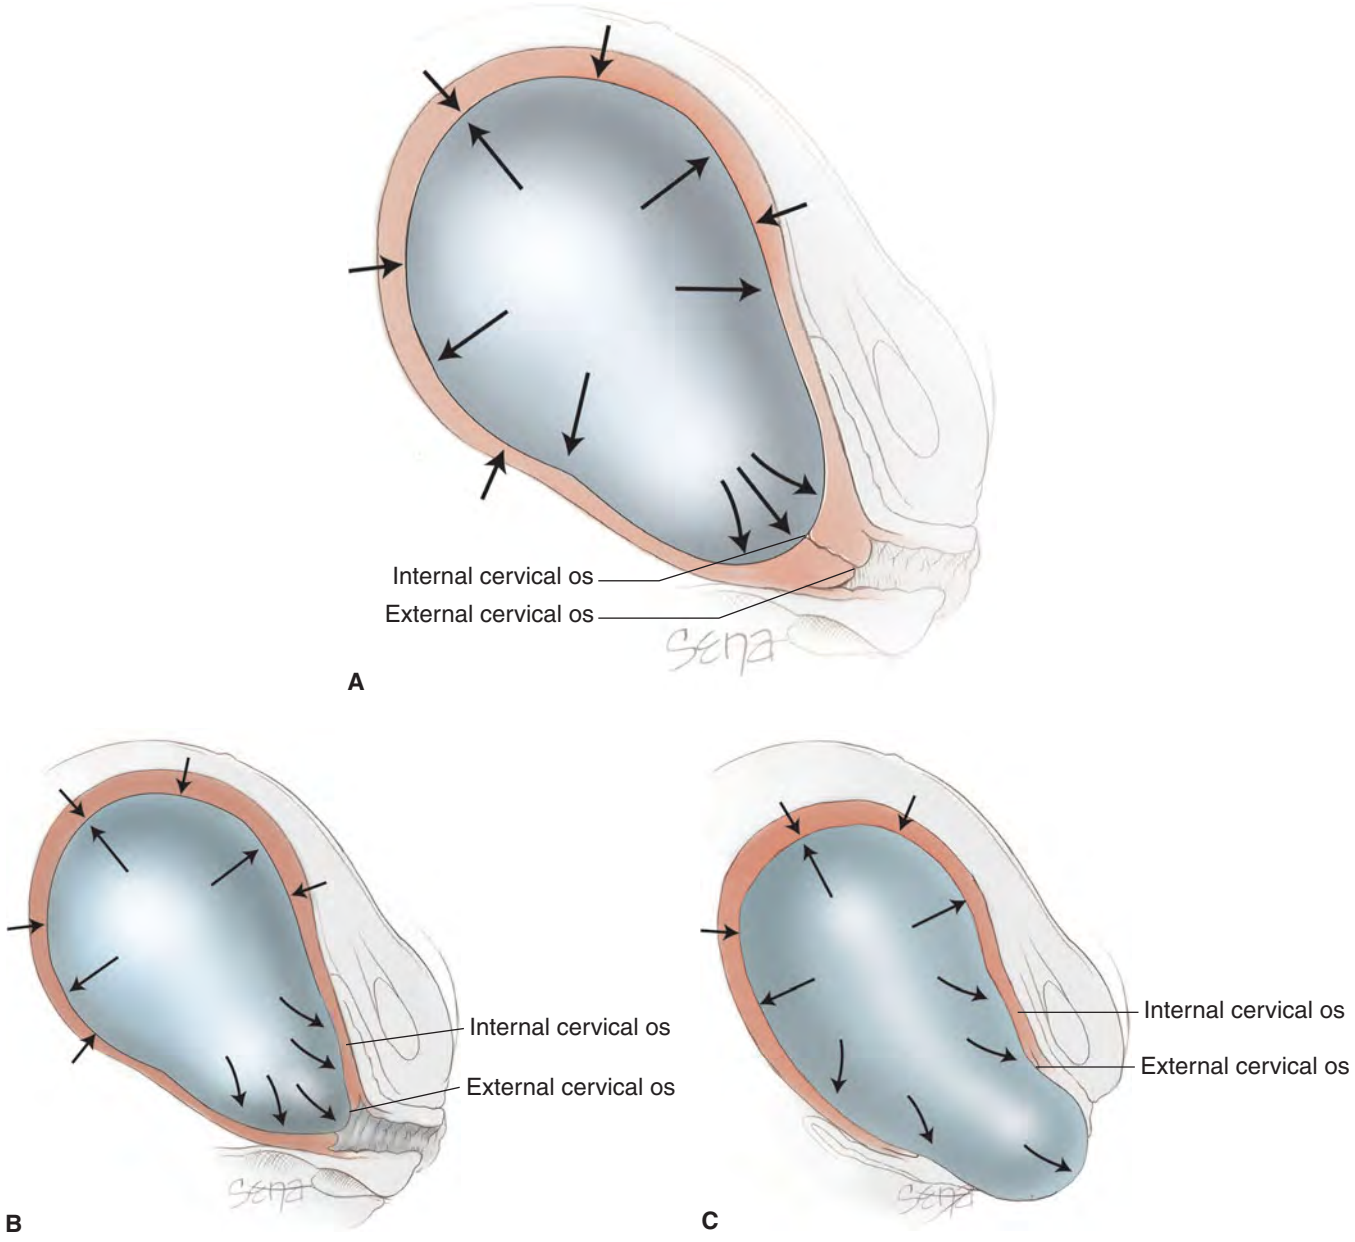

FIGURE 6-8 Hydrostatic action of membranes in effecting cervical effacement and dilatation. With labor progression, note the changing relations of the internal and external os in **(A)**, **(B)**, and **(C)**. Although not shown in this diagram, with membrane rupture, the presenting part, applied to the cervix and the forming lower uterine segment, acts similarly.

most important structures are the levator ani muscle and the fibromuscular connective tissue covering its upper and lower surfaces. There are marked changes in the biomechanical properties of these structures and the vaginal wall during parturition resulting from changes in structure or composition of the extracellular matrix (Lowder and co-workers, 2007; Rahn and associates, 2008). The levator ani consists of the pubovisceral, puborectalis, and iliococcygeus muscles, which close the lower end of the pelvic cavity as a diaphragm. Thereby, a concave upper and a convex lower surface are presented (Chap. 2, p. 33). The posterior and lateral portions of the pelvic floor, which are not spanned by the levator ani, are occupied bilaterally by the piriformis and coccygeus muscles.

The levator ani muscle varies in thickness from 3 to 5 mm, although its margins encircling the rectum and vagina are somewhat thicker. During pregnancy, the levator ani usually undergoes hypertrophy, forming a thick band that extends backward from the pubis and encircles the vagina about 2 cm above the plane of the hymen. On contraction, the levator ani draws both the rectum and the vagina forward and upward in the direction of the symphysis pubis and thereby acts to close the vagina. The more superficial muscles of the perineum are too delicate to serve more than an accessory function.

In the first stage of labor, the membranes, when intact, and the fetal presenting part serve to dilate the upper vagina. The most marked change consists of the stretching of levator ani

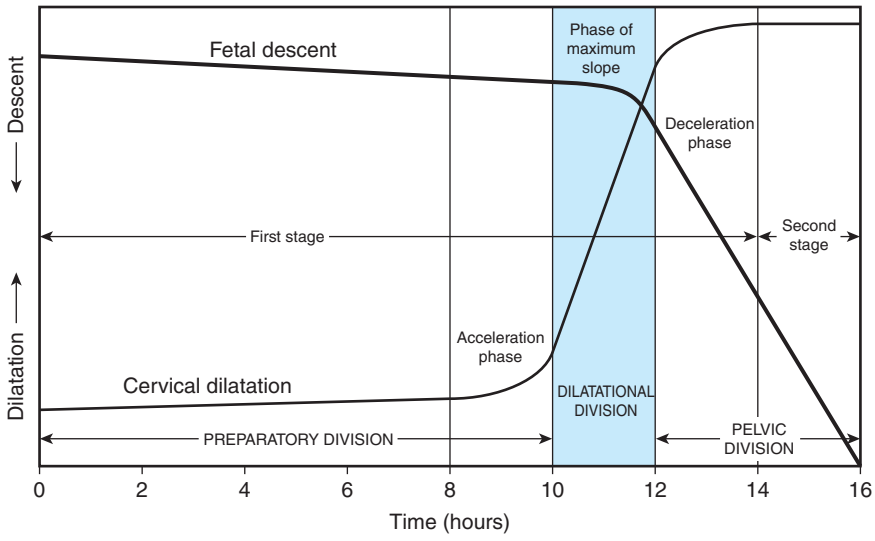

FIGURE 6-9 Labor course divided on the basis of expected evolution of the dilatation and descent curves into three functional divisions. The preparatory division includes the latent and acceleration phases. The dilatational division is the phase of maximum slope of dilatation. The pelvic division encompasses both the deceleration phase and the second stage, which is concurrent with the phase of maximum slope of fetal descent. (Redrawn from Friedman, 1978.)

muscle fibers. This is accompanied by thinning of the central portion of the perineum, which becomes transformed from a wedge-shaped, 5-cm-thick mass of tissue to a thin, almost transparent membranous structure less than 1 cm thick. When the perineum is distended maximally, the anus becomes markedly dilated and presents an opening that varies from 2 to 3 cm in diameter and through which the anterior wall of the rectum bulges. The extraordinary number and size of the blood vessels that supply the vagina and pelvic floor result in substantive blood loss if these tissues are torn.

Third Stage of Labor: Delivery of Placenta and Membranes

This stage begins immediately after delivery of the fetus and involves the separation and expulsion of the placenta and membranes. As the neonate is born, the uterus spontaneously contracts around its diminishing contents. Normally, by the time the infant is completely delivered, the uterine cavity is nearly obliterated. The organ consists of an almost solid mass of muscle, several centimeters thick, above the thinner lower segment. The uterine fundus now lies just below the level of the umbilicus.

This sudden diminution in uterine size is inevitably accompanied by a decrease in the area of the placental implantation site (Fig. 6-10). For the placenta to accommodate itself to this reduced area, it increases in thickness, but because of limited placental elasticity, it is forced to buckle. The resulting tension pulls the weakest layer of the decidua—the decidua spongiosa—from that site. Thus, placental separation follows disproportion created between the unchanged placental size and the reduced size of the implantation site. During cesarean delivery, this phenomenon may be directly observed when the placenta is implanted posteriorly.

Cleavage of the placenta is aided greatly by the loose structure of the spongy decidua, which may be likened to the row of perforations between postage stamps. As separation proceeds, a hematoma forms between the separating placenta and the decidua. The hematoma is usually the result, rather than the cause of the separation, because in some cases bleeding is negligible. The hematoma may, however, accelerate cleavage. Because placental separation is through its spongy layer, part of the decidua is cast off with the placenta, whereas the rest remains attached to the myometrium. The amount of decidual tissue retained at the placental site varies.

The placenta ordinarily separates within minutes after delivery. Occasionally, some degree of separation begins even before the third stage of labor. This probably accounts for certain cases of fetal heart rate decelerations that occur just before fetal expulsion.

Separation of Fetal Membranes

The great decrease in uterine cavity surface area simultaneously throws the fetal membranes—the amniochorion and the

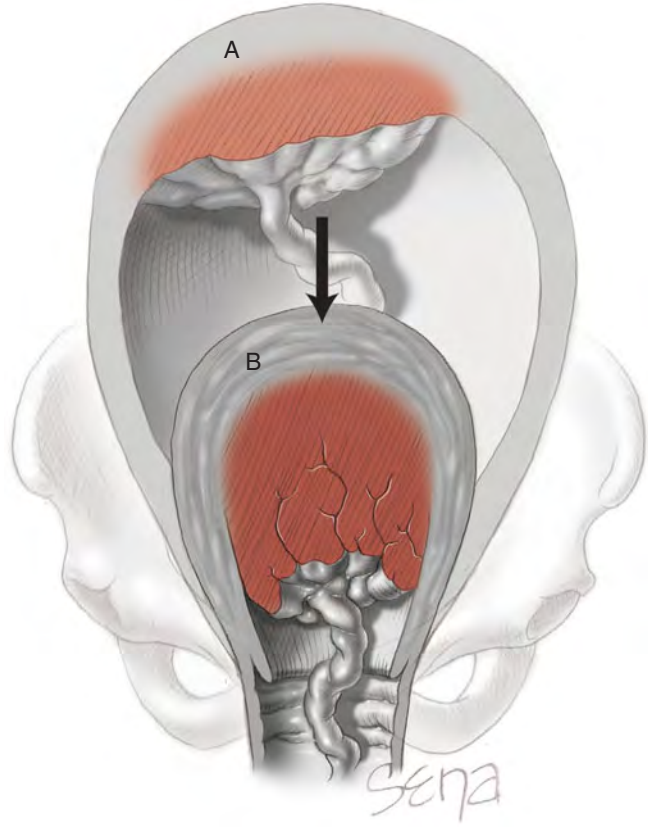

FIGURE 6-10 Diminution in size of the placental site after birth of the infant. **A.** Spatial relations before birth. **B.** Placental spatial relations after birth.

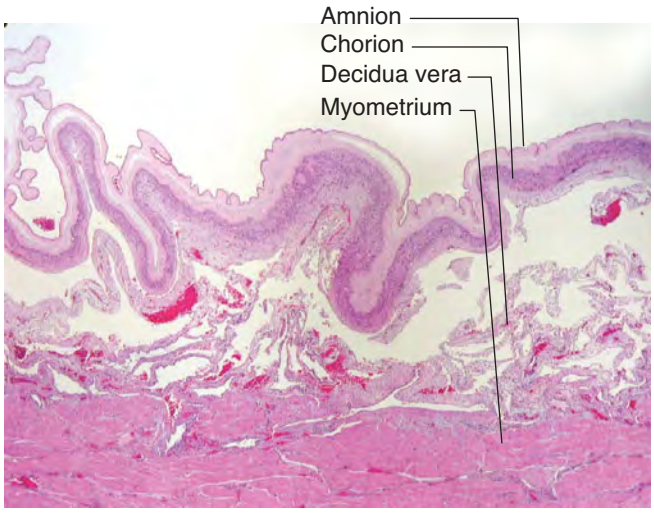

FIGURE 6-11 Postpartum, membranes are thrown up into folds as the uterine cavity decreases in size (Used with permission from Dr. Kelley S. Carrick.).

parietal decidua—into innumerable folds (Fig. 6-11). Membranes usually remain in situ until placental separation is nearly completed. These are then peeled off the uterine wall, partly by further contraction of the myometrium and partly by traction that is exerted by the separated placenta, which lies in the lower segment or upper vagina. Following separation, the body of the uterus normally forms an almost solid mass of muscle, the anterior and posterior walls of which, each measuring 4 to 5 cm in thickness, lie in close apposition such that the uterine cavity is almost obliterated.

Placental Extrusion

After the placenta has separated and occupies the lower uterine segment or upper vagina, it may be expelled by increased abdominal pressure. Women in the recumbent position, however, frequently cannot expel the placenta spontaneously. Thus, completion of the third stage is accomplished usually by alternately compressing and elevating the fundus, while exerting minimal traction on the umbilical cord (Fig. 17-31, p. 398).

Most commonly during placental delivery, a retroplacental hematoma forms and pushes the center forward and causes it to separate toward the uterine cavity. Weighted by this hematoma, the placenta descends, drags the membranes, and peels them from their uterine attachment. Consequently, the glistening amnion, covering the placental surface, presents at the vulva. The retroplacental hematoma either follows the placenta or is found within the inverted sac. In this process, known as the *Schultze mechanism* of placental expulsion, blood from the placental site pours into the membrane sac and does not escape externally until after extrusion of the placenta. In the other method of placental extrusion, known as the *Duncan mechanism,* the placenta separates first at the periphery. As a result, blood collects between the membranes and the uterine wall and escapes from the vagina. In this circumstance, the placenta descends sideways, and the maternal surface appears first.

Phase 4 of Parturition: The Puerperium

Immediately and for about an hour or so after delivery, the myometrium remains in a state of rigid and persistent contraction and retraction. This directly compresses large uterine vessels and allows thrombosis of their lumens (Fig. 2-14, p. 25). For this reason, severe postpartum hemorrhage is prevented.

Concurrently during the early puerperium, a maternal-type behavior pattern develops and *maternal-neonatal bonding* begins. The onset of lactogenesis and milk let-down in mammary glands also is, in an evolutionary sense, crucial to the bringing forth of young. Both compression of uterine vessels and maternal-type behavior patterns are mediated by oxytocin (p. 159).

Uterine involution and cervical repair, both remodeling processes that restore these organs to the nonpregnant state, follow in a timely fashion. These protect the reproductive tract from invasion by commensal microorganisms and restore endometrial responsiveness to normal hormonal cyclicity. Reinstitution of ovulation signals preparation for the next pregnancy. This generally occurs within 4 to 6 weeks after birth, but it is dependent on the duration of breast feeding. Infertility usually persists as long as breast feeding is continued because of lactation-induced, prolactin-mediated anovulation and amenorrhea (Chap. 32, p. 694).

PHYSIOLOGICAL AND BIOCHEMICAL PROCESSES REGULATING PARTURITION

The physiological processes that result in the initiation of parturition and the onset of labor remain poorly defined. There are two general contemporaneous theorems concerning labor initiation. Viewed simplistically, these are the *loss of function of pregnancy maintenance factors* and the *synthesis of factors that induce parturition.* Selected tenets of these two postulates are incorporated into most theorems.

Some investigators also speculate that the mature fetus is the source of the initial signal for parturition commencement. Others suggest that one or more uterotonins, produced in increased amounts, or an increase in the population of its myometrial receptors is the proximate cause. Indeed, an obligatory role for one or more uterotonins is included in most parturition theories, as either a primary or a secondary phenomenon in the final events of childbirth. Both rely on careful regulation of smooth muscle contraction.

Anatomical and Physiological Considerations of the Myometrium

There are unique characteristics of smooth muscle, including myometrium, compared with those of skeletal muscle that may confer advantages for the myometrium in the efficiency of uterine contractions and delivery of the fetus. First, the degree of smooth-muscle cell shortening with contractions may be one order of magnitude greater than that attained in striated muscle cells. Second, forces can be exerted in smooth muscle cells in multiple directions, whereas the contraction force generated by skeletal muscle is always aligned with the axis of the muscle fibers. Third, smooth muscle is not organized in the same

manner as skeletal muscle. In myometrium, the thick and thin filaments are found in long, random bundles throughout the cells. This plexiform arrangement aids greater shortening and force-generating capacity. Lastly, greater multidirectional force generation in the uterine fundus compared with that of the lower uterine segment permits versatility in expulsive force directionality. These forces thus can be brought to bear irrespective of the fetal lie or presentation.

Regulation of Myometrial Contraction and Relaxation

Myometrial contraction is controlled by the transcription of key genes, which produce proteins that repress or enhance cellular contractility. These proteins function to: (1) enhance the interactions between the actin and myosin proteins that cause muscle contraction; (2) increase excitability of individual myometrial cells; and (3) promote intracellular cross talk that allow development of synchronous contractions.

Actin-Myosin Interactions

The interaction of myosin and actin is essential to muscle contraction. This interaction requires that actin be converted from a globular to filamentous form. Moreover, actin must be attached to the cytoskeleton at focal points in the cell membrane to allow development of tension (Fig. 6-12). Actin must partner with myosin, which is comprised of multiple light and heavy chains. The interaction of myosin and actin causes activation of adenosine triphosphatase, adenosine triphosphate hydrolysis, and force generation. This interaction is effected by enzymatic phosphorylation of the 20-kDa light chain of myosin (Stull and colleagues, 1988, 1998). This phosphorylation reaction is catalyzed by the enzyme *myosin light-chain kinase*, which

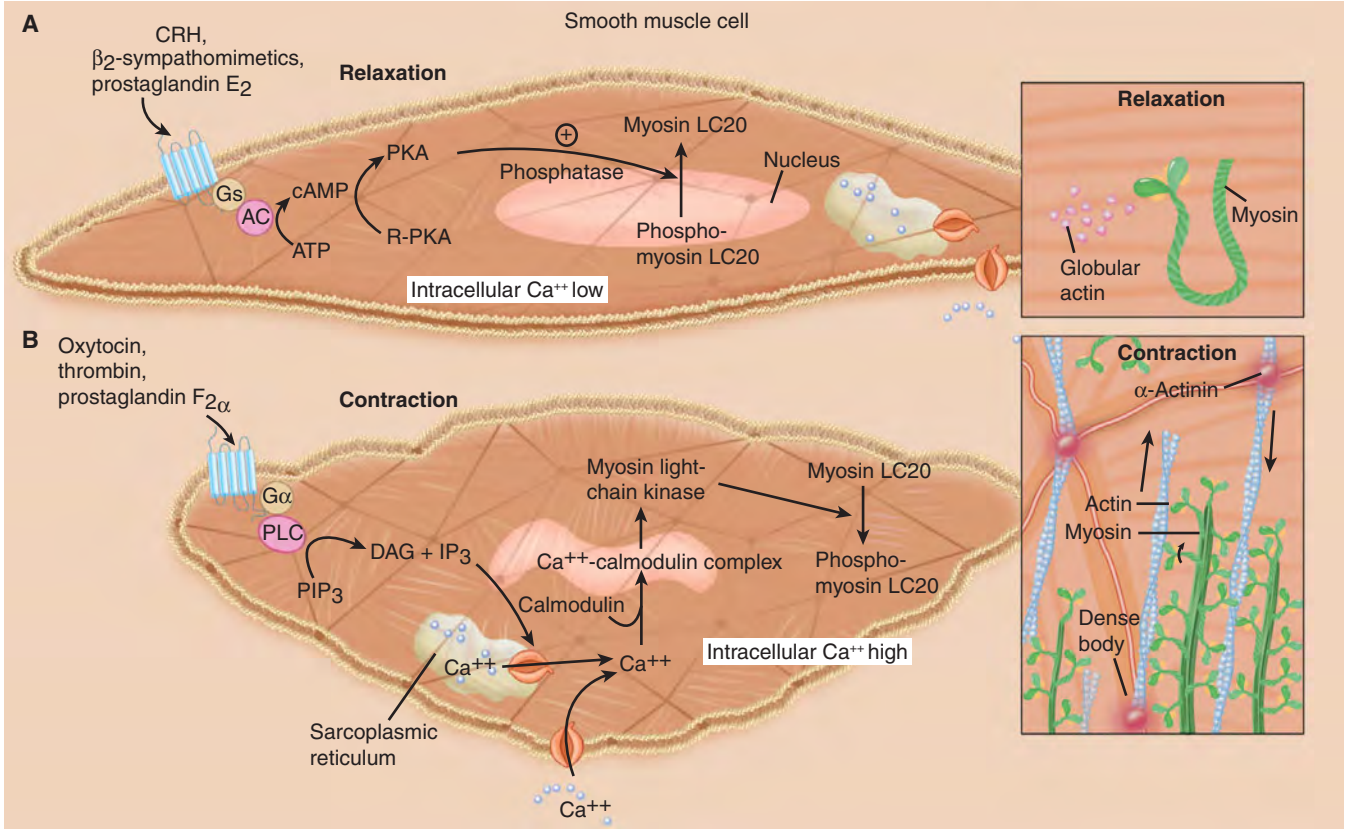

FIGURE 6-12 Uterine myocyte relaxation and contraction. **A.** Uterine relaxation is maintained by factors that increase myocyte cyclic adenosine monophosphate (cAMP). This activates protein kinase A (PKA) to promote phosphodiesterase activity with dephosphorylation of myosin light-chain kinase (MLCK). There are also processes that serve to maintain actin in a globular form, and thus to prevent fibril formation necessary for contractions. **B.** Uterine contractions result from reversal of these sequences. Actin now assumes a fibrillar form, and calcium enters the cell to combine with calmodulin to form complexes. These complexes activate MLCK to bring about phosphorylation of the myosin light chains. This generates ATPase activity to cause sliding of myosin over the actin fibrils, which is a uterine contractor. (AC = adenylyl cyclase; Ca^{++} = calcium; DAG = diacylglycerol; Gs and Gα = G-receptor proteins; IP_3 = inositol triphosphate; LC20 = light chain 20; PIP_3 = phosphatidylinositol 3, 4, 5–triphosphate; PLC = phospholipase C; R-PKA = inactive protein kinase.) (Adapted from Smith R: Parturition. *N Engl J Med* 356(3):271–283, with permission. Copyright © 2007 Massachusetts Medical Society. All rights reserved.)

is activated by calcium. Calcium binds to calmodulin, a calcium-binding regulatory protein, which in turn binds to and activates myosin light-chain kinase.

Intracellular Calcium

Agents that promote contraction act on myometrial cells to increase intracellular cytosolic calcium concentration—$[Ca^{2+}]_i$—or allow an influx of extracellular calcium through ligand- or voltage-regulated calcium channels (see Fig. 6-12). For example, prostaglandin $F_{2\alpha}$ and oxytocin bind their receptors during labor, which opens ligand-activated calcium channels. Activation of these receptors also releases calcium from internal stores in the sarcoplasmic reticulum. This leads to a drop in electronegativity within the cell. Voltage-gated ion channels open, additional calcium ions move into the cell, and cellular depolarization follows. The increase in $[Ca^{2+}]_i$ is often transient, but contractions can be prolonged through the inhibition of myosin phosphatase activity (Woodcock and associates, 2004).

Conditions that decrease $[Ca^{2+}]_i$ and increase intracellular concentrations of cyclic adenosine monophosphate (cAMP) or cyclic guanosine monophosphate (cGMP) ordinarily promote uterine relaxation. Animal studies reveal the importance of small conductance calcium-activated K^+ isoform 3 (SK3) channels in maintenance of uterine relaxation. Expression of the SK3 channel declines at the end of pregnancy as contractility is increased (Pierce and colleagues, 2008). Agents such as corticotropin-releasing hormone (CRH) and prostaglandin E_2 increase intracellular cAMP. Another potential mechanism for maintenance of relaxation is the promotion of actin in a globular form rather than in fibrils, which is required for contraction (Macphee and Lye, 2000; Yu and Lopéz Bernal, 1998).

In addition to myocyte contractility, myocyte excitability is also regulated by changes in the electrochemical potential gradient across the plasma membrane. Prior to labor, myocytes maintain a relatively high interior electronegativity. This state is maintained by the combined actions of the ATPase-driven sodium-potassium pump and the large conductance, voltage- and Ca^{2+}-sensitive K channel—*maxi-K channels* (Parkington and Coleman, 2001). During uterine quiescence, the maxi-K channel is open and allows potassium to leave the cell to maintain interior electronegativity. At the time of labor, changes in electronegativity lead to depolarization and contraction (Brainard and colleagues, 2005; Chanrachakul and co-workers, 2003).

Another important facet of uterine contractility is the need for myocytes to work in synchrony to allow powerful waves of myometrial contraction. These contractions must be coordinated, be of sufficient amplitude, and be interspersed with periods of uterine relaxation to allow appropriate placental blood flow. As parturition progresses, there is increased synchronization of electrical uterine activity.

Myometrial Gap Junctions

As in other muscle cells, the cellular signals that control myometrial contraction and relaxation can be effectively transferred between cells through intercellular junctional channels. Communication is established between myometrial cells by gap junctions, which aid the passage of electrical or ionic coupling currents as well as metabolite coupling. The transmembrane channels that make up the gap junctions consist of two protein "hemichannels" (Sáez and associates, 2005). These are termed *connexons*, and each is composed of six *connexin* subunit proteins (Fig. 6-13). These pairs of connexons establish a conduit between coupled cells for the exchange of small molecules that can be nutrients, waste products, metabolites, second messengers, or ions.

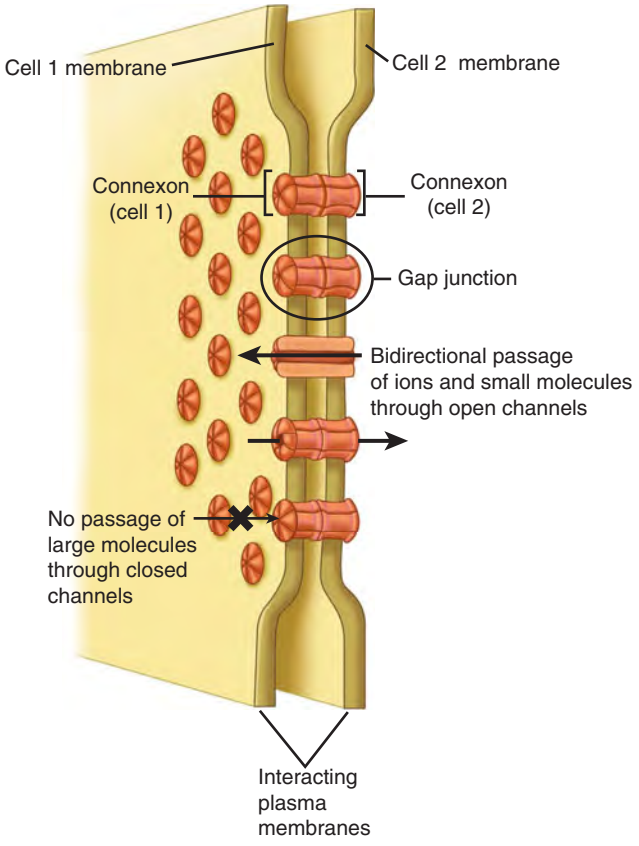

FIGURE 6-13 The protein subunits of gap junction channels are called connexins. Six connexins form a hemichannel (connexon), and two connexons (one from each cell) form a gap junction channel. Connexons and gap junction channels can be formed from one or more connexin proteins. The composition of the gap junction channel is important for their selectivity with regard to passage of molecules and communication between cells.

Optimal numbers of functional permeable gap junctions between myometrial cells are believed to be important for electrical myometrial synchrony. At least 21 human connexin genes have been identified. Four described in the uterus are connexins 26, 40, 43, and 45. Because connexin 43 junctions are scarce in the nonpregnant uterus, they are thought to be most important in gap junction formation during parturition. Most certainly, these increase in size and abundance during human parturition (Chow and Lye, 1994). Finally, mouse models deficient in connexin 43-enriched gap junctions exhibit delayed parturition, further supporting their role (Döring and colleagues, 2006; Tong, 2009).

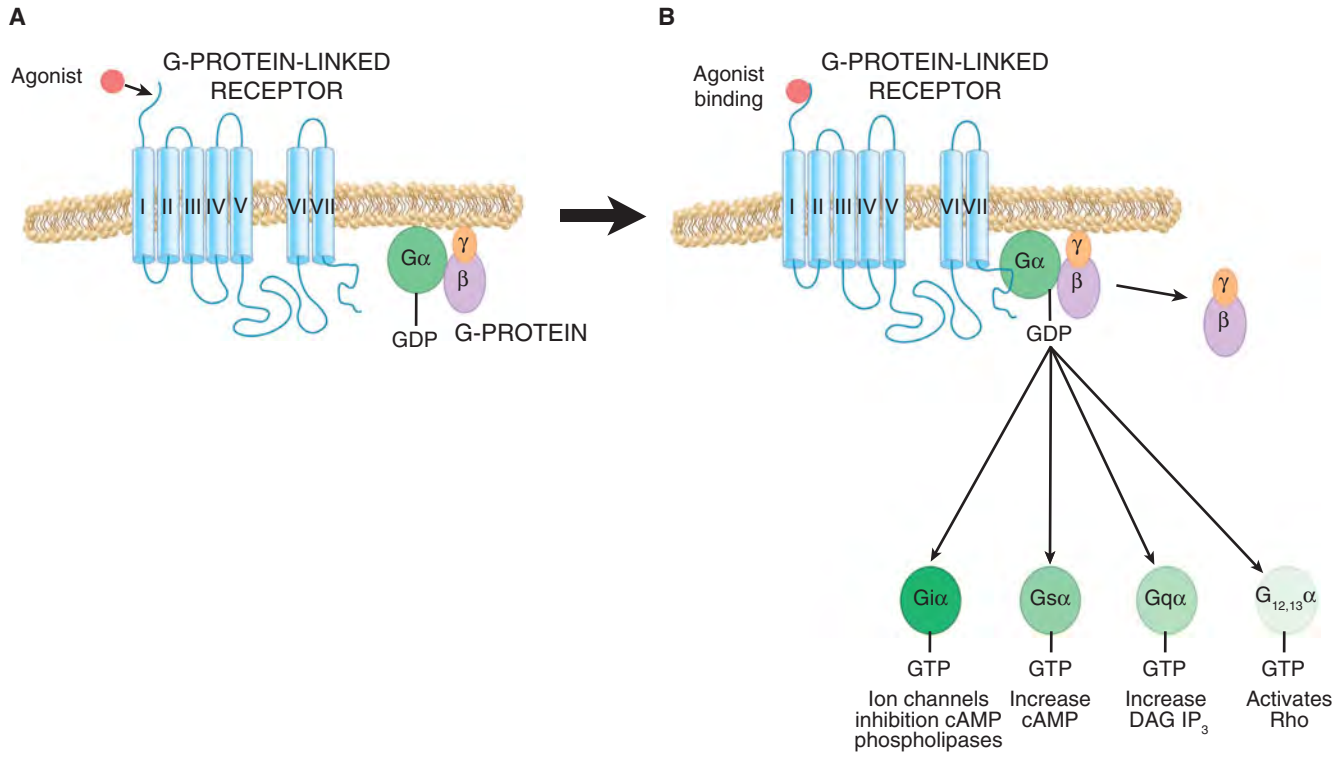

FIGURE 6-14 G-protein-coupled receptor signal transduction pathways. **A.** Receptors coupled to heterotrimeric guanosine-triphosphate (GTP)-binding proteins (G proteins) are integral transmembrane proteins that transduce extracellular signals to the cell interior. G-protein-coupled receptors exhibit a common structural motif consisting of seven membrane-spanning regions. **B.** Receptor occupation promotes interaction between the receptor and the G protein on the interior surface of the membrane. This induces an exchange of guanosine diphosphate (GDP) for GTP on the G protein α subunit and dissociation of the α subunit from the βγ heterodimer. Depending on its isoform, the GTP-α subunit complex mediates intracellular signaling either indirectly by acting on effector molecules such as adenylyl cyclase (AC) or phospholipase C (PLC), or directly by regulating ion channel or kinase function. (cAMP = cyclic adenosine monophosphate; DAG = diacylglycerol; IP_3 = inositol triphosphate.)

Cell Surface Receptors

There are various cell surface receptors that can directly regulate myocyte contractile state. Three major classes are G-protein-linked, ion channel-linked, and enzyme-linked. Multiple examples of each have been identified in human myometrium. These further appear to be modified during the phases of parturition. Most G-protein-coupled receptors are associated with adenylyl cyclase activation—for example, CRHR1α and the LH receptors (Fig. 6-14). Other G-protein-coupled myometrial receptors, however, are associated with G-protein–mediated activation of phospholipase C.

Ligands for the G-protein-coupled receptors include neuropeptides, hormones, and autacoids. Many of these are available to the myometrium during pregnancy in high concentration by several routes. Modes include *endocrine*, via maternal blood; *paracrine*, via contiguous tissues or adjacent cells; or *autocrine*, by direct synthesis in the myocyte (Fig. 6-15). Importantly, myometrial response to a hormone can change during pregnancy. It therefore is conceivable that hormonal myometrial action is regulated by expression of the G-protein-coupled receptor, its associated G-proteins, and the effector plasma membrane proteins.

Cervical Dilatation During Labor

Cervical dilatation is characterized by a large influx of leukocytes into the cervical stroma (Sakamoto and co-workers, 2004, 2005). Cervical tissue levels of leukocyte chemoattractants such as IL-8 are increased just after delivery, as are IL-8 receptors. Identification of genes upregulated just after vaginal delivery further suggests that dilatation and early stages of postpartum repair are aided by inflammatory responses, apoptosis, and activation of proteases that degrade extracellular matrix components (Hassan and associates, 2006; Havelock and co-workers, 2005). The composition of glycosaminoglycans, proteoglycans, and poorly formed collagen fibrils that were necessary during ripening and dilatation must be rapidly removed to allow reorganization and recovery of cervical structure. In the days that follow completion of parturition, rapid recovery of cervical structure involves processes that resolve inflammation, promote tissue repair, and recreate dense cervical connective tissue and structural integrity.

Phase 1: Uterine Quiescence and Cervical Competence

The myometrial quiescence of parturition phase 1 is so remarkable and successful that it probably is induced by multiple

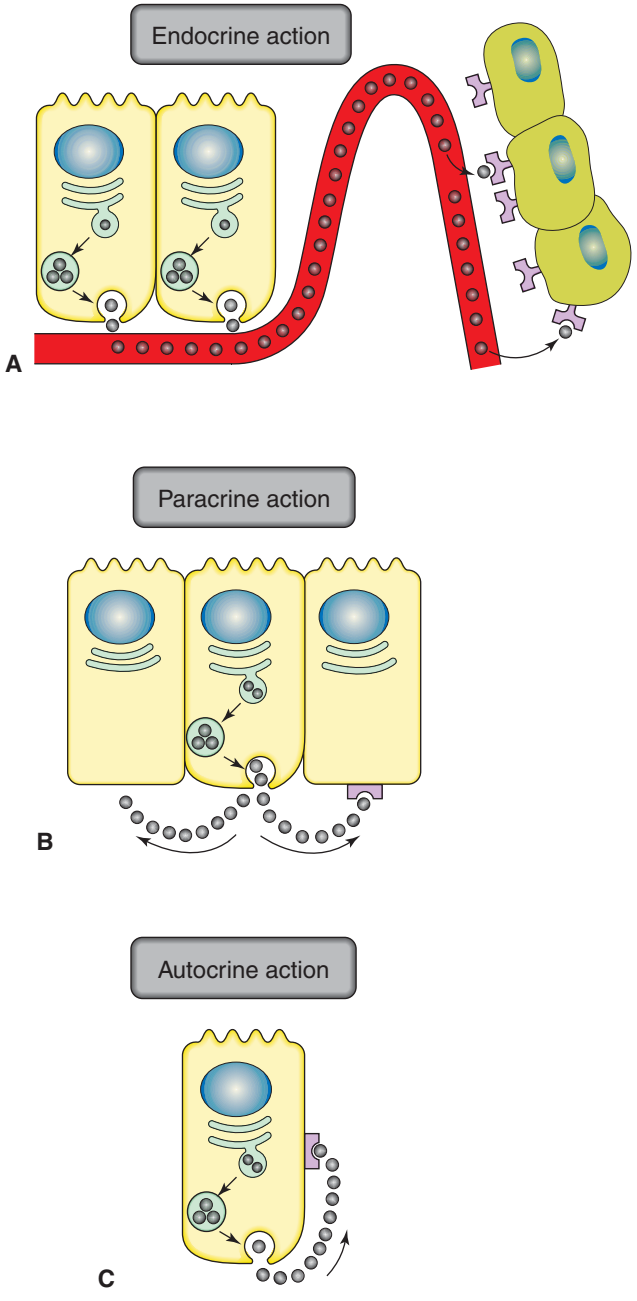

FIGURE 6-15 Different forms of cellular communication are depicted. **A.** Endocrine—chemical messenger travels through blood vessels to reach distant target cells. **B.** Paracrine—chemical messengers are released and diffuse to nearby target cells. **C.** Autocrine—chemical messengers are released by a cell whose membrane receptors then bind the messenger. (From Halvorson, 2008, with permission.)

independent and cooperative biomolecular processes. Individually, some of these processes may be redundant so that pregnancy may continue in the absence of one or more that normally contribute to pregnancy maintenance. It is likely that all manners of molecular systems—neural, endocrine, paracrine, and autocrine—are called on to implement and coordinate a state of relative uterine unresponsiveness. Moreover, a complementary system that protects the uterus against agents that could perturb the tranquil state of phase 1 also must be in place (Fig. 6-16).

Phase 1 of human parturition and its quiescent state are likely the result of many factors that include:

- Actions of estrogen and progesterone via intracellular receptors
- Myometrial cell plasma membrane receptor-mediated increases in cAMP
- The generation of cGMP
- Other systems, including modifications in myometrial cell ion channels.

Progesterone and Estrogen Contributions to Phase 1

In many species, the role of the sex steroid hormones is clear—progesterone inhibits and estrogen promotes the events leading to parturition. In humans, however, it seems most likely that both estrogen and progesterone are components of a broader-based molecular system that implements and maintains phase 1 of parturition. In many species, the removal of progesterone—or *progesterone withdrawal*—directly precedes the progression of phase 1 into phase 2 of parturition. In addition, providing progesterone to some species will delay parturition via a decrease in myometrial activity and continued maintenance of cervical competency (Challis and Lye, 1994). Studies in these species have led to a better understanding of why the progesterone-replete myometrium of phase 1 is relatively noncontractile.

Plasma levels of estrogen and progesterone in normal pregnancy are enormous and in great excess of the affinity constants for their receptors. For this reason, it is difficult to comprehend how relatively subtle changes in the ratio of their concentrations could modulate physiological processes during pregnancy. The teleological evidence, however, for an increased progesterone-to-estrogen ratio in the maintenance of pregnancy and a decline in the progesterone-to-estrogen ratio for parturition is overwhelming. In all species studied to date, including humans, administration of the progesterone-receptor antagonist mifepristone (RU486) or onapristone will promote some or all key features of parturition. These include cervical ripening, increased cervical distensibility, and increased uterine sensitivity to uterotonins (Bygdeman and co-workers, 1994; Chwalisz, 1994; Wolf and colleagues, 1993).

The exact role of estrogen in regulating human uterine activity and cervical competency is even less well understood. That said, it appears that estrogen can act to promote progesterone responsiveness, and in doing so, promote uterine quiescence. The estrogen receptor, acting via the estrogen-response element of the progesterone-receptor gene, induces progesterone-receptor synthesis, which allows increased progesterone-mediated function.

Steroid Hormone Regulation of Myometrial Cell-to-Cell Communication. Progesterone likely increases uterine quiescence by direct or indirect effects that cause decreased expression

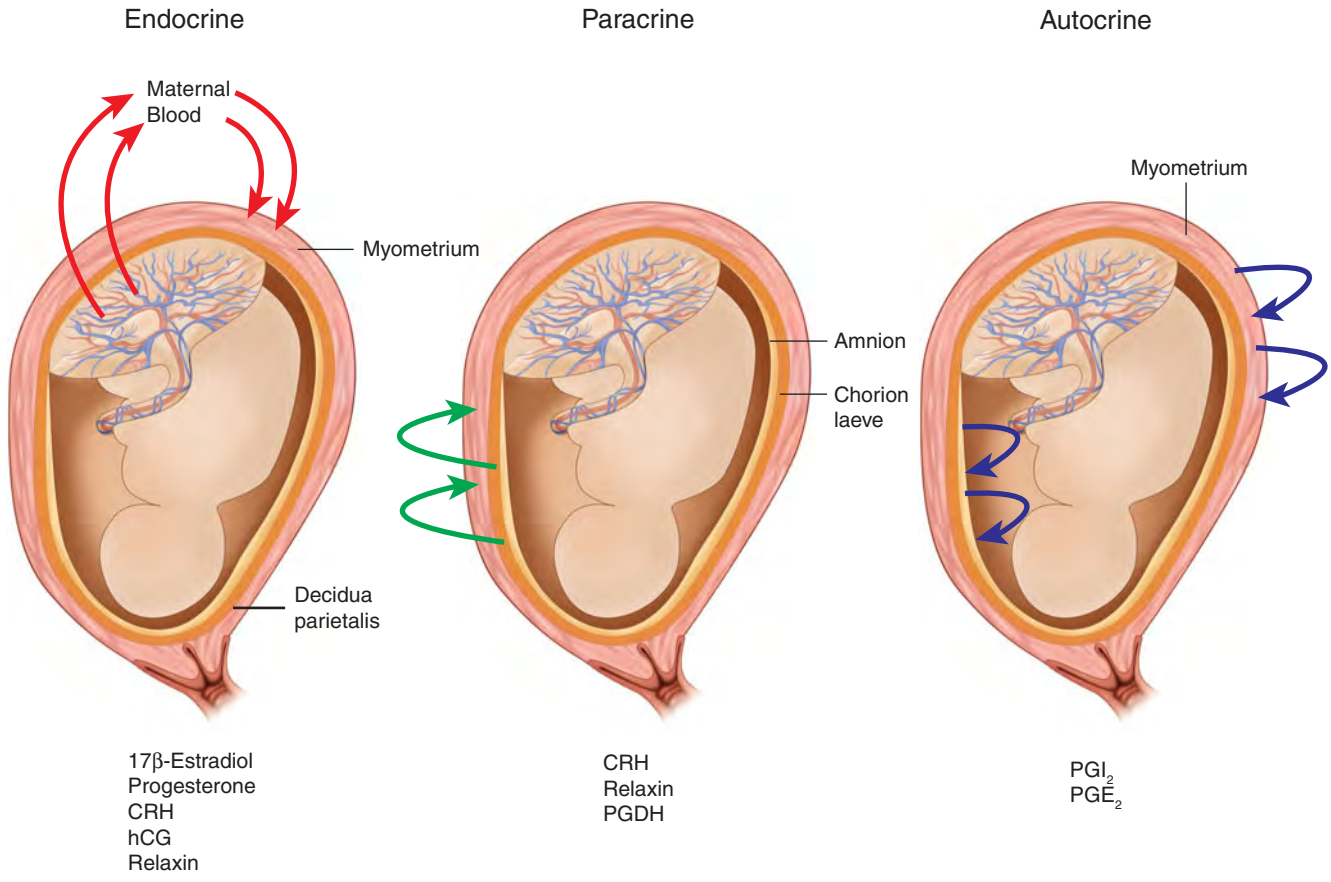

FIGURE 6-16 Theoretical fail-safe system involving endocrine, paracrine, and autocrine mechanisms for the maintenance of phase 1 of parturition, uterine quiescence. (CRH = corticotropin-releasing hormone; hCG = human chorionic gonadotropin; PGE_2 = prostaglandin E_2; PGI_2= prostaglandin I_2; PGDH = 15-hydroxy prostaglandin dehydrogenase.)

of the contraction-associated proteins (CAPs). Progesterone has been shown to inhibit expression of the gap junctional protein connexin 43 in several rodent models of labor, and progesterone administration prevents or delays labor (Fig. 6-17). Conversely, inhibition of progesterone activity at midgestation using the progesterone-receptor antagonist RU486 leads to a premature induction of myometrial connexin 43 protein production, and thus stimulates labor.

Estrogen treatment also promotes myometrial gap junction formation in some animals by increasing connexin 43 synthesis. The simultaneous administration of anti-estrogens prevents this (Burghardt and colleagues, 1984). Progesterone treatment, however, negates the stimulatory effect of estrogen on the development of gap junctions in some animals.

G-Protein–Coupled Receptors That Promote Myometrial Relaxation

A number of G-protein-coupled receptors that normally are associated with $G_{\alpha s}$-mediated activation of adenylyl cyclase and increased levels of cAMP are present in myometrium. These receptors together with appropriate ligands may act—in concert with sex steroid hormones—as part of a fail-safe system to maintain uterine quiescence (Price and associates, 2000; Sanborn and colleagues, 1998).

Beta-Adrenoreceptors. The β-adrenergic receptors have served as prototypes of cAMP signaling in causing myometrium relaxation. Most commonly, β-adrenergic receptors mediate $G_{\alpha s}$-stimulated increases in adenylyl cyclase, increased levels of cAMP, and myometrial cell relaxation. The rate-limiting factor in the β-receptor system is likely the number of receptors expressed and the level of adenylyl cyclase expression. The number of G-proteins in most systems far exceeds the number of receptors and effector molecules. These properties have led to development of β-mimetic agents that are used clinically to promote uterine quiescence and thereby forestall labor. Examples are ritodrine and terbutaline, which are discussed in Chapter 36 (p. 823).

Luteinizing Hormone (LH) and Human Chorionic Gonadotropin (hCG) Receptors. The G-protein-coupled receptor for LH-hCG has been demonstrated in myometrial smooth muscle and blood vessels (Lei and co-workers, 1992; Ziecik and colleagues, 1992). Levels of myometrial LH-hCG receptors during pregnancy are greater before than during labor (Zuo and colleagues, 1994). Chorionic gonadotropin acts to activate adenylyl cyclase by way of a plasma membrane receptor-$G_{\alpha s}$-linked system. This decreases contraction frequency and force and decreases the number of tissue-specific myometrial cell gap junctions (Ambrus

and Rao, 1994; Eta and co-workers, 1994). Thus, high circulating levels of hCG may be one mechanism causing uterine quiescence.

Relaxin. This peptide hormone consists of an A and B chain and is structurally similar to the insulin family of proteins (Bogic and associates, 1995; Weiss, 1995). Relaxin mediates lengthening of the pubic ligament, cervical softening, vaginal relaxation, and inhibition of myometrial contractions. There are two separate human relaxin genes, designated H1 and H2. The H1 gene is primarily expressed in the decidua, trophoblast, and prostate, whereas the H2 gene is primarily expressed in the corpus luteum.

Relaxin in plasma of pregnant women is believed to originate exclusively by secretion from the corpus luteum. Plasma levels peak at about 1 ng/mL between 8 and 12 weeks and thereafter decline to lower levels that persist until term. The plasma membrane receptor for relaxin—*relaxin family peptide receptor 1 (RXFP1)*—mediates activation of adenylyl cyclase. Relaxin may promote myometrial relaxation. Although it inhibits contractions of nonpregnant myometrial strips, it does not inhibit those of uterine tissue taken from pregnant women.

Relaxin also effects cervical remodeling through cell proliferation and modulation of extracellular matrix components such as collagen and hyaluronan (Park and associates, 2005). Consistent with a role in cervical remodeling, mice deficient in relaxin or its RXFP1 receptor have difficult parturition and in some cases, are unable to deliver their young (Feng and co-workers, 2005).

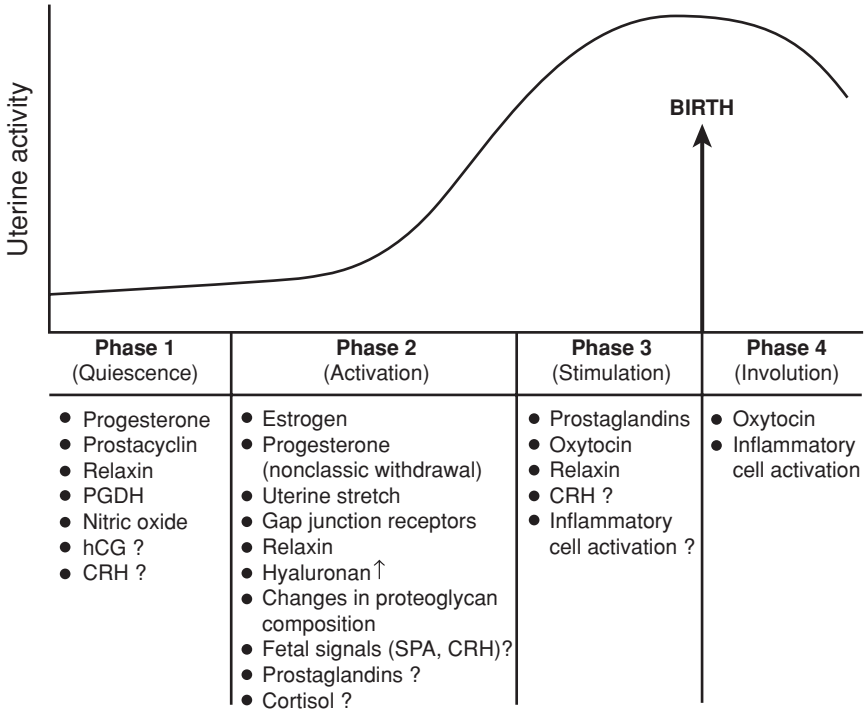

FIGURE 6-17 The key factors thought to regulate the phases of parturition. (CRH = corticotropin-releasing hormone; hCG = human chorionic gonadotropin; SPA = surfactant protein A.) (Adapted from JRG Challis, DM Sloboda, N Alfaidy, et al., 2002, *Reproduction*, Vol. 124, No. 1, p. 2, © Society for Reproduction and Fertility 2002, by permission.)

Corticotropin-Releasing Hormone (CRH). This hormone is synthesized in the placenta and hypothalamus. As discussed later, CRH plasma levels increase dramatically during the final 6 to 8 weeks of normal pregnancy and have been implicated in the mechanisms controlling the timing of human parturition (Smith, 2007; Wadhwa and colleagues, 1998). Recent studies reveal a dual role of CRH during pregnancy and labor that is mediated by specific CRH-receptor variants and the signalling pathways they initiate (Zhang and co-workers, 2008). During phase 2, CRH binds the receptor CRH-R1, which acting through G5α protein and adenylate cyclase, leads to production of cAMP and subsequent inhibition of myometrial activity. In contrast, at term, CRH can activate the Gqα protein pathway, which favors myometrial contraction. Another aspect of CRH regulation is union of CRH to its binding protein, which can limit bioavailability. CRH-binding protein levels are high during pregnancy and are reported to decline at the time of labor.

Prostaglandins. The prostanoids interact with a family of eight different G-protein-coupled receptors, several of which are expressed in myometrium (Myatt and Lye, 2004). Prostaglandins most commonly have been considered as uterotonins. However, they have diverse effects, and some act as smooth muscle relaxants.

The major synthetic pathways involved in prostaglandin biosynthesis are shown in Figure 6-18. Prostaglandins are produced using plasma membrane–derived arachidonic acid, which usually is released by the action of the phospholipases A_2 or C on membrane phospholipids. Arachidonic acid can then act as substrate for both type 1 and type 2 prostaglandin H synthase—PGHS-1 and -2, also called cyclooxygenase-1 and -2—COX-1 and 2. Both PGHS isoforms convert arachidonic acid to the unstable endoperoxide prostaglandin G_2 and then to prostaglandin H_2. These enzymes are the target of many nonsteroidal anti-inflammatory drugs (NSAIDs). Indeed, ability of specific NSAIDs to work as tocolytics was considered promising until they were shown to have adverse effects on fetal physiology and development (see Chap. 14, p. 319) (Loudon and coworkers, 2003; Olson and colleagues, 2003, 2007). Through prostaglandin isomerases, prostaglandin H_2 is converted to active prostaglandins, including PGE_2, $PGF_{2\alpha}$, and PGI_2.

Prostaglandin isomerase expression is tissue-specific, thus controlling the relative production of various prostaglandins. Another important control point for prostaglandin activity is its metabolism, which most often is through the action of 15-hydroxyprostaglandin dehydrogenase (PGDH). Expression of this enzyme can be regulated in the uterus, which is important because of its ability to rapidly inactivate prostaglandins to their 15-keto metabolites.

The effect of prostaglandins on tissue targets is complicated in that there are a number of G-protein-coupled prostaglandin

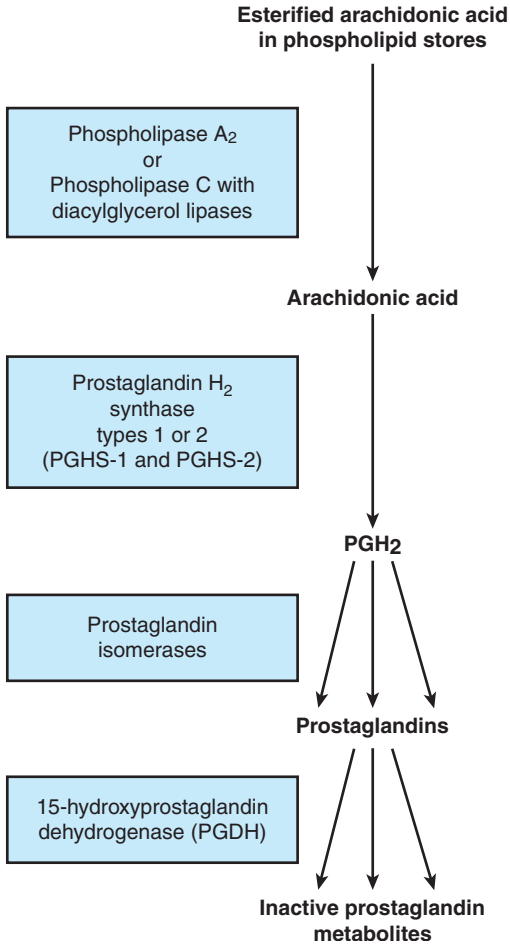

FIGURE 6-18 Overview of the prostaglandin biosynthetic pathway.

receptors (Coleman and associates, 1994). This family of receptors is classified according to the binding specificity of a given receptor to a particular prostaglandin. The receptors are TP—thromboxane A_2; DP—PGD_2; IP—prostacyclin or PGI_2; FP—$PGF_{2\alpha}$ receptor; and $EP_{1,2,3,\text{and } 4}$-PGE_2 receptors. Both PGE_2 and PGI_2 could potentially act to maintain uterine quiescence by increasing cAMP signaling, yet PGE_2 can promote uterine contractility through binding to EP_1 and EP_3 receptors. And also, PGE_2, PGD_2, and PGI_2 have been shown to cause vascular smooth muscle relaxation and vasodilatation in many circumstances. Thus, either the generation of specific prostaglandins or the relative expression of the various prostaglandin receptors may determine myometrial responses to prostaglandins (Lyall, 2002; Olson, 2003, 2007; Smith, 2001; Smith, 1998, and all their colleagues).

In addition to gestational changes, other studies show that there may be regional changes in the upper and lower uterine segments. Expression of COX-2 was shown to be spatially regulated in myometrium and cervix in pregnancy and labor, and an increasing concentration gradient from the fundus to the cervix was noted (Havelock and associates, 2005). Thus, it is entirely possible that prostanoids contribute to myometrial relaxation at one stage of pregnancy and to regional—fundal—myometrial contractions—after initiation of parturition (Myatt and Lye, 2004). Animal studies suggest changes in relative levels of PGE_2 receptors in the term cervix (Schmitz and co-workers, 2006).

Atrial and Brain Natriuretic Peptides and Cyclic Guanosine Monophosphate (cGMP)

Activation of guanylyl cyclase increases intracellular cGMP levels, which also promotes smooth muscle relaxation (Word and colleagues, 1993). Guanylate cyclase activity and cGMP content is increased in pregnant myometrium before labor starts compared with after labor has begun (Telfer and colleagues, 2001). Intracellular cGMP levels can be stimulated by either atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP) receptors, which are both present in myometrium during pregnancy (Itoh and co-workers, 1994). BNP is secreted by amnion in large amounts, and ANP is expressed in placenta (Itoh and associates, 1993; Lim and Gude, 1995).

Soluble guanylyl cyclase is also activated by nitric oxide, which because of its hydrophobic nature, readily penetrates the plasma membrane to enter cells. Nitric oxide reacts with iron and stimulates it to produce cGMP and myometrial relaxation (Izumi and colleagues, 1993). Nitric oxide is synthesized in decidua, myometrial blood vessels, and nerves (Yallampalli and colleagues, 1994a, 1994b). Its role in possible uterine quiescence is not understood.

Accelerated Uterotonin Degradation and Phase 1 of Parturition

In addition to pregnancy-induced compounds that stimulate myometrial cell refractoriness, there are striking increases in the activities of enzymes that degrade or inactivate endogenously produced uterotonins. Some of these and their degradative enzymes include PGDH, which degrades prostaglandins; enkephalinase and endothelins; oxytocinase and oxytocin; diamine oxidase and histamine; catechol *O*-methyltransferase and catecholamines; angiotensinases and angiotensin-II; and platelet-activating factor (PAF) acetylhydrolase and PAF. Activities of several of these enzymes are increased by progesterone action and many decrease late in gestation (Bates, 1979; Casey, 1980; Germain, 1994, and all their colleagues).

Phase 2: Uterine Activation and Cervical Ripening

Classical Progesterone Withdrawal and Parturition

In species that exhibit progesterone withdrawal, progression of parturition to labor can be blocked by administering progesterone to the mother. In pregnant women, however, there are conflicting reports as to whether or not progesterone administration can delay the timely onset of parturition or prevent preterm labor. Some studies suggest that progesterone neither prevents preterm labor nor appears to extend labor, but others suggest the opposite (Mackenzie and associates, 2006). Clinically, any advantages to the use of progesterone or its metabolite, 17-hydroxyprogesterone, to decrease the incidence of preterm labor in high-risk populations seem minimal (Fonseca, 2007; Meis, 2003; Rouse, 2007, and all their colleagues). The 17-hydroxyprogesterone molecule binds and activates the

progesterone receptor less so than progesterone. Further research may help explain its differential action and how it could be better used to prevent preterm labor.

Progesterone Receptor Antagonists and Human Parturition

When the steroidal antiprogestin, mifepristone or RU486, is administered during the latter phase of the ovarian cycle, it induces menstruation prematurely. It is also an effective abortifacient during early pregnancy (see Chap. 9, p. 232). Mifepristone is a classical steroid antagonist, acting at the level of the progesterone receptor. Although less effective in inducing abortion or labor in women later in pregnancy, mifepristone appears to have some effect on cervical ripening and increasing myometrial sensitivity to uterotonins (Chwalisz and Garfield, 1994; Chwalisz, 1994; Berkane and associates, 2005). These data suggest that humans have a mechanism for progesterone inactivation, whereby the myometrium and cervix becomes refractory to the blocking actions of progesterone.

Functional Progesterone Withdrawal in Human Parturition

As an alternative to classical progesterone withdrawal resulting from decreased secretion, research has focused on unique human mechanisms that have evolved to inhibit progesterone action. In theory, functional progesterone withdrawal or antagonism could be mediated through several mechanisms:

- Changes in the relative expression of the nuclear progesterone receptor (PR) protein isoforms, PR-A, PR-B, and PR-C
- Changes in the relative expression of membrane-bound progesterone receptors
- Posttranslational modifications of the progesterone receptor
- Alterations in progesterone receptor activity through changes in the expression of co-activators or co-repressors that directly influence receptor function
- Local inactivation of progesterone by steroid-metabolizing enzymes or synthesis of a natural antagonist.

Indeed, there is experimental evidence that lends support to each of these possibilities. Evidence now suggests that progesterone receptor activity is decreased late in gestation. As discussed in Chapter 3 (p. 41), there are numerous isoforms of the receptor—these include PR-A, PR-B, and PR-C. In vitro studies have led to the concept that PR-B is the principal mediator of progesterone actions, whereas PR-A and PR-C decrease progesterone responsiveness by repressing the transcriptional activation of the PR-B isoform. With respect to functional progesterone withdrawal, in a series of studies, it has been shown that there is a shift in the relative ratio of PR-A to PR-B within the myometrium late in gestation (Madsen, 2004; Mesiano, 2002; Pieber, 2001, and all their colleagues). Analysis of placental tissues for PR-A and PR-B suggests that the ratio is similarly modified in decidua and chorion, but that there is decreased overall progesterone receptor expression in the amnion (Haluska and co-workers, 2002). Similarly, studies of cervical stroma suggest changes in receptor isoforms (Stjernholm-Vladic and associates, 2004). And Condon and associates (2006) reported that myometrial PR-C to PR-B ratio increased, but *only* in fundal—and not lower-segment—myometrium. PR coactivators have also been shown to decline in term myometrium, which may contribute to reduced progesterone action (Condon and associates, 2003).

In addition to the nuclear progesterone receptors described above, a number of membrane-associated progesterone receptors have been identified that include mPR_{α}, mPR_{β}, and mPR_{γ}. The first two couple to inhibitory G-proteins. Ligand binding to these receptors decreases cAMP levels and increases myosin phosphorylation, both of which promote uterine contractility. Although still not entirely clear, current evidence suggests that changes in expression of membrane PR isoforms may also promote the transition from myometrial quiescence to activation (Karteris and co-workers, 2006).

There is evidence in human and rodent models that local action of enzymes catabolize progesterone to metabolites that have a weak affinity for the progesterone receptor. One of these enzymes is steroid 5α-reductase type 1. In mice that cannot express this enzyme, the cervix does not ripen and parturition does not ensue (Mahendroo and colleagues, 1999). Similarly, mice deficient in the enzyme 20α-hydroxy-steroid dehydrogenase have delayed parturition (Piekorz and associates, 2005). A decline in 17β-hydroxysteroid dehydrogenase type 2 in the human cervix at term results in a net increase in estrogen and decline in progesterone (Andersson and co-workers, 2008).

And lastly, there is some support for antiprogestin-like activities of glucocorticoids on progesterone receptor activity (Karalis and co-workers, 1996). Because glucocorticoids play an important role in parturition initiation in several species, examining their potential role as an antiprogestin in humans warrants further study.

Taken together, all of these observations support the concept that multiple pathways exist for a functional progesterone withdrawal that includes changes in PR isoform and receptor coactivator levels and in local hormone metabolism to less active products.

Oxytocin Receptors

It is still controversial whether oxytocin plays a role in the early phases of uterine activation, or whether its sole function is in the expulsive phase of labor. Most studies of regulation of myometrial oxytocin receptor synthesis have been performed in the rat and mouse. Disruption of the oxytocin receptor gene in the mouse does not affect parturition. This suggests that, at least in this species, multiple systems likely ensure that parturition occurs. There is little doubt, however, that there is an increase in myometrial oxytocin receptors during phase 2 of parturition. Moreover, their activation results in increased phospholipase C activity and subsequent increases in cytosolic calcium and uterine contractility.

Progesterone and estradiol appear to be the primary regulators of oxytocin receptor expression. Estradiol treatment in vivo or in myometrial explants increases myometrial oxytocin receptors. This action, however, is prevented by simultaneous treatment with progesterone (Fuchs and colleagues, 1983). Progesterone also may act within the myometrial cell to increase

oxytocin receptor degradation and inhibit oxytocin activation of its receptor at the cell surface (Bogacki and associates, 2002; Soloff and colleagues, 1983). These data indicate that one of the mechanisms whereby progesterone maintains uterine quiescence is through the inhibition of myometrial oxytocin response.

The increase in oxytocin receptors in nonhuman species appears to be mainly regulated either directly or indirectly by estradiol. Treatment of several species with estrogen leads to a uterine oxytocin receptors increase (Blanks and co-workers, 2003; Challis and Lye, 1994). The level of oxytocin receptor mRNA in human myometrium at term is greater than that found in preterm myometrium (Wathes and co-workers, 1999). Thus, increased receptors at term may be attributable to increased gene transcription. An estrogen response element, however, is not present in the oxytocin receptor gene, suggesting that the stimulatory effects of estrogen may be indirect.

Human studies suggest that inflammatory-related rapid-response genes may regulate oxytocin receptors (Bethin, 2003; Kimura, 1999; Massrieh, 2006, and all their colleagues). These receptors also are present in human endometrium and in decidua at term and stimulate prostaglandin production (Fuchs and associates, 1981). In addition, these receptors are found in the myometrium and at lower levels, in amniochorion–decidual tissues (Benedetto and associates, 1990; Wathes and co-workers, 1999).

Relaxin

Although relaxin may play a role in maintenance of uterine quiescence, it also has roles in phase 2 of parturition. These include remodeling of the extracellular matrix of the uterus, cervix, vagina, breast, and pubic symphysis as well as promoting cell proliferation and inhibiting apoptosis. Relaxin's actions on cell proliferation and apoptosis are mediated through the G-protein-coupled receptor, RXFP1, whereas some but not all actions of relaxin on matrix remodeling are mediated through RXFP1 (Samuel and co-workers, 2009; Yao and associates, 2008). Although the precise mechanisms for modulation of matrix turnover have not been fully elucidated, relaxin appears to mediate synthesis of glycosaminoglycans and proteoglycans and to degrade matrix macromolecules such as collagen by induction of matrix metalloproteases. Relaxin promotes growth of the cervix, vagina, and pubic symphysis and is necessary for breast remodeling for lactation. Consistent with its proposed roles, mice deficient in relaxin or the RXFP1 receptor have protracted labor, reduced growth of the cervix, vagina, and symphysis, and are unable to nurse because of incomplete nipple development (Feng, 2005; Park, 2005; Yao, 2008, and all their associates).

Fetal Contributions to Initiation of Parturition

It is intellectually intriguing to envision that the mature human fetus provides the signal to initiate parturition. Teleologically, this seems most logical because such a signal could be transmitted in several ways to suspend uterine quiescence. The fetus may provide a signal through a blood-borne agent that acts on the placenta. Research is ongoing to better understand the fetal signals that contribute to the initiation of parturition (Mendelson, 2009). Although signals may arise from the fetus, it is likely that the uterus and cervix first must be prepared for labor before a uterotonin produced by the fetus or elsewhere can be optimally effective (Casey and MacDonald, 1994).

Uterine Stretch and Parturition

There is now considerable evidence that fetal growth is an important component in uterine activation in phase 1 of parturition. In association with fetal growth, significant increases in myometrial tensile stress and amnionic fluid pressure follow (Fisk and co-workers, 1992). With uterine activation, stretch is required for induction of specific contraction-associated proteins (CAPs). Stretch increases expression of the gap junction protein—connexin 43, as well as oxytocin receptors. Others have hypothesized that stretch plays an integrated role with fetal–maternal endocrine cascades of uterine activation (Lyall and co-workers, 2002; Ou and colleagues, 1997, 1998).

Clinical support for a role of stretch comes from the observation that multifetal pregnancies are at a much greater risk for preterm labor than singletons (Gardner and co-workers, 1995). Preterm labor is also significantly more common in pregnancies complicated by hydramnios (Many and associates, 1996). Although the mechanisms causing preterm birth in these two examples are debated, a role for uterine stretch must be considered.

Cell signaling systems used by stretch to regulate the myometrial cell continue to be defined. This process—*mechanotransduction*—may include activation of cell-surface receptors or ion channels, transmission of signals through extracellular matrix, or release of autocrine molecules that act directly on myometrium (Shynlova and co-workers, 2009). For example, the extracellular matrix protein, fibronectin, and its cell surface receptor, alpha 5 integrin receptor, are induced in the rodent in response to stretch (Shynlova and colleagues, 2007). This interaction may aid force transduction during labor contraction by anchoring hypertrophied myocytes to the uterine extracellular matrix.

Fetal Endocrine Cascades Leading to Parturition

The ability of the fetus to provide endocrine signals that initiate parturition has been demonstrated in several species. More than 30 years ago, Liggins and associates (1967, 1973) demonstrated that the fetus provides the signal for the timely onset of parturition in sheep. This signal was shown to come from the fetal hypothalamic-pituitary-adrenal axis (Whittle and co-workers, 2001).

Defining the exact mechanisms regulating human parturition has proven more difficult, and all evidence suggests that it is not regulated in the exact manner seen in the sheep. Even so, activation of the human fetal hypothalamic–pituitary–adrenal placental axis is considered a critical component of normal parturition. Moreover, premature activation of this axis is considered to prompt many cases of preterm labor (Challis and co-workers, 2000, 2001). As in the sheep, steroid products of the human fetal adrenal gland are believed to have effects on the placenta and membranes that eventually transform myometrium from a quiescent to contractile state. A key component in the human

may be the unique ability of the placenta to produce large amounts of corticotropin-releasing hormone (CRH).

Actions of Corticotropin-Releasing Hormone on the Fetal Adrenal Gland

The human fetal adrenal glands are morphologically, functionally, and physiologically remarkable organs. At term, the fetal adrenal glands weigh the same as those in the adult and are similar in size to the adjacent fetal kidney (Chap. 3, p. 69). The daily steroid production by the fetal adrenal glands near term is estimated to be 100 to 200 mg/day. This is higher than the 30 to 40 mg/day seen in adult glands at rest. Within the fetal adrenal gland, steroidogenic function and zonation differ from the adult. For example, significant amounts of cortisol are not produced in the fetal gland until the last trimester. As a result, fetal cortisol levels increase during the last weeks of gestation (Murphy, 1982). During this same period, levels of dehydroepiandrosterone sulfate (DHEA-S) production also are increasing significantly, leading to increases in maternal estrogens, particularly estriol.

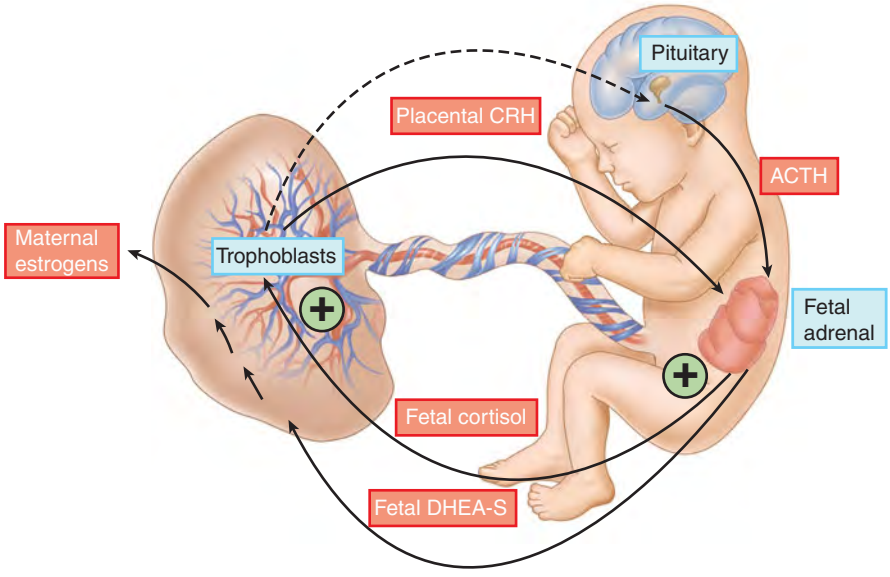

FIGURE 6-19 The placental–fetal adrenal endocrine cascade. In late gestation, placental corticotropin-releasing hormone (CRH) stimulates fetal adrenal production of dehydroepiandrosterone sulfate (DHEA-S) and cortisol. The latter stimulates production of placental CRH, which leads to a feed-forward cascade that enhances adrenal steroid hormone production. (ACTH = adrenocorticotropic hormone.)

These increases in fetal adrenal gland activity contrast with fetal pituitary adrenocorticotropic hormone (ACTH) levels, which do not increase until actual labor onset. Thus, substantial growth and increased steroid synthesis during latter gestation is at a time when fetal plasma ACTH levels are low (Winters and co-workers, 1974). It is presumed that alternate stimuli for growth and steroidogenesis are likely placentally derived. In support of this, the fetal zone of the adrenal gland undergoes rapid involution immediately after birth, when placenta-derived factors are no longer available.

Many favor CRH of placental origin to be a critical agent for fetal adrenal hypertrophy and increased steroidogenesis in late pregnancy. Some in vitro studies have shown that CRH stimulates fetal adrenal DHEA-S and cortisol biosynthesis (Parker and associates, 1999; Smith and co-workers, 1998). The ability of CRH to regulate the adrenal glands and of the adrenals to regulate placental CRH production supports the idea of a feed-forward endocrine cascade that initiates late in gestation (Fig. 6-19).

Placental Corticotropin-Releasing Hormone Production.

A CRH hormone identical to maternal and fetal hypothalamic CRH is synthesized by the placenta in relatively large amounts (Grino and associates, 1987; Saijonmaa and colleagues, 1988). One important difference is that, unlike hypothalamic CRH, which is under glucocorticoid negative feedback, cortisol has been shown to *stimulate* placental CRH production (Jones and co-workers, 1989; Marinoni and associates, 1998). This ability makes it possible to create a feed-forward endocrine cascade that does not end until separation of the fetus from the placenta at delivery.

Maternal plasma CRH levels are low in the first trimester and rise from midgestation to term. In the last 12 weeks, CRH plasma levels rise exponentially, peaking during labor and then falling precipitously after delivery (Frim and associates, 1988; Sasaki and colleagues, 1987). Amnionic fluid CRH levels similarly increase in late gestation. And although umbilical cord blood CRH levels are lower than those in maternal circulation, they are within the range of concentrations that are found to stimulate fetal adrenal steroidogenesis (Goland and co-workers, 1986, 1993; Perkins and associates, 1995).

Corticotropin-releasing hormone is the only trophic hormone–releasing factor to have a specific serum binding protein. During most of pregnancy, it appears that CRH-binding protein (CRH-BP) binds most maternal circulating CRH. Binding likely inactivates ACTH-stimulating activity of placental CRH (Lowry, 1993). During later pregnancy, however, CRH-BP levels in both maternal plasma and amnionic fluid decline at the same time CRH levels are strikingly increasing. This leads to markedly increased levels of bioavailable CRH (Perkins and co-workers, 1995; Petraglia and associates, 1997).

In pregnancies in which the fetus can be considered to be "stressed" from various complications, concentrations of CRH in fetal plasma, amnionic fluid, and maternal plasma are increased compared with those seen in normal gestation (Berkowitz, 1996; Goland, 1993; McGrath, 2002; Perkins, 1995, and all their co-workers). The placenta is likely the source for this increased CRH. For example, placental CRH content was fourfold higher in placentas from women with preeclampsia than in those from normal pregnancies (Perkins and co-workers, 1995). Moreover, the biological impact of increased CRH levels is likely to be amplified in such instances as a result

of subnormal levels of CRH-BP (Petraglia and co-workers, 1996). Such increases in placental CRH production during normal gestation and the excessive secretion of placental CRH in complicated pregnancies may play a role in the normal gestational increases in fetal adrenal cortisol synthesis (Murphy, 1982). It also may result in the supranormal levels of umbilical cord blood cortisol noted in stressed neonates (Falkenberg and colleagues, 1999; Goland and co-workers, 1994).

Corticotropin-Releasing Hormones and Parturition Timing

Placental CRH has been proposed to play several roles in parturition regulation. Placental CRH may enhance fetal cortisol production to provide positive feedback so that the placenta produces more CRH. Resulting high levels of CRH may modulate myometrial contractility via interaction with the CRH receptor isoform, CRH-R1d. This isoform is known to enhance myometrial contractile response (Grammatopoulos, 1994, 1995, 1999; Hillhouse, 1993; Markovic, 2007, and all their colleagues). It has also been proposed that cortisol affects the myometrium indirectly by stimulating the fetal membranes to increase prostaglandin synthesis.

And finally, CRH has been shown to stimulate fetal adrenal C_{19}-steroid synthesis, thereby increasing substrate for placental aromatization. Increased production of estrogens would shift the estrogen-to-progesterone ratio and promote the expression of a series of contractile proteins in the myometrium, leading to a loss of myometrial quiescence.

Some have proposed that the rising level of CRH at the end of gestation reflects a *fetal-placental clock* (McLean and colleagues, 1995). CRH levels vary greatly among women, and it appears that the rate of increase in maternal CRH levels is a more accurate predictor of pregnancy outcome than is a single measurement (Leung and associates, 2001; McGrath and Smith, 2002). In this regard, the placenta and fetus, through endocrinological events, influence the timing of parturition at the end of normal gestation.

Fetal Lung Surfactant and Parturition

Surfactant protein A (SP-A) produced by the fetal lung is required for lung maturation. Its levels are increased in amnionic fluid at term in women and mice. Recent studies in the mouse suggest that the increasing SP-A concentrations in amnionic fluid activate fluid macrophages to migrate into the myometrium and induce a transcription factor—*nuclear factor-kB* (Condon and co-workers, 2004). This factor activates inflammatory response genes in the myometrium, which in turn promote uterine contractility. This model supports the supposition that fetal signals play a role in parturition initiation. The exact mechanisms by which SP-A activates myometrial contractility in women, however, remains to be clarified as studies in women suggest that fetal macrophages in the amnionic cavity do not enter the myometrium during labor (Kim and colleagues, 2006; Leong and associates, 2008). Pulmonary surfactant and components of surfactant such as platelet activating factor, when secreted into human amnionic fluid, have been reported to stimulate prostaglandin synthesis (PGE_2) and uterine contractility. This supports a function of SP-A in human parturition (Lopez and co-workers, 1988; Toyoshima and associates, 1995).

Fetal Anomalies and Delayed Parturition

There is fragmentary evidence that pregnancies with markedly diminished estrogen production may be associated with prolonged gestation. Some of these "natural experiments" include fetal anencephaly with adrenal hypoplasia and placental sulfatase deficiency. The broad range of gestational length seen with these disorders questions the exact role of estrogen in human parturition initiation.

Other fetal abnormalities that prevent or severely reduce the entry of fetal urine into amnionic fluid—renal agenesis, or into lung secretions—pulmonary hypoplasia, do not prolong human pregnancy. Thus, a fetal signal through the paracrine arm of the fetal–maternal communication system does not appear to be mandated for parturition initiation.

Some brain anomalies of the fetal calf, fetal lamb, and sometimes the human fetus delay the normal timing of parturition. More than a century ago, Rea (1898) observed an association between fetal anencephaly and prolonged human gestation. Malpas (1933) extended these observations and described a pregnancy with an anencephalic fetus that was prolonged to 374 days—53 weeks. He concluded that the association between anencephaly and prolonged gestation was attributable to anomalous fetal brain–pituitary–adrenal function. The adrenal glands of the anencephalic fetus are very small and at term, may be only 5 to 10 percent as large as those of a normal fetus. This is caused by developmental failure of the fetal zone that normally accounts for most of fetal adrenal mass and production of C_{19}-steroid hormones (see Chap. 3, p. 70). Such pregnancies are also associated with delayed labor (Anderson and Turnbull, 1973). These findings are suggestive that in humans, as in sheep, the fetal adrenal glands are important for the timely onset of parturition.

Systems to Ensure Success of Phase 3 of Parturition

Phase 3 of parturition is synonymous with uterine contractions that bring about progressive cervical dilatation and delivery. Current data favor the *uterotonins theory of labor initiation.* Increased uterotonin production would follow once phase 1 is suspended and uterine phase 2 processes are implemented. A number of uterotonins may be important to the success of phase 3, that is, active labor (see Fig. 6-17). Just as multiple processes likely contribute to myometrial unresponsiveness of phase 1 of parturition, other processes may contribute jointly to a system that ensures labor success.

Uterotonins that are candidates for labor induction include oxytocin, prostaglandins, serotonin, histamine, PAF, angiotensin II, and many others. All have been shown to stimulate smooth muscle contraction through G-protein coupling.

Oxytocin and Phase 3 of Parturition

Late in pregnancy, during phase 2 of parturition, there is a 50-fold or more increase in the number of myometrial oxytocin receptors (Fuchs and associates, 1982; Kimura and co-workers, 1996). This increase coincides with an increase in uterine contractile responsiveness to oxytocin (Soloff and co-workers, 1979). Moreover, prolonged gestation is associated with a delay in the increase of these receptors (Fuchs and colleagues, 1984).

Oxytocin—literally, *quick birth*—was the first uterotonin to be implicated in parturition initiation. This nanopeptide is synthesized in the magnocellular neurons of the supraoptic and paraventricular neurons (Fig. 6-20). The prohormone is transported with its carrier protein, *neurophysin*, along the axons to the neural lobe of the posterior pituitary gland in membrane-bound vesicles for storage and later release. The prohormone is converted enzymatically to oxytocin during transport (Gainer and colleagues, 1988; Leake, 1990). Although oxytocin does not appear to cause the initiation of parturition, it may be one of several participants to ensure labor effectiveness.

Role of Oxytocin in Phases 3 and 4 of Parturition. Because of successful labor induction with oxytocin, it was logically suspected in parturition initiation. First, in addition to its effectiveness in inducing labor at term, oxytocin is a potent uterotonin and occurs naturally in humans. Subsequent observations provide additional support for this theory:

- The number of oxytocin receptors strikingly increases in myometrial and decidual tissues near the end of gestation
- Oxytocin acts on decidual tissue to promote prostaglandin release
- Oxytocin is synthesized directly in decidual and extraembryonic fetal tissues and in the placenta (Chibbar and associates, 1993; Zingg and colleagues, 1995).

Although little evidence suggests a role for oxytocin in phase 2 of parturition, abundant data support its important role during second-stage labor and the puerperium—phase 4 of parturition. Specifically, there are increased maternal serum oxytocin levels: (1) during second-stage labor—the end of phase 3 of parturition, (2) in the early postpartum period, and (3) during breast feeding—phase 4 of parturition (Nissen and co-workers, 1995). Immediately after delivery of the fetus, placenta, and membranes—completion of parturition phase 3—firm and persistent uterine contraction and retraction are essential to prevent postpartum hemorrhage. Oxytocin likely causes persistent contractions.

Oxytocin infusion in women promotes increased levels of mRNAs in myometrial genes that encode proteins essential for uterine involution. These include interstitial collagenase, monocyte chemoattractant protein-1, interleukin-8, and urokinase plasminogen activator receptor. Therefore, oxytocin action at the end of labor and during phase 3 of parturition may be involved in uterine involution.

Prostaglandins and Phase 3 of Parturition

Although their role in phase 2—activation phase—of noncomplicated pregnancies is less well defined, a critical role for prostaglandins in phase 3 of parturition is clear (MacDonald and Casey, 1993). Evidence supportive of this theory includes:

- Levels of prostaglandins—or their metabolites, in amnionic fluid, maternal plasma, and maternal urine are increased during labor (Keirse, 1979)
- Treatment of pregnant women with prostaglandins, by any of several routes of administration, causes abortion or labor at all stages of gestation (Novy and Liggins, 1980)
- Administration of prostaglandin H synthase type 2 (PGHS-2) inhibitors to pregnant women will delay spontaneous labor onset and sometimes arrest preterm labor (Loudon and co-workers, 2003)

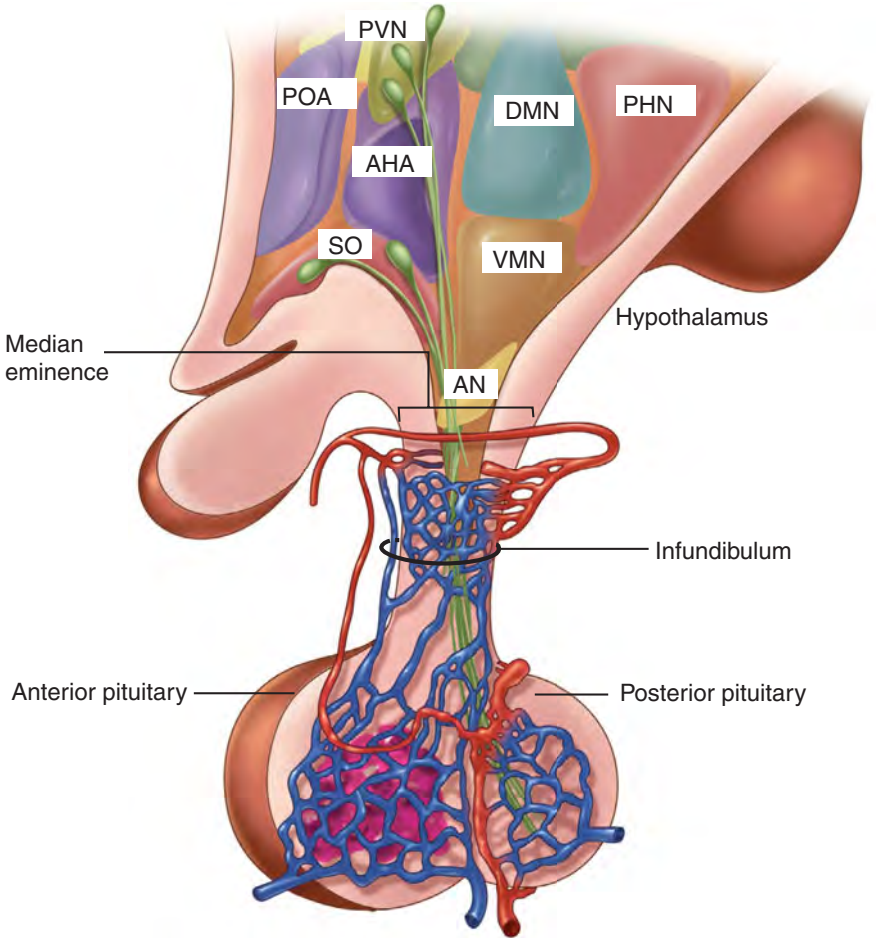

FIGURE 6-20 Hypothalamic-pituitary-adrenal (HPA) axis. Many reproductive functions are regulated by the HPA axis. During parturition, the magnocellular neurons in the maternal hypothalamus synthesize oxytocin, a uterotonin. Oxytocin in its prohormone form is transported to the posterior pituitary for storage and subsequent release. The fetal HPA axis begins to secrete hormones as early as 6-8 weeks of fetal life. During pregnancy and parturition, this axis plays important roles in regulating fetal DHEA-S production, which is the precursor for estrogen synthesis in the placenta, and in CRH production by the fetus and placenta. (AHA = anterior hypothalamic area; AN = arcuate nucleus; DMN = Dorsomedial nucleus; PHN = posterior hypothalamic nucleus; POA = preoptic area; PVN = paraventricular nucleus; SO = supraoptic nucleus; VMN = ventromedial nucleus.)

- Prostaglandin treatment of myometrial tissue in vitro sometimes causes contraction, dependent on the prostanoid tested and the physiological status of the tissue treated.

Uterine Events Regulating Prostaglandin Production. During labor, the production of prostaglandins within the myometrium and decidua is an efficient mechanism of activating contractions. For example, PG synthesis is high and unchanging in the decidua during phase 2 and 3 of parturition, in support of a role of prostaglandins in activation and stimulation. The receptor for $PGF_{2\alpha}$ is increased in the decidua at term, and this increase most likely is the regulatory step in PG action in the uterus. The myometrium synthesizes PGHS-2 with the onset of labor, but most PG likely comes from the decidua.

The fetal membranes and placenta also produce prostaglandins. Prostaglandins, primarily PGE_2, but also $PGF_{2\alpha}$, are detected in amnionic fluid at all stages of gestation. As the fetus grows, prostaglandins levels in the amnionic fluid increase gradually. The major increases in amnionic fluid, however, are demonstrable after labor begins (Fig. 6-21). There are higher levels, which likely result as the cervix dilates and exposes decidual tissue (Fig. 6-22). These increased levels in the forebag as compared with the upper compartment are believed to be the result of an inflammatory response that signals the events leading to active labor. Together, the increases in cytokines and

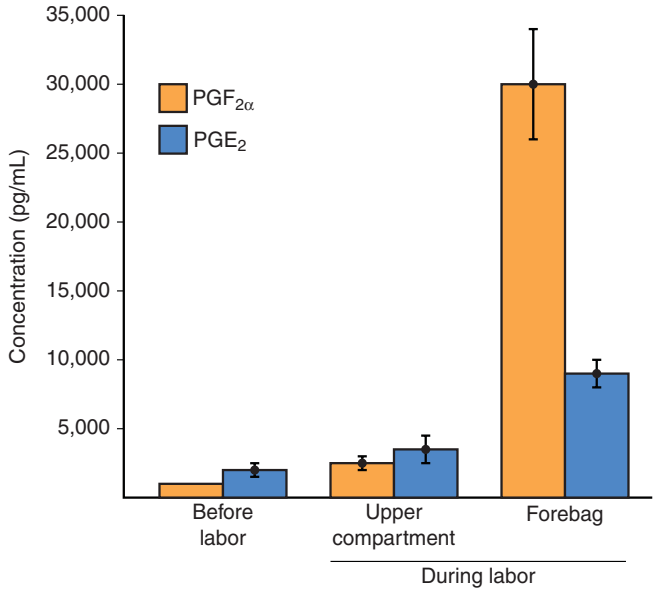

FIGURE 6-21 Mean (±SD) concentrations of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and prostaglandin E_2 (PGE_2) in amnionic fluid at term before labor and in the upper and forebag compartments during labor at all stages of cervical dilatation. (Data from MacDonald and Casey, 1993.)

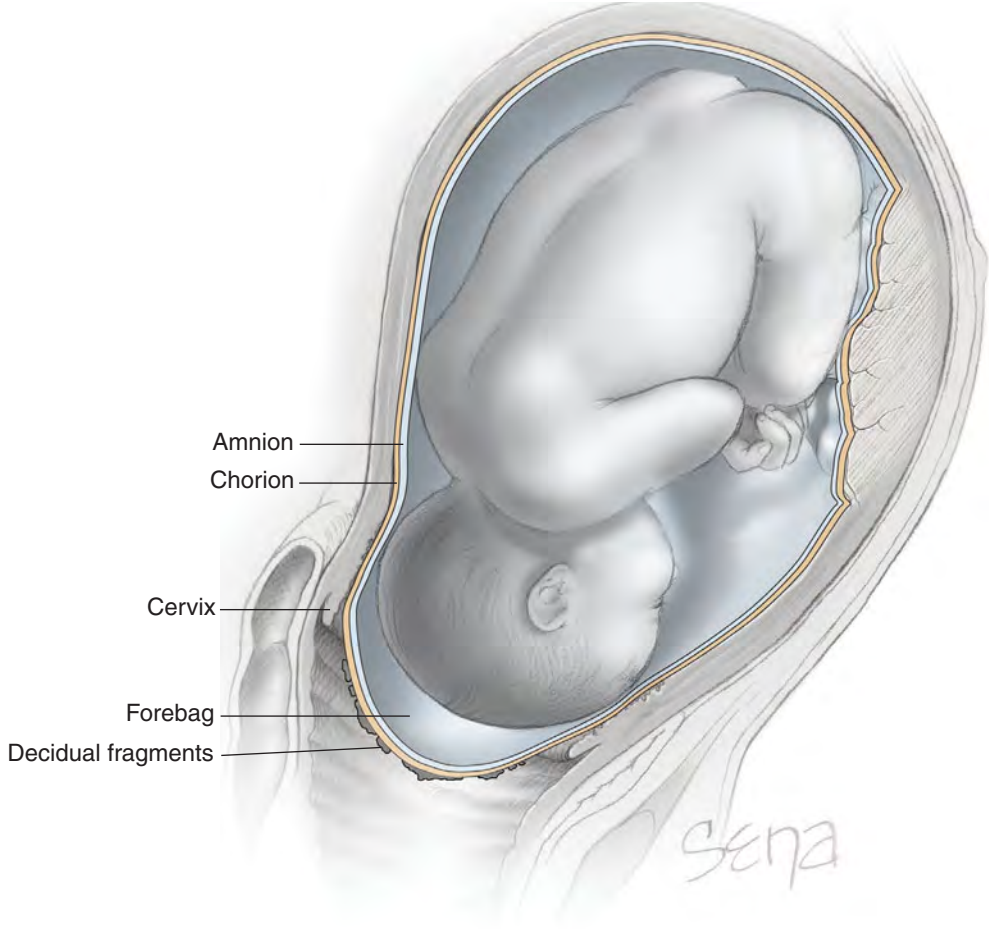

FIGURE 6-22 Sagittal view of the exposed forebag and attached decidual fragments after cervical dilatation during labor. (Redrawn from MacDonald and Casey, 1996.)

prostaglandins further degrade the extracellular matrix, thus weakening fetal membranes.

Findings of Kemp and co-workers (2002) and Kelly (2002) support a possibility that inflammatory mediators aid cervical dilatation and alterations to the lower uterine segment. It can be envisioned that they, along with the increased prostaglandins measured in vaginal fluid during labor, add to the relatively rapid cervical changes that are characteristic of parturition.

Platelet-Activating Factor (PAF)

There are a number of allergic and inflammatory responses in which PAF is involved. This mediator is produced in basophils, neutrophils, eosinophils, monocytes, and endothelial cells. The PAF receptor is a member of the G-protein–coupled receptor family of transmembrane receptors. Its stimulation by PAF increases myometrial cell calcium levels and promotes uterine contractions. Levels of PAF in amnionic fluid are increased during labor, and PAF treatment of myometrial tissue promotes contraction (Nishihara and associates, 1984; Zhu and colleagues, 1992). This factor is inactivated enzymatically by PAF-acetylhydrolase (PAF-AH), which is present in macrophages, which are found in large numbers in decidua (Prescott and associates, 1990). Thus, the myometrium may be protected from PAF action by PAF-AH during pregnancy.

Endothelin-1

The endothelins are a family of 21-amino acid peptides that powerfully induce myometrial contraction (Word and colleagues, 1990). The endothelin A receptor is preferentially expressed in smooth muscle and effects an increase in intracellular calcium. Endothelin-1 is produced in myometrium, and its potential contribution to phase 3 of parturition is not defined. Although endothelin-1 is also synthesized in amnion, it is unlikely that it is transported from the amnion or amnionic fluid to the myometrium without degradation (Eis and colleagues, 1992). Enkephalinase, which catalyzes the degradation of endothelin-1, is highly active in chorion laeve (Germain and associates, 1994).

Angiotensin II

There are two G-protein-linked angiotensin II receptors-expressed in the uterus—AT1 and AT2. In nonpregnant women, the AT2 receptor is predominant, but the AT1 receptor is preferentially expressed in pregnant women (Cox and associates, 1993). Angiotensin II binding to the plasma-membrane receptor evokes contraction. During pregnancy, the vascular smooth muscle that expresses the AT2 receptor is refractory to the pressor effects of infused angiotensin II (see Chap. 5, p. 120). In myometrium near term, however, angiotensin II may be another component of the uterotonin system of phase 3 of parturition. A potential mechanism for increased angiotensin II responsiveness in preeclampsia via increased levels of heterodimers between the vasopressor receptor AT1 and the vasodepressor receptor B2 also emphasizes a role of angiotensin II in the normal physiology of parturition (Quitterer and associates, 2004).

Corticotropin-Releasing Hormone (CRH)

Late in pregnancy—phase 2 or 3 of parturition—modification in the CRH receptor favors a switch from cAMP formation to increased myometrial cell calcium levels via protein kinase C activation. Oxytocin acts to attenuate CRH-stimulated accumulation of cAMP in myometrial tissue, and CRH augments the contraction-inducing potency of a given dose of oxytocin in human myometrial strips (Quartero and colleagues, 1991, 1992). Finally, CRH acts to increase myometrial contractile force in response to $PGF_{2\alpha}$ (Benedetto and associates, 1994).

Contribution of Intrauterine Tissues to Parturition

Although they have a potential role in parturition initiation, amnion, chorion laeve, and decidua parietalis more likely have an alternative role. The membranes and decidua comprise an important tissue shell around the fetus that serves as a physical, immunological, and metabolic shield that protects against the untimely initiation of parturition. Late in gestation, however, the fetal membranes may indeed act to prepare for labor.

Amnion. Virtually all of the membrane's tensile strength—resistance to tearing and rupture—is provided by the amnion (Chap. 3, p. 59). This avascular tissue is highly resistant to penetration by leukocytes, microorganisms, and neoplastic cells. It also constitutes a selective filter to prevent fetal particulate-bound lung and skin secretions from reaching the maternal compartment. In this manner, maternal tissues are protected from amnionic fluid constituents that could adversely affect decidual or myometrial function or adverse events such as amnionic fluid embolism (see Chap. 35, p. 788).

Several bioactive peptides and prostaglandins that cause myometrial relaxation or contraction are synthesized in amnion (**Fig. 6-23**). Late in pregnancy, amnionic prostaglandin biosynthesis is increased and phospholipase A_2 and PGHS-2 show increased activity (Johnson and colleagues, 2002). Accordingly, many hypothesize that prostaglandins regulate events leading to parturition. It is likely that amnion is the major source for amnionic fluid prostaglandins, and their role in activation of cascades that promote membrane rupture is clear. The influence of amnion-derived prostaglandins on uterine quiescence and activation, however, is less clear. This is because prostaglandin transport from the amnion through the chorion to access maternal tissues is limited by expression of the inactivating enzyme, prostaglandin dehydrogenase.

Chorion Laeve. This tissue layer also is primarily protective, and it provides immunological acceptance. The chorion laeve is also enriched with enzymes that inactivate uterotonins—for example, prostaglandin dehydrogenase (PGDH), oxytocinase, and enkephalinase (Cheung and co-workers, 1990; Germain and associates, 1994). As noted, PGDH inactivates amnion-derived prostaglandins. With chorionic rupture, this barrier would be lost, and prostaglandins could readily influence adjacent decidua and myometrium.

There is also evidence that PGDH levels found in the chorion decline during labor. This would allow increased prostaglandin-stimulated matrix metalloproteinase (MMP) activity associated with membrane rupture. It would further allow PG entry into the maternal compartment to promote myometrial contractility (Patel, 1999; Van Meir, 1996; Wu, 2000, and all their co-workers).

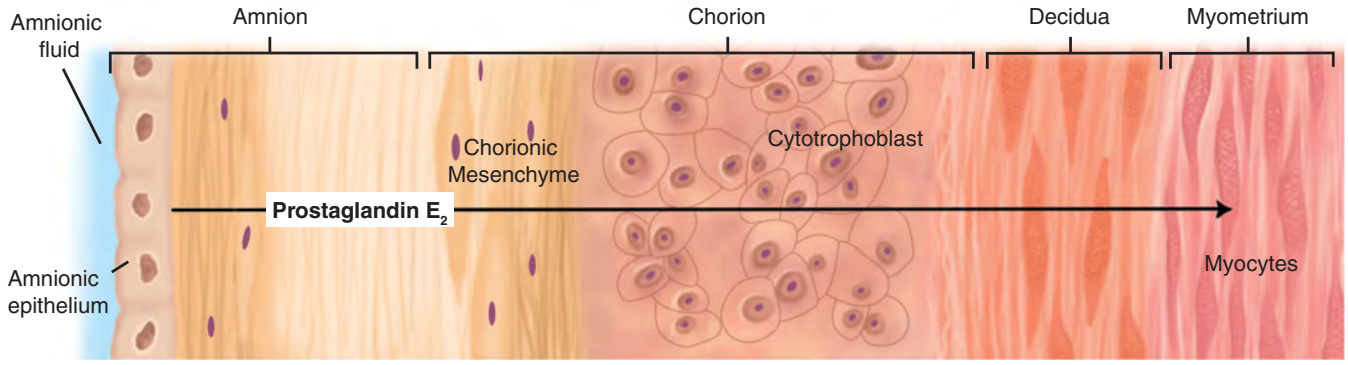

FIGURE 6-23 The amnion synthesizes prostaglandins, and late in pregnancy, synthesis is increased by increased phospholipase A_2 and prostaglandin H synthase, type 2 (PGHS-2) activity. During pregnancy, the transport of prostaglandins from the amnion to maternal tissues is limited by expression of the inactivating enzymes, prostaglandin dehydrogenase (PGDH), in the chorion. During labor, PGDH levels decline, and amnion-derived prostaglandins can influence membrane rupture and uterine contractility. The role of decidual activation in parturition is unclear but may involve local progesterone metabolism and increased prostaglandin receptor concentrations, thus enhancing uterine prostaglandin actions and cytokine production. (Adapted from Smith, 2007.)

It is likely that progesterone maintains chorion PGDH expression, whereas cortisol decreases its expression. Thus, PGDH levels would decrease late in gestation as fetal cortisol production increases and as part of progesterone withdrawal.

Decidua Parietalis. A metabolic contribution of decidua parietalis to parturition initiation is an appealing possibility for both anatomical and functional reasons. The generation of decidual uterotonins that act in a paracrine manner on contiguous myometrium is intuitive. In addition, decidua expresses steroid metabolizing enzymes such as 20_{α}HSD and steroid 5_{α}R1 that may regulate local progesterone withdrawal. There is also evidence that decidual activation is an accompaniment of human parturition (Casey and MacDonald, 1988a, 1988b, 1990; MacDonald and colleagues, 1991). The central question is whether decidual activation precedes or follows labor onset.

Decidual activation appears to be localized to the exposed decidual fragments lining the forebag. Trauma, hypoxia, and exposure of forebag decidua to endotoxin lipopolysaccharide, microorganisms, and interleukin-1β (IL-1β) in the vaginal fluids provoke an inflammatory reaction—an inevitable and consistent sequela of labor. With this inflammation, cytokines are produced that can either increase uterotonin production—principally prostaglandins, or act directly on myometrium to cause contraction—for example, tumor necrosis factor-α (TNF-α) and interleukins 1, 6, 8, and 12. These molecules also can act as chemokines that recruit to the myometrium neutrophils and eosinophils, which further increase contractions and labor (Keelan and co-workers, 2003).

There is uncertainty whether PG concentration or output from the decidua increases with term labor onset. Olson and Ammann (2007) suggest that the major regulation of decidual PG action is not PG synthesis, but rather increased expression of the $PGF_{2\alpha}$ receptor.

Regulation of Phase 3 and 4 of Parturition: Summary

It is likely that multiple and possibly redundant processes contribute to the success of the three active labor phases once phase 1 of parturition is suspended and phase 2 is implemented. Phase 3 is highlighted by increased activation of G-protein-coupled receptors that inhibit cAMP formation, increase intracellular calcium stores, and promote interaction of actin and myosin and subsequent force generation. Simultaneously, cervical proteoglycan composition and collagen structure are altered to a form that promotes tissue distensibility and increased compliance. The net result is initiation of coordinated myometrial contractions of sufficient amplitude and frequency to dilate the prepared cervix and push the fetus through the birth canal. The source of regulatory ligands for these receptors varies from endocrine hormones such as oxytocin to locally produced prostaglandins.

In phase 4 of parturition, a complicated series of repair processes are initiated to resolve inflammatory responses and remove glycosaminoglycans, proteoglycans, and structurally compromised collagen. Simultaneously, matrix and cellular components required for complete uterine involution are synthesized, and the dense connective tissue and structural integrity of the cervix is reformed.

PHYSIOLOGY AND BIOCHEMISTRY OF PRETERM LABOR

Preterm birth has major human consequences—after congenital anomalies, it is the greatest cause of neonatal morbidity and mortality (Chap. 36, p. 804). Spontaneous preterm labor with intact fetal membranes is the most common cause of preterm delivery and accounts for about half of preterm births. In another quarter, preterm premature rupture of the membranes is almost always followed by preterm delivery. Many factors increase the likelihood of preterm delivery. Some of these are genetics, infection, nutrition, behavior, and the environment (Fig. 6-24).

Genetic Influence on Preterm Birth

Analogous to other complex disease processes, multiple coexistent genetic alterations and environment may lead to preterm birth (Esplin and Varner, 2005; Ward, 2008). There are polymorphisms

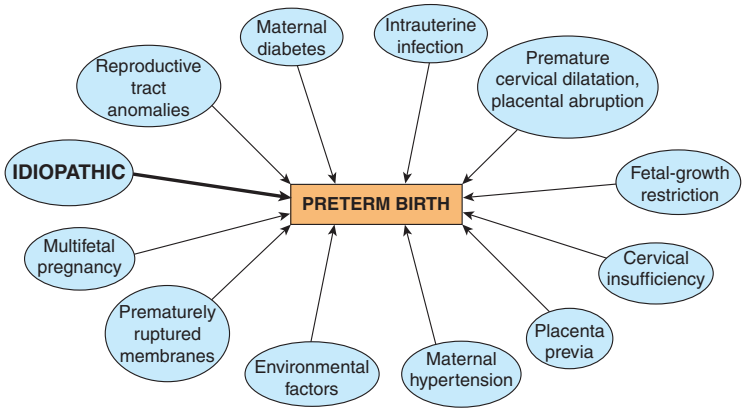

FIGURE 6-24 Risks for preterm birth. Approximately 50 percent of preterm births are idiopathic.

in genes associated with inflammation and infection and in those associated with collagen turnover (Velez and colleagues, 2008). Inherited mutations in genes regulating collagen assembly predispose individuals to cervical insufficiency or prematurely ruptured membranes (Anum, 2009; Wang, 2006; Warren, 2007, and all their associates).

Preterm Prematurely Ruptured Membranes (PPROM)

This term defines spontaneous rupture of the fetal membranes before 37 completed weeks and *before labor onset* (American College of Obstetricians and Gynecologists, 2007). Such rupture likely has a variety of causes, but many believe intrauterine infection to be a major predisposing event (Gomez and colleagues, 1997; Mercer, 2003).

Some studies suggest that the pathogenesis of preterm rupture relates to increased apoptosis of membranes' cellular components and to increased levels of specific proteases in membranes and amnionic fluid. Much of the membranes' tensile strength is provided by the extracellular matrix within the amnion. Interstitial amnionic collagens, primarily types I and III, are produced in mesenchymal cells and are the structural component most important for its strength (Casey and MacDonald, 1996). For that reason, collagen degradation has been a focus of research.

The matrix metalloproteinase (MMP) family is involved with normal tissue remodeling and particularly with collagen degradation. The MMP-2, MMP-3, and MMP-9 members of this family are found in higher concentrations in amnionic fluid from pregnancies with PPROM (Park and colleagues, 2003; Romero and associates, 2002). The activity of MMPs is in part regulated by tissue inhibitors of matrix metalloproteinases (TIMPs). Several of these inhibitors are found in lower concentrations in amnionic fluid from women with PPROM. Elevated MMP levels found at a time when protease inhibitor expression decreases supports further that their expression alters amnionic tensile strength. Studies of amniochorion explants have demonstrated that the expression of MMPs can be increased by treatment with IL-1, TNF-α, and IL-6 (Fortunato and colleagues, 1999a,b, 2002). Thus, MMP induction may be part of an inflammatory process. Proteins involved in the synthesis of mature cross-linked collagen or matrix proteins that bind collagen and promote tensile strength have also been found to be altered in PPROM (Wang and associates, 2006).

In pregnancies with PPROM, the amnion exhibits a higher degree of cell death than that in the term amnion (Arechavaleta-Velasco and colleagues, 2002; Fortunato and Menon, 2003). Markers of apoptosis with PPROM also show increased levels compared with those of term membranes. In vitro studies indicate that apoptosis is likely regulated by bacterial endotoxin IL-1β and TNF-α. Taken together, these observations suggest that many cases of PPROM result from activation of collagen degradation, alterations in collagen assembly, and cell death all leading to a weakened amnion.

A number of studies have been done to ascertain the incidence of infection-induced PPROM. Bacterial cultures of amnionic fluid support a role for infection in a significant proportion. A review of 18 studies comprised of almost 1500 women with PPROM found that in a third, bacteria were isolated from amnionic fluid (Goncalves and co-workers, 2002). Because of these findings, some have given prophylactic antimicrobial treatment to prevent PPROM. Although results are conflicting, there is evidence that early treatment of selected asymptomatic lower genital tract infections and active periodontal inflammation will reduce the incidence of PPROM and preterm birth (Chap. 36, p. 812).

Thus, there is compelling evidence that infection causes a significant proportion of PPROM cases. The inflammatory response that leads to membrane weakening is currently being defined. Research is focused on mediators of this process with a goal of identification of early markers for women at risk for PPROM.

Spontaneous Preterm Labor

Pregnancies with intact fetal membranes and spontaneous preterm labor—for clinical as well as research purposes—must be distinguished from those complicated by PPROM. Even so, pregnancies complicated by spontaneous preterm labor do not constitute a homogeneous group characterized singularly by early initiation of parturition. Among the more common associated findings are multifetal pregnancy, intrauterine infection, bleeding, placental infarction, premature cervical dilatation, cervical incompetence, uterine fundal abnormalities, and fetal anomalies. Severe maternal illness as a result of nonobstetrical infections, autoimmune diseases, and gestational hypertension also increases the risks for preterm labor. Taken together, these disorders cause about half of spontaneous preterm deliveries, and their relative contribution varies between populations.

Although there are unique aspects to each cause of preterm labor, recent studies have suggested that they share certain common denominators. Thus, fetal or maternal conditions provide important clues. It seems important to reemphasize that the actual process of preterm labor should be considered a final step—one that results from premature uterine activation that was initiated weeks before the onset of labor. Indeed, many forms of spontaneous preterm labor that result from premature initiation

of phase 2 of parturition may be viewed in this light. Although the end result in preterm birth is the same as at term, namely cervical ripening and myometrial activation, recent studies question the idea that preterm birth is simply acceleration of the normal process. Identification of both common and uncommon factors has begun to explain the physiological processes of human parturition at term and preterm. Three major causes of spontaneous preterm labor include uterine distension, maternal–fetal stress, and infection.

Uterine Distension

There is no doubt that multifetal pregnancy and hydramnios lead to an increased risk of preterm birth (Chap. 39, p. 869). It is likely that early uterine distension acts to initiate expression of contraction-associated proteins (CAPs) in the myometrium. The CAP genes influenced by stretch include those coding for gap junction proteins such as connexin 43, for oxytocin receptors, and for prostaglandin synthase (Korita, 2002; Lyall, 2002; Sooranna, 2004, all their colleagues). Thus, excessive uterine stretch causes premature loss of myometrial quiescence.

Uterine stretch also leads to early activation of the placental-fetal endocrine cascade shown in Figure 6-17. The resulting early rise in maternal CRH and estrogen levels can further enhance the expression of myometrial CAP genes (Warren and co-workers, 1990; Wolfe and colleagues, 1988).

Finally, the influence of uterine stretch should be considered with regard to the cervix. For example, cervical length is an important risk factor for preterm birth in multifetal pregnancies (Goldenberg and co-workers, 1996). Prematurely increased stretch and endocrine activity may initiate events that shift the timing of uterine activation, including premature cervical ripening.

Maternal-Fetal Stress

The complexities of measuring "stress" lead to difficulty in defining its exact role (Lobel, 1994). That said, considerable evidence shows a correlation between some sort of maternal stress and preterm birth (Hedegaard, 1993; Hobel, 2003; Ruiz, 2003; Zambrana, 1999, and all their co-workers). Moreover, there is a correlation between maternal psychological stress and the placental–adrenal endocrine axis that provides a potential mechanism for stress-induced preterm birth (Lockwood, 1999; Wadhwa and associates, 2001).

As discussed earlier, the last trimester is marked by rising maternal serum levels of placental-derived CRH. This hormone works with ACTH to increase adult and fetal adrenal steroid hormone production, including the initiation of fetal cortisol biosynthesis. Rising levels of maternal and fetal cortisol further increase placental CRH secretion, which develops a feed-forward endocrine cascade that does not end until delivery (see Fig. 6-19). Rising levels of CRH further stimulate fetal adrenal DHEA-S biosynthesis, which acts as substrate to increase maternal plasma estrogens, particularly estriol.

It has been hypothesized that a premature rise in cortisol and estrogens results in an early loss of uterine quiescence. Supporting this hypothesis are numerous studies indicating that spontaneous preterm labor is associated with an early rise in maternal CRH levels (Holzman, 2001; McGrath, 2002; Moawad, 2002, and all their co-workers). Levels of CRH in term and preterm women are similar. However, women destined for preterm labor exhibit a rise in CRH levels 2 to 6 weeks earlier (McLean and co-workers, 1995). This has been described as early as 18 weeks' gestation, leading some to suggest that CRH determination may provide a useful marker for preterm delivery. Because of large variations in CRH levels among pregnant women, however, a single CRH measurement has low sensitivity (Leung and colleagues, 2001; McGrath and associates, 2002). It may be that the *rate of increase* in maternal CRH levels may be a more accurate predictor of preterm birth. Confounding factors include CRH variability among ethnic groups. Another is that placental CRH enters the fetal circulation—albeit at lower levels than in the maternal circulation. In vitro studies have shown that CRH can directly stimulate fetal adrenal production of DHEA-S and cortisol (Parker and colleagues, 1999; Smith and co-workers, 1998).

If preterm delivery is associated with early activation of the fetal adrenal-placental endocrine cascade, maternal estrogen levels would likely be prematurely elevated. This is true, and an early rise of serum estriol concentrations is noted in women with subsequent preterm labor (Heine and co-workers, 2000; McGregor and associates, 1995). Physiologically, this premature rise in estrogens may alter myometrial quiescence.

Taken together, these observations suggest that preterm birth is associated, in many cases, with a maternal-fetal biological stress response. The nature and variety of the stressors that activate this cascade likely are broad. For example, CRH or estriol levels are prematurely elevated in preterm birth due to infection and multifetal pregnancies (Gravett and colleagues, 2000; Warren and co-workers, 1990). Thus, activation of this axis may be considered a common feature for initiation of phase 1 of parturition.

Infection and Preterm Labor

There is great interest in the role of infection as a primary cause of preterm labor in pregnancies with intact membranes. Many cases of preterm labor may result from intrauterine infection. This concept has been promoted because of widespread suspicion that subclinical infection is a common accompaniment and cause of preterm labor. The term "subclinical" has been used to describe infection that is accompanied by little or no clinical evidence of infection (Goncalves and co-workers, 2002; Iams and colleagues, 1987).

Certainly microorganisms are not recovered from the amnionic fluid in all women with preterm labor, In fact, the incidence of positive cultures varies from 10 to 40 percent and averages 15 percent (Goncalves and co-workers, 2002). Importantly, these women were more likely to develop clinical chorioamnionitis and preterm PROM than women with sterile cultures. Their neonates are also more likely to have complications (Hitti and co-workers, 2001). Although more severe when intra-amniotic infection is detected, intra-amniotic inflammation in the absence of detectable microorganisms is also a risk factor for the development of a fetal inflammatory response (Lee and associates, 2007, 2008). The earlier the onset of preterm labor, the greater is the likelihood of documented amnionic fluid infection (Goldenberg and associates, 2000; Watts

and colleagues, 1992). At the same time, however, the incidence of culture-positive amnionic fluids collected by amniocentesis during spontaneous term labor is similar or even greater than it is during preterm labor (Gomez and colleagues, 1994; Romero and co-workers, 1993). It has been suggested that at term, amnionic fluid is infiltrated by bacteria as a consequence of labor, whereas in preterm pregnancies, bacteria represent an important cause of labor. Although plausible, this explanation questions the contribution of fetal infection as a major contributor to preterm birth.

Certainly, there are considerable data that associate chorioamnionitis with preterm labor (Goldenberg and associates, 2002; Üstün and colleagues, 2001). In such infections, the microbes may invade maternal tissue only and not amnionic fluid. Despite this, endotoxins can stimulate amnionic cells to secrete cytokines that enter amnionic fluid. This scenario may serve to explain the apparently contradictory observations concerning an association between amnionic fluid cytokines and preterm labor, in which microbes were not detectable in the amnionic fluid.

Sources for Intrauterine Infection. The patency of the female reproductive tract, although essential for achievement of pregnancy and delivery, is theoretically problematic during phase 1 of parturition. It has been suggested that bacteria can gain access to intrauterine tissues through: (1) transplacental transfer of maternal systemic infection, (2) retrograde flow of infection into the peritoneal cavity via the fallopian tubes, or (3) ascending infection with bacteria from the vagina and cervix. The lower pole of the fetal membrane–decidual junction is contiguous with the orifice of the cervical canal, which in turn is patent to the vagina. This anatomical arrangement provides a passageway for microorganisms, and ascending infection is considered to be the most common. A thoughtful description of the potential degrees of intrauterine infection has been provided by Goncalves and coworkers (2002). They categorize intrauterine infection into four stages of microbial invasion that include bacterial vaginosis—stage I, decidual infection—stage II, amnionic infection—stage III, and finally, fetal systemic infection—stage IV. As expected, progression of these stages is thought to increase the effects on preterm birth and neonatal morbidity.

Based on these insights, it is straightforward to construct a theory for the pathogenesis of infection-induced preterm labor (Fig. 6-25). Ascending microorganisms colonize the decidua and possibly the membranes, where they then may enter

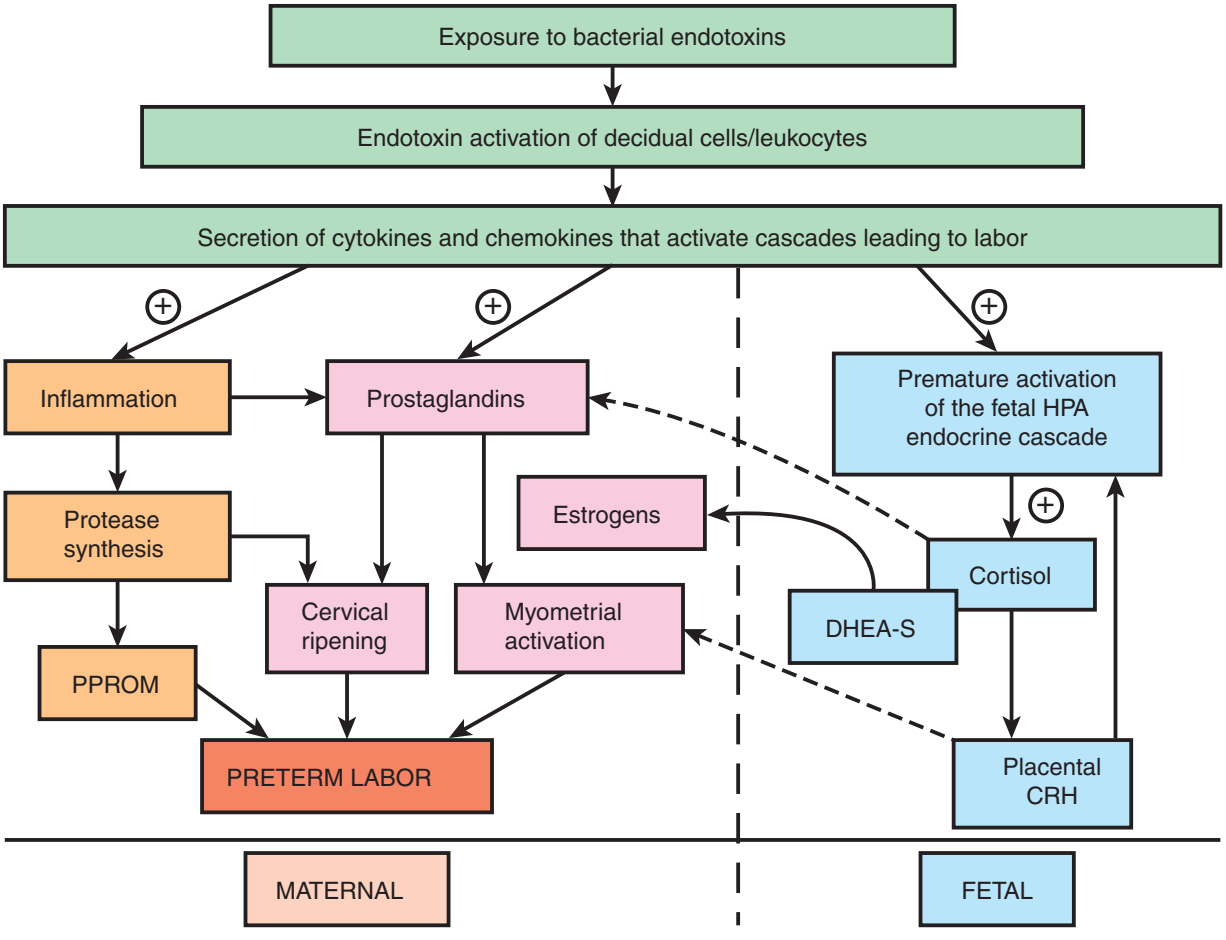

FIGURE 6-25 Potential pathways for infection-induced preterm birth. Exposure to bacterial endotoxins causes an early initiation of the normal processes associated with parturition, including cervical ripening, loss of uterine quiescence, and increased production of uterotonins. (CRH = corticotropin-releasing hormone; DHEA-S =dehydroepiandrosterone sulfate; HPA = hypothalamic–pituitary–adrenal; PPROM = preterm prematurely ruptured membranes.)

the amnionic sac. Lipopolysaccharide or other toxins elaborated by bacteria induce cytokine production in cells within the decidua, membranes, or fetus itself. Both lipopolysaccharide and cytokines then provoke prostaglandin release from the membranes, the decidua, or both. These influence both cervical ripening and loss of myometrial quiescence (Challis, 2002; Keelan, 2003; Loudon, 2003; Olson, 2003; and all their associates).

Microbes Associated with Preterm Birth. Some microorganisms—examples include *Gardnerella vaginalis, Fusobacterium, Mycoplasma hominis,* and *Ureaplasma urealyticum*—are detected more commonly than others in amnionic fluid of women with preterm labor (Gerber, 2003; Hillier, 1988; Romero, 1989; Yoon, 1998, and all their co-workers). This finding was interpreted by some as presumptive evidence that specific microorganisms are more commonly involved as pathogens in the induction of preterm labor. Another interpretation, however, is that given direct access to the membranes after cervical dilatation, selected microorganisms, such as fusobacteria, that are more capable of burrowing through these exposed tissues will do so. Fusobacteria are found in the vaginal fluid of only 9 percent of women but in 28 percent of positive amnionic fluid cultures from preterm labor pregnancies with intact membranes (Chaim and Mazor, 1992). Further studies are needed to better define these interactions.

Intrauterine Inflammatory Response to Infection. The initial inflammatory response elicited by bacterial toxins is mediated, in large measure, by specific receptors on mononuclear phagocytes, decidual cells, and trophoblasts. These *toll-like receptors* represent a family of receptors that has evolved to recognize pathogen-associated molecules (Janssens and Beyaert, 2003). Toll-like receptors are present in the placenta on trophoblast cells as well as on fixed and invading leukocytes (Chuang and Ulevitch, 2000; Gonzalez and colleagues, 2007; Holmlund and co-workers, 2002). Under the influence of ligands such as bacterial lipopolysaccharide, these receptors increase release of chemokines, cytokines, and prostaglandins as part of an inflammatory response. One example is IL-1β, which is produced rapidly after lipopolysaccharide stimulation (Dinarello, 2002). This cytokine in turn acts to promote a series of responses that include: (1) increased synthesis of others, that is, TNF-α, IL-6, and IL-8; (2) proliferation, activation, and migration of leukocytes; (3) modifications in extracellular matrix proteins; and (4) mitogenic and cytotoxic effects such as fever and acute phase response (El-Bastawissi and colleagues, 2000). Also, IL-1 promotes prostaglandin formation in many tissues, including myometrium, decidua, and amnion (Casey and co-workers, 1990). Thus, there appears to be a cascade of events once an inflammatory response is initiated that can result in preterm labor.

Origin of Cytokines in Intrauterine Infection. Cytokines within the normal term uterus are likely important for normal and preterm labor. The transfer of cytokines such as IL-1 from decidua across the membranes into amnionic fluid appears to be severely limited. Thus, it is likely that cytokines produced in maternal decidua and myometrium will have effects on that side, whereas cytokines produced in the membranes or in cells within the amnionic fluid will not be transferred to maternal tissues. In most cases of inflammation resulting from infection, resident and invading leukocytes produce the bulk of cytokines. Indeed, leukocytes—mainly neutrophils, macrophages, and T lymphocytes—infiltrate the cervix, lower uterine segment, and fundus at the time of labor. It was also shown that with preterm labor, leukocytes invade both membranes and cervix. Thus, invading leukocytes may be the major source of cytokines at the time of labor. Along with proinflammatory cytokines recent studies in women and animal models highlight the importance of the anti-inflammatory limb of the immune response in the parturition process (Gotsch and colleagues, 2008; Timmons and co-workers, 2009).

Immunohistochemical studies have shown in the term laboring uterus that both invading leukocytes and certain parenchymal cells produce cytokines. These leukocytes appear to be the primary source of myometrial cytokines, including IL-1, IL-6, IL-8, and TNF-α (Young and co-workers, 2002). By contrast, in the decidua, both stromal cells and leukocytes are likely to contribute because they have been shown to produce these same cytokines. In the cervix, glandular and surface epithelial cells appear to produce IL-6, IL-8, and TNF-α. Of these, IL-8 is considered a critical cytokine in cervical dilation, and it is produced in both cervical epithelial and stromal cells.

The presence of cytokines in amnionic fluid and their association with preterm labor has been well documented. But their exact cellular origin—with or without culturable microorganisms—has not been well defined. Although the rate of IL-1 secretion from forebag decidual tissue is great, Kent and colleagues (1994) found that there is negligible in vivo transfer of radiolabeled IL-1 across the membranes. Amnionic fluid IL-1 probably does not arise from amnion tissue, fetal urine, or fetal lung secretions. It most likely is secreted by mononuclear phagocytes or neutrophils activated and recruited into the amnionic fluid. Therefore, IL-1 in amnionic fluid likely is generated in situ from newly recruited cells. This scenario is supported by immunohistochemical studies (Young and co- workers, 2002). Thus, the amount of amnionic fluid IL-1 would be determined by the number of leukocytes recruited, their activational status, or the effect of amnionic fluid constituents on their rate of IL-1 secretion.

Leukocyte infiltration may be regulated by fetal membrane synthesis of specific chemokines. In term labor, there are increased amnionic fluid concentrations of the potent chemoattractant and monocyte-macrophage activator, *monocyte chemotactic protein-1 (MCP-1)*. As is true for prostaglandins and other cytokines, the levels of MCP-1 are much higher in the forebag compared with the upper compartment (Esplin and co-workers, 2003). Levels in preterm labor were significantly higher than those found in normal term amnionic fluid (Jacobsson and colleagues, 2003). It has been proposed that MCP-1 may be the factor that initiates fetal leukocyte infiltration of the placenta and membranes. In addition, the production of MCP-1 may act as a marker for intra-amnionic infection and inflammation.

Summary of Preterm Labor

Preterm labor is a pathological condition with multiple etiologies and has recently been termed the *preterm parturition syndrome* (Romero and associates, 2006). Most research in this field has been focused on the role of infection in mediating preterm birth. It is possible that intrauterine infection causes some cases currently categorized as idiopathic spontaneous preterm labor. There are a variety of sites for intrauterine infection—maternal, fetal, or both—and increasing evidence that the inflammatory response may have distinct and compartment-specific functions that differ between uterus, fetal membranes, and cervix in normal birth. Thus, determining the proportion of pregnancies that end prematurely because of infection is difficult. That said, it is clear that infection does not explain all causes of preterm birth.

In recent years, our understanding of other influences on the parturition process such as maternal nutrition before or during pregnancy, genetics, and dynamic regulation of changes in the extracellular matrix have led to new avenues of research and a broader understanding of this complicated and multifactorial process. The current and future application of genomic and bioinformatics as well as molecular and biochemical studies will shed light on pathways involved in term and preterm labor and identify processes critical to all phases of cervical remodeling and uterine function.

SECTION 3

ANTEPARTUM

CHAPTER 7

Preconceptional Counseling

BENEFITS OF PRECONCEPTIONAL COUNSELING 174
CHRONIC MEDICAL DISORDERS 175
GENETIC DISEASES 177
PRECONCEPTIONAL COUNSELORS 180
PRECONCEPTIONAL COUNSELING VISIT 180

In 2006, the Centers for Disease Control and Prevention defined preconceptional care as "a set of interventions that aim to identify and modify biomedical, behavioral, and social risks to a woman's health or pregnancy outcome through prevention and management." In addition, it established the following goals for improving preconceptional care:

1. Improve knowledge, attitudes, and behaviors of men and women related to preconceptional health.
2. Assure that all women of childbearing age receive preconceptional care services—including evidence-based risk screening, health promotion, and interventions—that will enable them to enter pregnancy in optimal health.
3. Reduce risks indicated by a previous adverse pregnancy outcome through interconceptional interventions to prevent or minimize recurrent adverse outcomes.
4. Reduce the disparities in adverse pregnancy outcomes.

The American College of Obstetricians and Gynecologists (2005a) also has reinforced the importance of preconceptional and interpregnancy care. Moreover, recent data from the Centers for Disease Control and Prevention describe the health status of women who gave birth to live-born infants in the United States in 2004 (Table 7-1). This table demonstrates the high prevalence of many conditions that may be amenable to intervention during the preconceptional and interpregnancy periods (D'Angelo and associates, 2007).

BENEFITS OF PRECONCEPTIONAL COUNSELING

Randomized trials that evaluate preconceptional counseling efficacy are scarce, partly because withholding such counseling would be unethical. In addition, because maternal and perinatal outcomes are dependent on the interaction of various maternal, fetal, and environmental factors, it is often difficult to ascribe salutary outcomes to a specific intervention (Moos, 2004). That said, there are a few prospective and case-control studies that clearly demonstrate the successes of preconceptional counseling.

Unplanned Pregnancy

Counseling about potential pregnancy risks and preventative strategies must be provided before conception. By the time most women realize they are pregnant—1 to 2 weeks after the first missed period—the fetal spinal cord has already formed and the heart is beating. Thus, many prevention strategies, for example folic acid to prevent neural-tube defects, are ineffective if initiated at this time. It is estimated that up to half of all pregnancies are unplanned, and that these may be at greatest risk (American College of Obstetricians and Gynecologists, 2006; Finer and Henshaw, 2006). Women with unintended pregnancy are more likely to be young or single; have lower educational attainment; use tobacco, alcohol, or illicit drugs; and not supplement with folate (Cheng, 2009; Dott, 2009; Postlethwaite, 2009, and all their associates).

To assess the effectiveness of preconceptional counseling to reduce unintended pregnancies, Moos and colleagues (1996) studied the effects of a preconceptional care program instituted in a health department clinic. The 456 women given preconceptional counseling had a 50-percent greater likelihood of describing their subsequent pregnancies as intended compared

TABLE 7-1. Prevalence of Prepregnancy Maternal Behaviors, Experiences, Health Conditions, and Previous Poor Birth Outcomes in the United States in 2004

Factor	Prevalence (percent)
Tobacco use	23.2
Alcohol use	50.1
Multivitamin use	35.1
Contraceptive nonuse[a]	53.1
Dental visit	77.8
Health counseling	30.3
Physical abuse	3.6
Stress	18.5
Underweight	13.2
Overweight	13.1
Obesity	21.9
Diabetes	1.8
Asthma	6.9
Hypertension	2.2
Heart problem	1.2
Anemia	10.2
Prior low-birthweight infant	11.6
Prior preterm infant	11.9

[a]Among women who were not trying to become pregnant.
Data from D'Angelo and associates (2007).

with 309 women with health care but no counseling, and a 65-percent greater likelihood compared with women with no healthcare prior to pregnancy. Family planning and contraception are discussed in Chapter 32.

CHRONIC MEDICAL DISORDERS

Diabetes Mellitus

Because maternal and fetal pathology associated with hyperglycemia is well known, diabetes is the prototype of a condition for which preconceptional counseling is beneficial. Diabetes-associated risks to both mother and fetus are discussed in detail in Chapter 52. Most important, many of these complications can be avoided if glucose control is optimized before conception. The American College of Obstetricians and Gynecologists (2005c) has concluded that preconceptional counseling for women with pregestational diabetes mellitus is both beneficial and cost-effective and should be encouraged.

Recommendations of the American Diabetes Association (2004) for the content of preconceptional care are listed in Table 7-2. Importantly, it advises that the preconceptional goal is to obtain the lowest hemoglobin A_{1c} level possible without undue risk of hypoglycemia in the mother. In addition to assessing diabetic control during the preceding 6 weeks, hemoglobin A_{1c} measurement can also be used to compute risks for major anomalies (Fig. 7-1). Although these data are from women with severe diabetes, the incidence of fetal anomalies in

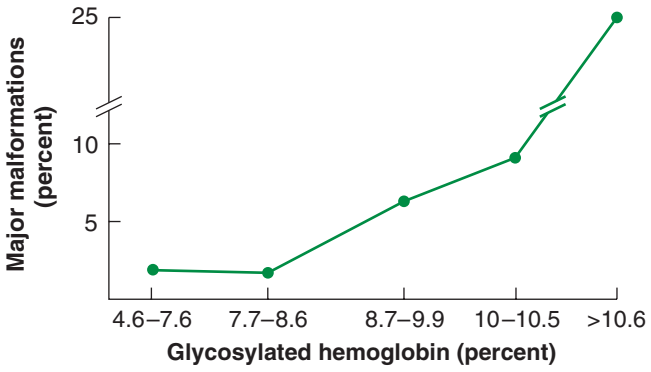

FIGURE 7-1. Relationship between first-trimester glycosylated hemoglobin values and risk for major congenital malformations in 320 women with insulin-dependent diabetes. (Data from Kitzmiller and associates, 1991.)

women who have gestational diabetes and fasting hyperglycemia is increased fourfold compared with that in normal women (Sheffield and associates, 2002).

Efficacy of Counseling in Diabetic Women

Preconceptional counseling has been shown to decrease diabetes-related complications at all stages of pregnancy. For example, Leguizamón and colleagues (2007) identified 12 clinical studies comparing the incidence of major congenital anomalies in a combined total of 1618 women with insulin-dependent diabetes mellitus who received preconceptional care with a combined total of 1599 who did not. The rates of congenital anomalies in the two groups were 2.7 and 8.3 percent, respectively. Importantly, 10 of the 12 studies showed that preconceptional care is associated with significantly fewer malformations.

Dunne and co-workers (1999) reported that diabetic women who received counseling sought prenatal care earlier, had lower hemoglobin A_{1c} levels, and were less likely to smoke during pregnancy. Of the women who received counseling, none were delivered before 30 weeks compared with 17 percent in an uncounseled cohort. Finally, counseled women had fewer macrosomic infants—25 versus 40 percent; they had no growth-restricted infants compared with 8.5 percent; they had no neonatal deaths compared with 6 percent; and their infants had half as many admissions to the intensive care nursery—17 versus 34 percent. Similarly, Temple and associates (2006) found lower rates of adverse pregnancy outcome and preterm delivery in those receiving prepregnancy care.

It follows that preconceptional counseling reduces healthcare costs in diabetic women. Indeed, based upon their literature review, Reece and Homko (2007) found that for every dollar spent on a preconceptional care program for diabetic women between $1.86 and $5.19 was saved in direct medical costs averted. Surprisingly, despite such benefits, the proportion of diabetic women receiving preconceptional care remains low. In a study of approximately 300 women with diabetes enrolled in a managed-care plan, Kim and colleagues (2005) found that only about half reported receiving preconceptional counseling. Among the uninsured, the rates are undoubtedly even lower.

TABLE 7-2. American Diabetes Association Recommendations for the Preconceptional Care of Women with Diabetes

Medical and obstetrical history

- Duration and type of diabetes
- Acute complications, including history of infections, ketoacidosis, and hypoglycemia
- Chronic complications, including retinopathy, nephropathy, hypertension, atherosclerotic vascular disease, and neuropathy
- Diabetes management, including insulin regimen, use of glucose lowering agents, self-glucose monitoring regimens and results, nutrition, and physical activity
- Concomitant medical conditions
- Menstrual and pregnancy history, contraceptive use
- Support systems

Physical examination

- Blood pressure, including testing for orthostatic changes
- Retinal examination with pupillary dilatation
- Cardiovascular examination for evidence of cardiac or peripheral vascular disease—if present, screen for evidence of coronary artery disease
- Neurological examination

Laboratory evaluation

- Hemoglobin A_{1c}
- Serum creatinine
- Urine protein: protein excretion >190 mg/24 hours may increase the risk for hypertensive disorders during pregnancy (see Chap. 34, p. 719); protein excretion >400 mg/24 hours may increase the risk for fetal-growth restriction (see Chap. 38, p. 843).
- Thyroid function tests: 5- to 10-percent coincidence of type 1 diabetes and thyroid dysfunction (see Chap. 53, p. 1134).

Initial management plan

- Counseling
  - Risk and prevention of congenital anomalies
  - Fetal and neonatal complications of maternal diabetes (see Chap. 52, p. 1113)
  - Effects of pregnancy on maternal diabetic complications (see Chap. 52, p. 1116)
  - Risks of obstetrical complications that occur with increased frequency in diabetic pregnancies (see Chap. 52, p. 1113)
  - Need for effective contraception until glycemia is well controlled
- Insulin regimen selected to achieve the following goals:
  - Capillary plasma glucose before meals = 80–110 mg/dL
  - Capillary plasma glucose 2 hours after meals less than 155 mg/dL[a]
- Monitor hemoglobin A_{1c} levels at 1- to 2-month intervals until stable with the goal to achieve a concentration less than 1 percent above the normal range

[a] There are no data to suggest that postmeal glucose monitoring has a specific role in preconception diabetes care beyond what is needed to achieve the target hemoglobin A_{1c}. Thus, a focus on preprandial monitoring is recommended initially to assist patients in self-selection of insulin doses.

Epilepsy

It is indisputable that women with epilepsy are two to three times more likely to have infants with structural anomalies than unaffected women (Wide and associates, 2004). Some reports indicate that epilepsy increases this risk, independent of the effects of antiseizure medication. This view is not held by all. Holmes and colleagues (2001) compared pregnancy outcomes in 509 epileptic women who took antiseizure medication with 606 who did not. They found that fetuses exposed to one drug had significantly fewer malformations than those exposed to two or more drugs—21 versus 28 percent. By contrast, the incidence of fetal defects of epileptic mothers who did not take medication was 8.5 percent—the same as in fetuses of women without seizure disorders.

Preconceptional counseling usually includes efforts to achieve control with monotherapy and with medications considered least teratogenic (Adab, 2004; Aguglia, 2009; Tomson, 2009, and all their associates). As shown in Table 7-3, some regimens used individually are less teratogenic than others. Results of a prospective registry, for example, indicate that the overall risk of major malformations associated with lamotrigine monotherapy is comparable with that of the general population. The risks of antiseizure medication are described in detail in Chapter 14 (p. 317). According to Jeha and Morris (2005), the American Academy of

TABLE 7-3. Antiepileptic Treatment Regimens and Their Association with Major Congenital Malformations

Regimen	Range of Major Congenital Malformations (percent)
Any antiepileptic drug	7.9
Lamotrigine monotherapy	2.1–2.9
Carbamazepine monotherapy	2.0–5.2
Phenobarbital monotherapy	4.7–6.5
Phenytoin monotherapy	3.4–10.5
Valproic acid monotherapy	8.6–16.7
Untreated	0.8–5.0
General population	1.6–2.2

Jeha LE and Morris HH. Optimizing outcomes in pregnant women with epilepsy. Cleve Clin J Med 2005; 72:938-945. Reprinted with permission. Copyright © 2005 Cleveland Clinic. All rights reserved.

Neurology recommends consideration for discontinuation of antiseizure medication in select women, including those who:

1. Have been seizure-free for 2 to 5 years
2. Have a single seizure type
3. Have a normal neurological examination and normal intelligence
4. Have an electroencephalogram that has normalized with treatment.

Epileptic women also are advised to take supplemental folic acid. Biale and Lewenthal (1984) performed a case-control study to evaluate effects of periconceptional folate supplementation in women taking anticonvulsants. Although 10 of 66 (15 percent) unsupplemented pregnancies resulted in offspring with congenital malformations, none of 33 neonates of supplemented women had anomalies. Similarly, in a case-control study using the Hungarian National Birth Registry, Kjær and colleagues (2008) concluded that risk of congenital abnormalities in fetuses exposed to carbamazepine, phenobarbital, phenytoin, and primidone is reduced—but not eliminated—by folic acid supplementation.

Vajda and colleagues (2008) recently reported results from the Australian Register of Antiepileptic Drugs in Pregnancy. They found that the risk of seizures during pregnancy was 50 to 70 percent less if the prepregnancy year was seizure free. Once one year without seizures had elapsed, there seemed to be relatively little further advantage in deferring pregnancy to avoid seizures during pregnancy.

Other Chronic Diseases

Cox and co-workers (1992) reviewed pregnancy outcomes of 1075 high-risk women who received preconceptional counseling. The 240 women with hypertension, renal disease, thyroid disease, asthma, or heart disease had significantly better outcomes than with their previous pregnancies. Indeed, 80 percent of those counseled were delivered of normal infants, compared with only 40 percent in the previous gestation which lacked prepregnancy counseling.

GENETIC DISEASES

The Centers for Disease Control and Prevention (2007) estimate that birth defects affect about one in every 33 babies born in the United States each year. Moreover, these defects are currently the leading cause of infant mortality and account for 20 percent of deaths. The benefits of preconceptional counseling usually are measured by comparing the incidence of new cases before and after initiation of a counseling program. Some examples of congenital conditions that clearly benefit from counseling include neural-tube defects, phenylketonuria, the thalassemias, Tay-Sachs, and other genetic diseases more common in individuals of Eastern European Jewish descent. Screening for heritable genetic diseases, including cystic fibrosis and fragile X syndrome, is further discussed in Chapter 13 (p. 297).

Neural-Tube Defects (NTDs)

The incidence of these defects is 1 to 2 per 1000 live births, and they are second only to cardiac anomalies as the most frequent structural fetal malformation (see Chap. 12, p. 281). Some NTDs, as well as congenital heart defects, are associated with a specific mutation in the methylene tetrahydrofolate reductase gene (677C → T). Adverse effects of this appear to be largely overcome by periconceptional folic acid supplementation (Ou and colleagues, 1996). Although its role is still controversial, low levels of vitamin B_{12} preconceptionally, similar to folate, may increase the risk of neural-tube defects (Molloy and co-workers, 2009; Thompson and colleagues, 2009).

The Medical Research Council on Vitamin Study Research Group (1991) conducted a randomized double-blind study of preconceptional folic acid therapy at 33 centers in seven European countries. Women with a previous affected child who took supplemental folic acid before conception and throughout the first trimester reduced their NTD recurrence risk by 72 percent. Perhaps more importantly, because 90 to 95 percent of infants with NTDs are born to women with no prior family history, Czeizel and Dudas (1992) showed that supplementation reduced the *a priori* risk of a *first* NTD occurrence.

Despite such benefit, in recent years, only 40 to 50 percent of women have taken folic acid supplementation during the periconceptional period (de Jong-van den Berg and co-workers, 2005; Goldberg and colleagues, 2006). The strongest predictor of use appears to be consultation with a health-care provider before conception. To improve supplementation, many countries fortify wheat and maize flour with folic acid to lower rates of NTDs (Bell and Oakley, 2008; Hamner and associates, 2009).

Phenylketonuria (PKU)

This inherited disorder of phenylalanine metabolism is an example of a disease in which the fetus is not at risk to inherit the disorder, but may be damaged by maternal disease. Specifically, individuals with PKU who eat an unrestricted diet have abnormally high blood phenylalanine levels. As discussed in Chapter 12 (p. 277), this amino acid readily crosses the placenta and can damage developing fetal organs, especially neural and cardiac tissues (Table 7-4). With appropriate preconceptional counseling and adherence to a phenylalanine-restricted diet before pregnancy,

TABLE 7-4. Frequency of Complications in the Offspring of Women with Untreated Phenylketonuria (Blood Phenylamine >1200 μmol/L)

Complication	Frequency in Affected Pregnancies (percent)
Spontaneous abortions	24
Mental retardation	92
Microcephaly	73
Congenital heart disease	12
Intrauterine growth restriction	40

Adapted with kind permission from Dr. François Maillot and Springer Science+Business Media: *Journal of Inherited Metabolic Disease*, A practical approach to maternal phenylketonuria management, Vol. 30, 2007, pp. 198–201, F Maillot, P Cook, M Lilburn, and PJ Lee, © SSIEM and Springer 2007.

the incidence of fetal malformations is dramatically reduced (Guttler, 1990; Hoeks, 2009; Koch, 1990, and all their associates).

The Maternal Phenylketonuria Collaborative Study confirmed the effectiveness of preconceptional care in almost 300 women with this disorder (Rouse and co-workers, 1997). Compared with infants whose mothers had poor dietary control, infants of those women with a low phenylalanine diet had a lower incidence of microcephaly—6 versus 15 percent, neurological abnormalities—4 versus 14 percent, and cardiac defects—none versus 16 percent. Similarly, Lee and colleagues (2005) found improved fetal birthweights, head circumferences, and intelligent quotient (IQ) scores in 110 newborns whose mothers began a phenylalanine-restricted diet before conception.

Thalassemias

These disorders of globin-chain synthesis are the most common single-gene disorders worldwide. As many as 200 million people carry a gene for one of these hemoglobinopathies, and hundreds of mutations are known to cause thalassemia syndromes (Chap. 51, p. 1090). In endemic areas such as Mediterranean and Southeast Asian countries, counseling and other prevention strategies have reduced the incidence of new cases by at least 80 percent (Angastiniotis and Modell, 1998). The American College of Obstetricians and Gynecologists (2007) recommends that individuals of such ancestry be offered carrier screening to allow them to make informed decisions regarding reproduction and prenatal diagnosis. Preimplantation genetic diagnosis of thalassemia is available for candidate patients (Chen and associates, 2008; Mohd Nasri and colleagues, 2009).

Experiences with a long-standing counseling program aimed at Montreal high school students at risk were summarized by Mitchell and colleagues (1996). During a 20-year period, 25,274 students of Mediterranean origin were counseled and tested for β-thalassemia. Within a few years of initiating the preconceptional program, all high-risk couples who requested prenatal diagnosis had already been counseled, and no affected children were born during those times.

Genetic Diseases More Prevalent in Individuals of Eastern European Jewish Descent

Most individuals of Jewish ancestry in North America are descended from Ashkenazi Jewish communities and are at an increased risk for having offspring with one of the autosomal recessive disorders listed in Table 7-5. The American College of Obstetricians and Gynecologists (2004) recommends preconceptional care for these women:

- The family history of individuals considering pregnancy—or who are already pregnant—should determine whether either member of the couple is of Eastern European (Ashkenazi) Jewish ancestry or has a relative with cystic fibrosis or a genetic condition listed in Table 7-5.
- Carrier screening for Tay-Sachs disease, Canavan disease, cystic fibrosis, and familial dysautonomia should be offered to Ashkenazi Jewish individuals before conception.
- Carrier screening is also available for mucolipidosis IV, Niemann-Pick disease type A, Fanconi anemia group C, Bloom syndrome, and Gaucher disease.
- When only one partner is of Ashkenazi Jewish descent, that individual should be screened first. If this individual is a carrier, the other partner is offered screening. The couple should be informed that the carrier frequency and detection rate in non-Jewish individuals is unknown for all of these disorders except Tay-Sachs disease and cystic fibrosis (see Table 7-5). Therefore, it is difficult to predict the couple's risk of having a child with the disorder.
- Individuals with a positive family history of one of these disorders should be offered carrier screening for the specific disorder and may benefit from genetic counseling (see Chap. 8, p. 200).
- When both partners are carriers of one of these disorders, they should be referred for genetic counseling and offered prenatal diagnosis.
- When an individual is found to be a carrier, he or she should be encouraged to inform relatives that they are at risk for carrying the same mutation.

Tay-Sachs Disease

The effectiveness of preconceptional counseling in reducing genetic disease has been most clearly demonstrated in Tay-Sachs disease. This disease is a severe, autosomal-recessive neurodegenerative disorder that leads to death in early childhood. In the early 1970s, there were approximately 60 new cases in the United States each year, primarily in individuals of Jewish heritage. An intensive worldwide campaign was initiated to counsel Jewish men and women of reproductive age to identify carriers through genetic testing, to provide prenatal testing for high-risk couples, and even to help heterozygote carriers choose unaffected mates. Within 8 years of the inception of this campaign, nearly 1 million young adults around the world had been tested and counseled. The incidence of new Tay-Sachs cases has plummeted to only approximately five new cases per year (Kaback and colleagues, 1993). Currently, most new cases are in the non-Jewish population.

TABLE 7-5. Clinical Features of Autosomal Recessive Genetic Diseases Frequent among Individuals of Eastern European Jewish Descent Amenable to Carrier Screening

Disorder	Disease Incidence	Carrier Frequency[a]	Detection Rate[a]	Description
Tay-Sachs disease	1/3000	1/30	Varies[b]	Caused by hexosaminidase A deficiency. Neurological motor and mental dysfunction with childhood death. No effective treatment
Canavan disease	1/6400	1/40	98%	Caused by aspartoacylase deficiency. Neurological disorder with developmental delay, hypotonia, large head, seizures, blindness, gastrointestinal reflux, and childhood death. No effective treatment
Cystic fibrosis	1/2500–3000	1/29	97%	See p. 178
Familial dysautonomia	1/3600	1/32	99%	Caused by mutations in IKBKAP gene. Neurological disorder with poor feeding, abnormal sweating, pain and temperature insensitivity, labile blood pressure, and scoliosis. No cure, but some treatments lengthen and improve quality of life
Fanconi anemia group C	1/32,000	1/89	99%	Usually caused by recessive mutation of any of several genes. Severe anemia, pancytopenia, developmental delay, failure to thrive, and later-childhood death. Congenital anomalies, microcephaly, and mental retardation may be present. Bone-marrow transplantation may be successful
Niemann-Pick disease type A	1/32,000	1/90	95%	Caused by sphingomyelinase deficiency. Neurodegenerative disorder with childhood death. No effective treatment
Mucolipidosis IV	1/62,500	1/127	95%	Neurodegenerative lysosomal storage disorder with growth failure, marked psychomotor retardation, and retinal degeneration. Life expectancy may be normal. There is no effective treatment
Bloom syndrome	1/40,000	1/100	95–97%	Increased chromosome breakage, susceptibility to infections and malignancies, growth deficiency, skin findings, and mental retardation. Death usually in 20s and related to cancer. No effective treatment
Gaucher disease (Type 1)	1/900	1/15	95%	Caused by β-glucosidase deficiency. Affects the spleen, liver, and bones. Develops at any age with a wide clinical spectrum including anemia, bruising and bleeding, hepatosplenomegaly, and osteoporosis. Enzyme therapy improves quality of life

[a]Non-Jewish carrier frequency and detection rates are unknown except for Tay-Sachs disease: 1 in 30 if French Canadian or Cajun ancestry and 1 in 300 for others, with a 98-percent carrier detection rate by Hex-A test.
[b]Detection is 98 percent by Hex-A test, 94 percent by DNA-based test.
Data from the American College of Obstetricians and Gynecologists (2004, 2005d) and the National Institute of Neurological Disorders and Stroke (2007a–d).

The American College of Obstetricians and Gynecologists (2005d) recommends the following regarding Tay-Sachs disease:

- Screening be offered before pregnancy if both members of a couple are of Ashkenazi Jewish, French-Canadian, or Cajun descent. Those with a family history consistent with Tay-Sachs disease should also be offered screening.
- When one member of a couple is at high risk as described above, but the other partner is not, the high-risk partner should be offered screening, especially if there is uncertainty about ancestry or if there is a consistent family history. If the high-risk partner is determined to be a carrier, the other partner also should be offered screening.

- Biochemical analysis by determining hexosaminidase A serum levels should be used for individuals in low-risk populations. Leukocyte testing must be used if the woman is already pregnant or taking oral contraceptives.
- Ambiguous or positive screening test results should be confirmed by biochemical and DNA analysis for the most common mutation. This will detect patients who carry genes associated with mild disease or pseudodeficiency states.
- If both partners are determined to be carriers of Tay-Sachs disease, genetic counseling and prenatal diagnosis should be offered.

PRECONCEPTIONAL COUNSELORS

Practitioners providing routine health maintenance have the best opportunity to provide preventive counseling. Gynecologists, internists, family practitioners, and pediatricians can do so at periodic health examinations. The occasion of a negative pregnancy test is an excellent time for counseling. Jack and associates (1995) administered a comprehensive preconceptional risk survey to 136 such women, and almost 95 percent reported at least one problem that could affect a future pregnancy. These included medical or reproductive problems—52 percent, family history of genetic diseases—50 percent, increased risk of human immunodeficiency virus (HIV)—30 percent, increased risk of hepatitis B and use of illegal substances—25 percent, alcohol use—17 percent, and nutritional risks—54 percent.

Basic advice regarding diet, alcohol and illicit drug use, smoking, vitamin intake, exercise, and other behaviors can be provided. Pertinent medical records should be reviewed. Counselors should be knowledgeable about relevant medical diseases, prior surgery, reproductive disorders, or genetic conditions, and must be able to interpret data and recommendations provided by other specialists. If the practitioner is uncomfortable providing counseling, the woman or couple should be referred to an appropriate counselor.

PRECONCEPTIONAL COUNSELING VISIT

Personal and Family History

A thorough review is taken of the medical, obstetrical, social, and family histories. Useful information is more likely to be obtained by asking specific questions about each history and about each family member than by asking general, open-ended questions. The interview may take 30 minutes to an hour. Some important information can be obtained by questionnaire, ideally at a routine prepregnancy visit. Prepared questionnaires are also available that address these topics. Answers are reviewed with the couple to ensure appropriate follow-up, including obtaining relevant medical records.

Medical History

Preconceptional counseling addresses all risk factors pertinent to mother and fetus. General points include how pregnancy will affect maternal health, and how a high-risk condition might affect the fetus. Finally, advice for improving outcome is provided. Almost any medical, obstetrical, or genetic condition warrants some consideration prior to pregnancy. These are discussed in terms of general maternal and fetal risks, and suggestions for prepregnancy evaluation are offered. More detailed information on specific diseases is found in their relevant chapters.

Genetic Diseases

Women whose ethnic background, race, or personal or family history places them at increased risk to have a fetus with a genetic disease should receive appropriate counseling. This includes the possibility of prenatal diagnosis as discussed in Chapter 13. These women may require additional counseling visits to a trained genetic counselor. They also may benefit from consultation with other specialists, for example, anesthesiologists, cardiologists, or surgeons.

Reproductive History

Questions are asked regarding infertility; abnormal pregnancy outcomes, including miscarriage, ectopic pregnancy, and recurrent pregnancy loss; and obstetrical complications such as preeclampsia, placental abruption, and preterm delivery (Stubblefield and co-workers, 2008). Regarding this last complication, most studies to date have not disclosed significant benefits of proposed prophylactic regimens such as treatment of bacterial vaginosis or other interconceptional antimicrobial regimens to prevent spontaneous preterm birth (Andrews and colleagues, 2006; Allsworth and Peipert, 2007).

History of a prior stillborn infant is especially important. This was recently reviewed by Silver (2007).

When identified, specific complications can be managed as outlined in discussions of these topics, which are found in later chapters of this text.

Social History

Maternal Age

Women at both ends of the reproductive-age spectrum have unique outcomes that are considered.

Adolescent Pregnancy. According to the Centers for Disease Control and Prevention, 7.6 percent of births in 2002 in the United States were in women between the ages of 15 and 19 years. Although this represented a 9-percent decline since 2000, the adolescent pregnancy rate remains among the highest of all industrialized nations (Ventura and colleagues, 2006). Adolescents are more likely to be anemic, and they are at increased risk to have growth-restricted infants, preterm labor, and a higher infant mortality rate (Fraser and associates, 1995; Usta and coworkers, 2008). The incidence of sexually transmitted diseases—common in adolescents—is even higher during pregnancy (Niccolai and colleagues, 2003).

Because most of their pregnancies are unplanned, adolescents rarely seek preconceptional counseling. These young women usually are still growing and developing and thus have greater caloric requirements than older women. The normal or underweight adolescent should be advised to increase caloric intake by 400 kcal/day. Alternatively, as discussed in Chapter 43, the obese adolescent likely does not need additional calories. Nonjudgmental questioning may elicit a history of substance abuse.

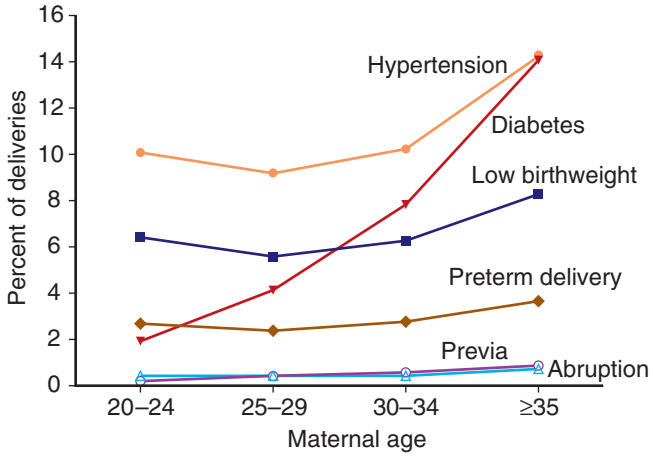

FIGURE 7-2. Incidence of selected pregnancy complications in relation to maternal age among 235,329 women delivered at Parkland Hospital, 1988–2007. (Used with permission from Dr. Donald McIntire.)

Pregnancy after Age 35. Currently, about 10 percent of pregnancies occur in women within this age group. The older woman is more likely to request preconceptional counseling, either because she has postponed pregnancy and now wishes to optimize her outcome, or because she plans to undergo infertility treatment. Some studies—including data from Parkland Hospital presented in Figure 7-2—indicate that after age 35, there is an increased risk for obstetrical complications as well as perinatal morbidity and mortality (Cunningham and Leveno, 1995; Huang and associates, 2008). The older woman who has a chronic illness or who is in poor physical condition usually has readily apparent risks. For the physically fit woman without medical problems, however, the risks are much lower than previously reported.

The maternal mortality rate is higher in women aged 35 and older. Compared with women in their 20s, women aged 35 to 39 are 2.5 times more likely and women aged 40 or more are 5.3 times more likely for pregnancy-related mortality (Geller and colleagues, 2006). According to Buehler and colleagues (1986), improved medical care may ameliorate these risks. They reviewed maternal deaths in the United States from 1974 through 1982. Through 1978, older women had a fivefold increased relative risk of maternal death compared with that of younger women. By 1982, however, the mortality rates for older women had decreased by 50 percent.

Maternal age-related fetal risks primarily stem from: (1) indicated preterm delivery for maternal complications such as hypertension and diabetes, (2) spontaneous preterm delivery, (3) fetal growth disorders related to chronic maternal disease or multifetal gestation, (4) fetal aneuploidy, and (5) pregnancies resulting from use of assisted reproductive technology.

Most researchers have found that fetal aneuploidy is the only congenital abnormality related to maternal age. A study of 577,000 births in British Columbia by Baird and co-workers (1991) and another of 574,000 live births in Sweden by Pradat (1992) found no association between nonaneuploid structural defects and maternal age. An exception was the study by Hollier and colleagues (2000) of nearly 103,000 pregnancies that included 3885 infants with congenital malformations delivered at Parkland Hospital. They reported that the incidence of nonaneuploid structural abnormalities increased significantly with maternal age. Some contend, however, that ascertainment bias was likely because older mothers commonly underwent targeted sonographic examination but not amniocentesis, and the study population was enriched with regional referrals for women with malformed fetuses.

Assisted Reproductive Techniques. Recall that older women have subfertility problems. And although the incidence of dizygotic twinning increases related to maternal age, the more important cause of multifetal gestation in older women follows the use of *assisted reproductive technology* and *ovulation induction*. Indeed, according to the Centers for Disease Control and Prevention, 40 percent of triplet and 17 percent of twin births in the United States in 2004 were the result of assisted reproductive technologies (Martin and associates, 2007). As discussed in Chapter 39 (p. 859), multifetal pregnancies account for much of the morbidity and mortality from preterm delivery (Schieve and colleagues, 2002; Strömberg and associates, 2002).

Over the past decade, experience has accrued that links assisted reproductive techniques to increased major congenital malformations. Hansen and co-workers (2002) reported that 9 percent of 837 infants conceived by in vitro fertilization and 8.6 percent of 301 infants conceived using intracytoplasmic sperm injection and had major birth defects—this compared with 4.2 percent in 4000 control women.

Paternal Age. Although there is an increased incidence of genetic diseases in offspring caused by new autosomal-dominant mutations in older men, the incidence is still low (see Chap. 12, p. 276). Accordingly, whether targeted sonographic examinations should be performed solely for advanced maternal or paternal age is controversial.

Recreational Drugs and Smoking

Fetal risks associated with alcohol, marijuana, cocaine, amphetamines, and heroin are discussed in Chapter 14 (see p. 326). The first step in preventing drug-related fetal risk is for the woman to honestly assess her usage. Questioning should be nonjudgmental. Alcoholism can be identified by asking the well-studied TACE questions, which correlate with *DSM-IV* criteria (Chang and associates, 1998). TACE is a series of four questions concerning *tolerance* to alcohol, being *annoyed* by comments about their drinking, attempts to *cut down*, and a history of drinking early in the morning—the *eye opener*.

In a Canadian study of more than 1000 postpartum patients, Tough and colleagues (2006) found that a high percentage of women reported alcohol use while trying to conceive. Specifically, nearly half of those planning for pregnancy reported a mean of 2.2 drinks daily during early gestation before they recognized that they were pregnant. Of note, Bailey and co-workers (2008) found that rates of binge drinking and marijuana use by men were unaffected by their partner's pregnancy. The frequency and pattern of such behaviors clearly underscore the opportunity for preconceptional counseling.

In 2005, approximately 10 percent of women giving birth in the United States smoked cigarettes, and this rate was roughly

doubled in those mothers between ages 18 and 24 years as well as in those who did not graduate from high school (Martin and associates, 2007). Smoking affects fetal growth in a dose-dependent manner. It increases the risk of premature rupture of membranes, placenta previa, fetal-growth restriction, and low birthweight (American College of Obstetricians and Gynecologists, 2005e). Even passive exposure to environmental tobacco smoke appears to negatively affect birthweight (Hegaard and associates, 2006). Smoking has also been associated with sudden infant death syndrome (Pollack and co-workers, 2001). Lastly, smoking increases the risk of pregnancy complications related to vascular damage, such as uteroplacental insufficiency and placental abruption (see Chap. 35, p. 761).

After counseling, the woman should be provided with a prepregnancy program to reduce or eliminate smoking. A number of resources to assist with such a program are available from the American College of Obstetricians and Gynecologists (2005e).

Environmental Exposures

Everyone is exposed to environmental substances, but fortunately only a few agents have an impact on pregnancy outcome (Windham and Fenster, 2008). Exposures to infectious organisms and chemicals impart the greatest risk.

Methyl mercury is a recognized environmental contaminant for which all pregnant women are potentially at risk because certain kinds of large fish are contaminated (see Chap. 14, p. 323). Mercury is a neurotoxin that readily crosses the placenta and has adverse fetal effects (Jedrychowski and collaborators, 2006). Accordingly, the U.S. Food and Drug Administration (FDA) (2004) has recommended that pregnant women not eat shark, swordfish, king mackerel, or tilefish, and that they consume no more than 12 ounces of other kinds of shellfish or other fish per week. Albacore or "white" tuna has more mercury than other canned tuna. Oken and colleagues (2003) have provided data showing that since the original FDA advisory, there has been a decline of ingestion by pregnant women of suspect fish species.

Electromagnetic Energy. There is no evidence in humans or animals that exposure to various electromagnetic fields such as high-voltage power lines, electric blankets, microwave ovens, and cellular phones causes adverse fetal effects (O'Connor, 1999; Robert, 1999). Electrical shock is discussed further in Chapter 42 (p. 942).

Lifestyle and Work Habits

A number of personal and work habits as well as lifestyle issues may affect pregnancy outcome.

Diet

Pica for ice, laundry starch, clay, dirt, or other nonfood items should be discouraged (see Chap. 8, p. 211). In some cases, it may represent an unusual physiological response to iron deficiency (Federman and colleagues, 1997). Many vegetarian diets are protein deficient but can be corrected by increasing egg and cheese consumption. As discussed in Chapter 43, obesity is associated with a number of maternal complications such as hypertension, preeclampsia, gestational diabetes, labor abnormalities, postterm pregnancy, cesarean delivery, and operative complications (American College of Obstetricians and Gynecologists, 2005b). It also appears to be associated with a range of structural anomalies (Stothard and colleagues, 2009). By comparing changes in prepregnancy body mass index (BMI), Villamor and Cnattingius (2006) found that modest increases in BMI before pregnancy could result in perinatal complications, even if a woman does not become overweight.

In addition to nutritional deficiencies, anorexia and bulimia increase the risk of associated maternal problems such as electrolyte disturbances, cardiac arrhythmias, and gastrointestinal pathology (Becker and associates, 1999). Pregnancy-related complications include greater risks of low birthweight, smaller head circumference, microcephaly, and small for gestational age (Kouba and co-workers, 2005).

Exercise

Conditioned pregnant women usually can continue to exercise throughout gestation (American College of Obstetricians and Gynecologists, 2002; Duncombe and associates, 2006). As discussed in Chapter 8 (p. 206), there are no data to suggest that exercise is deleterious during pregnancy. One caveat is that as pregnancy progresses, balance problems and joint relaxation may predispose to orthopedic injury. A woman should be advised not to exercise to exhaustion, and she should augment heat dissipation and fluid replacement. She should avoid supine positions, activities requiring good balance, and extreme weather conditions.

Domestic Abuse

Pregnancy can exacerbate interpersonal problems and is a time of increased risk from an abusive partner. According to the American College of Obstetricians and Gynecologists (2006), and as discussed in Chapter 42 (p. 936), from 1 to 20 percent of women are abused during pregnancy. Silverman and associates (2006) found that women reporting intimate partner violence during the year prior to pregnancy were at increased risk for a number of complications. These included hypertension, vaginal bleeding, hyperemesis, preterm delivery, and low-birthweight infants. Similarly, Rodrigues and colleagues (2008) found in a survey of more than 2600 consecutive postpartum women that 24 percent of mothers of preterm infants had experienced physical abuse during pregnancy compared with 8 percent of mothers of term newborns.

The interviewer should inquire about risk factors for domestic violence and should offer intervention as appropriate. Abuse is more likely in women whose partners abuse alcohol or drugs, are recently unemployed, have a poor education or low income, or have a history of arrest (Grisso and colleagues, 1999; Kyriacou and associates, 1999). In a survey of approximately 200 women who underwent violence screening during prenatal care, 97 percent reported that they were not embarrassed, angry, or offended when assessed (Renker and Tonkin, 2006).

Family History

The most thorough method for obtaining a family history is to construct a pedigree using the symbols shown in **Figure 7-3.** The health and reproductive status of each "blood relative" should be individually reviewed for medical illnesses, mental

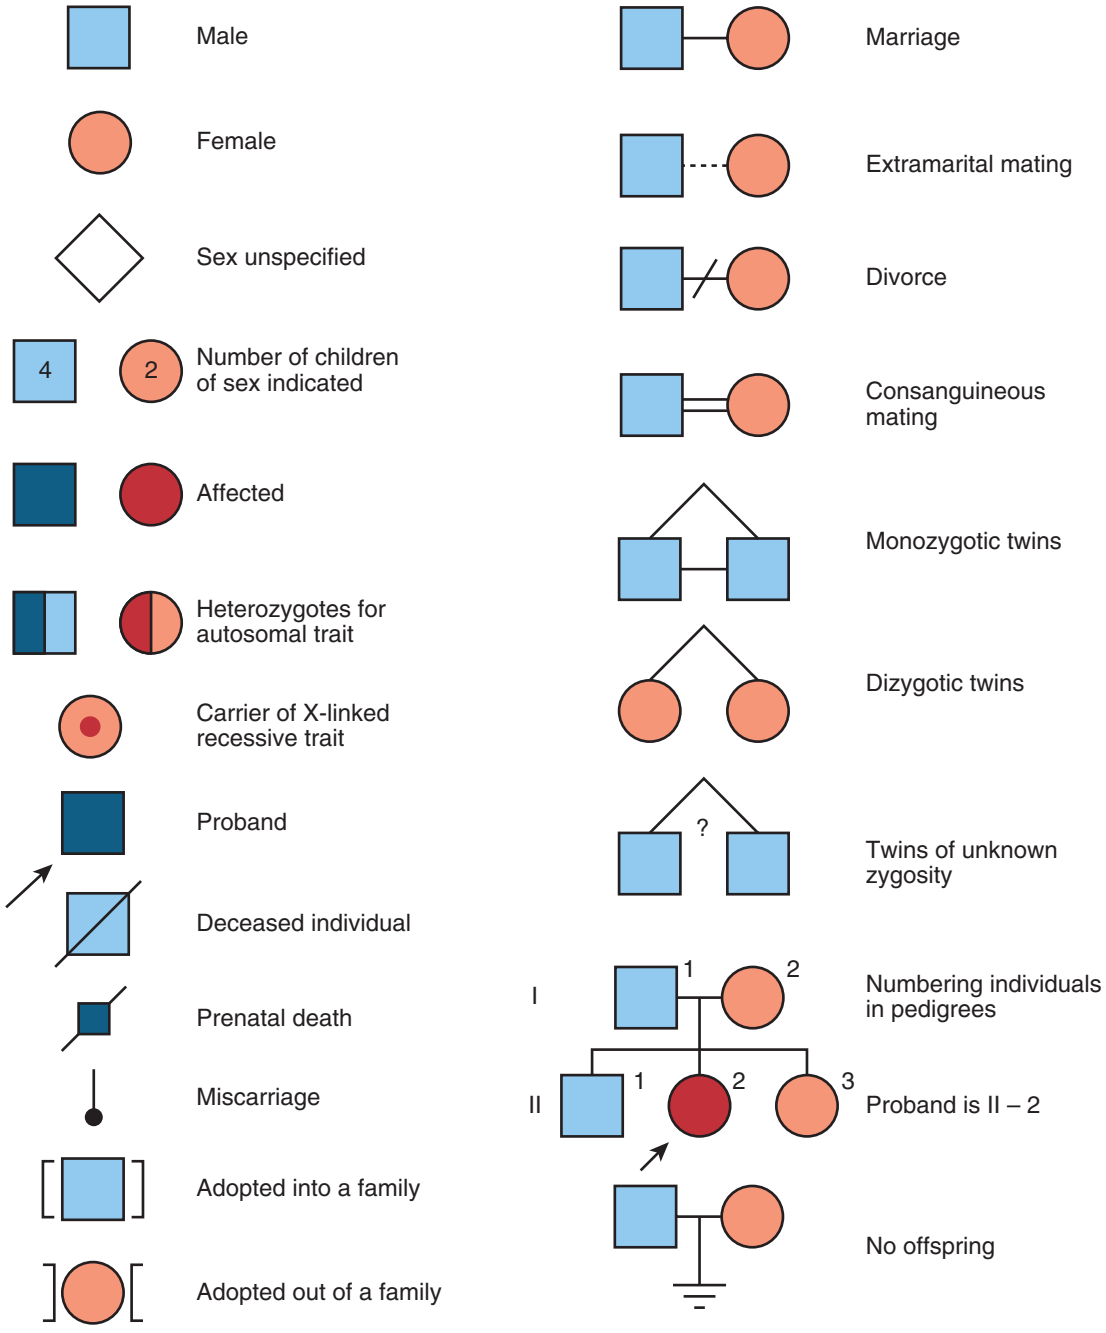

FIGURE 7-3. Symbols used for pedigree construction. (Redrawn from Thompson and colleagues, 1991.)

retardation, birth defects, infertility, and pregnancy loss. Certain racial, ethnic, or religious backgrounds may indicate increased risk for specific recessive disorders.

Although most women can provide some information regarding their history, their understanding may be limited. For example, several studies have shown that pregnant women often fail to report a birth defect in the family or report it incorrectly. It is thus important to verify the type of reported defect or genetic disease by reviewing pertinent medical records or by contacting affected relatives for additional information.

Immunizations

Preconceptional counseling includes assessment of immunity. Depending on health status, travel plans, and time of year, other immunizations may be indicated as discussed in Chapter 8 (see Table 8-10, p. 208). Vaccines consist of toxoids—for example, tetanus; killed bacteria or viruses—such as influenza, pneumococcus, hepatitis B, meningococcus, and rabies; or attenuated live viruses—including varicella-zoster, measles, mumps, polio, rubella, chickenpox, and yellow fever. Immunization during pregnancy with toxoids or with killed bacteria or viruses has not been associated with adverse fetal outcomes. Alternatively, live-virus vaccines are not recommended during pregnancy and ideally should be given at least 1 month before attempts to conceive. Women inadvertently given measles, mumps, rubella, or varicella vaccines during pregnancy, however, are not necessarily advised to seek pregnancy termination. Most reports indicate that immunization to any of these agents poses only a theoretical risk to

the fetus. Lastly, immunization to smallpox, anthrax, and other bioterrorist diseases should be discussed (see Chap. 58, p. 1230). Based upon their study of approximately 300 women who received smallpox vaccination near the time of conception, Ryan and co-workers (2008) found that rates of pregnancy loss, preterm birth, and birth defects were not higher than expected.

Screening Tests

Certain laboratory tests may be helpful in assessing the risk for and preventing some complications during pregnancy. These include basic tests that are usually performed during prenatal care and are discussed in Chapter 8. Some examples are that rubella, varicella, and hepatitis B immune status should be determined so that vaccination can be carried out as part of preconceptional care. A hemogram will exclude most serious inherited anemias. Hemoglobin electrophoresis is performed in individuals at increased risk—for example, African-Americans for sickle syndromes and women of Mediterranean or Asian origin for thalassemias. As discussed on page 178, couples of Jewish ancestry are candidates for carrier testing for Tay-Sachs and Canavan disease, whereas Caucasians of northern European descent may elect screening for cystic fibrosis.

More specific tests may assist the evaluation of women with certain chronic medical diseases (**Table 7-6**). Examples of some, but certainly not all, chronic diseases that may be assessed by prenatal testing include kidney and cardiovascular diseases and diabetes.

TABLE 7-6.

Condition	Reference Chapter	Recommendations for Preconceptional Counseling
Abnormal weight	Chap. 43, p. 946	Calculate BMI yearly. (see Fig. 43-1, p. 947). *BMI* $\geq$ *25 kg/m*^{2}: Counsel on diet. Test for diabetes and metabolic syndrome if indicated. BMI $\leq$ *18.5 kg/m*^{2}: Assess for eating disorder
Cardiovascular disease	Chap. 44, p. 961 Chap. 14, p. 325	Counsel on cardiac risks during pregnancy. Optimize cardiac function, and offer effective contraception during this time and for those not desiring conception. Discuss warfarin, ACE inhibitor, and ARB teratogenicity and if possible, switch to less dangerous agent when conception planned. Offer genetic counseling to those with congenital cardiac anomalies (see Table 44-4, p. 961). Review situations for infective endocarditis
Chronic hypertension	Chap. 45, p. 985 Chap. 14, p. 319	Counsel on specific risks during pregnancy. Assess those with long-standing HTN for ventricular hypertrophy, retinopathy, and renal disease. Counsel women taking ACE inhibitors and ARBs on drug teratogenicity, on effective contraception during use, and on the need to switch agents prior to conception
Asthma	Chap. 46, p. 996	Counsel on asthma risks during pregnancy. Optimize pulmonary function and offer effective contraception during this time. Treat women with pharmacological step therapy for chronic asthma based on ACOG-ACAAI (2000) recommendations
Thrombophilia	Chap. 47, p. 1014	Question for personal or family history of thrombotic events or recurrent poor pregnancy outcomes. If found, counsel and screen those contemplating pregnancy. Offer genetic counseling to those with known thrombophilia. Discuss warfarin teratogenicity, offer effective contraception during use, and switch to a less teratogenic agent, if possible, prior to conception
Renal disease	Chap. 48, p. 1039 Chap. 14, p. 319	Counsel on specific risks during pregnancy. Optimize blood pressure control and offer effective contraception during this time. Counsel women taking ACE inhibitors and ARBs on their teratogenicity, on effective contraception during use, and on the need to switch agents prior to conception

TABLE 7-6. Continued

Condition	Reference Chapter	Recommendations for Preconceptional Counseling
Gastrointestinal disease	Chap. 49, p. 1054 Chap. 14, p. 320	*Inflammatory bowel disease:* Counsel affected women on subfertility risks and risks of adverse pregnancy outcomes. Discuss teratogenicity of methotrexate and the other immunomodulators, about which less is known, e.g., mycophenolate mofetil, etc. Offer effective contraception during their use and switch agents, if possible, prior to conception
Hepatobiliary disease	Chap. 50, p. 1067	*Hepatitis B*: Vaccinate all high-risk women prior to conception (Table 8-10, p. 208). Counsel chronic carriers on transmission prevention to partners and fetus *Hepatitis C*: Screen high-risk women. Counsel affected women on risks of disease and transmission. Refer for treatment, discuss ramifications of treatment during pregnancy, and offer effective contraception
Hematological disease	Chap. 51, p. 1085	*Sickle-cell disease:* Screen all black women. Counsel those with trait or disease. Test partner if desired *Thalassemias:* Screen women of southeast asian or mediterranean ancestry
Diabetes	Chap. 52, p. 1113	Advocate good glucose control, especially in periconceptional period to decrease known teratogenicity of overt diabetes. Evaluate for retinopathy, nephropathy, hypertension, etc. (See Table 7-2, p. 176)
Thyroid disease	Chap. 53, p. 1126	Screen those with thyroid disease symptoms. Ensure iodine-sufficient diet. Treat overt hyper- or hypothyroidism prior to conception. Counsel on risks to pregnancy outcome
Connective tissue disease	Chap. 54, p. 1146 Chap. 14, p. 320	*RA*: Counsel on flare risk after pregnancy. Discuss methotrexate and leflunomide teratogenicity, as well as possible effects of other immunomodulators. Offer effective contraception during their use and switch agents prior to conception. Halt NSAIDS by 27 weeks' gestation *SLE*: Counsel on risks during pregnancy. Optimize disease and offer effective contraception during this time and for those not desiring conception. Discuss mycophenolate mofetil and cyclophosphamide teratogenicity as well as possible effects of newer immunomodulators. Effective contraception during their use. If possible, switch agents prior to conception
Neurological and psychiatric disorders	Chap. 55, p. 1164 Chap. 14, p. 323	*Depression:* Screen for symptoms of depression. In those affected, counsel on risks of treatment and of untreated illness and high risk of exacerbation during pregnancy and the puerperium *Seizure disorder:* optimize seizure control using monotherapy if possible. (see p. 176 and Table 7-3)
Dermatological disease	Chap. 56, p. 1191 Chap. 14, p. 324	Discuss isotretinoin and etretinate teratogenicity, effective contraception during their use, and need to switch agents prior to conception
Cancer	Chap. 57, p. 1193 Chap. 14, p. 320	Counsel on fertility preservation options prior to cancer therapy and on decreased fertility following certain agents. Offer genetic counseling to those with mutation-linked cancers. Evaluate cardiac function in those given cardiotoxic agents, such as adriamycin. Obtain mammography for those given childhood chest radiotherapy. Discuss SERM teratogenicity, effective contraception during their use, and need to switch agents prior to conception. Review chemotherapy and discuss possible teratogenic effects if continued during pregnancy

(*continued*)

TABLE 7-6. Continued

Condition	Reference Chapter	Recommendations for Preconceptional Counseling
Infectious diseases	Chap. 58, p. 1210	*Asymptomatic bacteriuria:* No role for preconceptional screening *Bacterial Vaginosis:* No role for preconceptional screening *Influenza:* Vaccinate women who will be pregnant during flu season. Vaccinate high-risk women prior to flu season *Malaria:* Counsel to avoid travel to endemic areas during conception. If unable, offer effective contraception during travel or provide chemoprophylaxis for those planning pregnancy *Rubella:* Screen for rubella immunity. If nonimmune, vaccinate and counsel on the need for effective contraception during the subsequent 3 months *Tuberculosis:* Screen high-risk women and treat prior to conception *Tetanus:* Update vaccination, as needed, in all reproductive-aged women *Varicella:* Question regarding immunity. If nonimmune, vaccinate.
STDs	Chap. 59, p. 1235	*Gonorrhea, syphilis, chlamydial infection:* Screen high-risk women and treat as indicated *HIV:* Screen at-risk women. Counsel affected women on risks during pregnancy and on perinatal transmission. Discuss initiation of treatment prior to pregnancy to decrease transmission risk. Offer effective contraception to those not desiring conception *HPV:* Provide PAP smear screening. Vaccinate candidate patients *HSV:* Provide serological screening to asymptomatic women with affected partners. Counsel affected women on risks of perinatal transmission and of preventative measures during the third trimester and labor

ACAAI = American College of Allergy, Asthma, and Immunology; ACE = angiotensin-converting enzyme inhibitor; ARB = angiotensin-receptor blocker; ACOG = American College of Obstetricians and Gynecologists; BMI = body mass index; HIV = human immunodeficiency virus; HPV = human papillomavirus; HSV = herpes simplex virus; HTN = hypertension; NSAID = nonsteroidal anti-inflammatory drug; RA = rheumatoid arthritis; SERM = selective estrogen-receptor modulator; SLE = systemic lupus erythematosus; STD = sexually transmitted disease.

CHAPTER 8

Prenatal Care

OVERVIEW OF PRENATAL CARE 189
ORGANIZATION OF PRENATAL CARE 190
NUTRITION 200
COMMON CONCERNS 205

Organized prenatal care in the United States was introduced largely by social reformers and nurses. In 1901, Mrs. William Lowell Putnam of the Boston Infant Social Service Department began a program of nurse visits to women enrolled in the home delivery service of the Boston Lying-in Hospital (Merkatz and colleagues, 1990). It was so successful that a prenatal clinic was established in 1911. In 1915, J. Whitridge Williams reviewed 10,000 consecutive deliveries at Johns Hopkins Hospital and concluded that 40 percent of 705 perinatal deaths could have been prevented by prenatal care. In 1954, Nicholas J. Eastman credited organized prenatal care with having "done more to save mothers' lives in our time than any other single factor" (Speert, 1980). In the 1960s, Dr. Jack Pritchard established a network of university-operated prenatal clinics located in the most underserved communities in Dallas County. In large part because of increased accessibility, currently more than 95 percent of medically indigent women delivering at Parkland Hospital receive prenatal care. Importantly and related, the perinatal mortality rate of women in this system is less than that of the United States overall.

OVERVIEW OF PRENATAL CARE

Almost a century after its introduction, prenatal care has become one of the most frequently used health services in the United States. In 2006, more than 4.2 million births were registered in the United States (Martin and associates, 2009). In 2001, there were approximately 50 million prenatal visits—the median was 12.3 visits per pregnancy—and as shown in Figure 8-1, many women had 17 or more visits.

A new birth certificate form was introduced in 2003 and is now used by 19 states, with the remaining 31 states continuing to use the 1989 form. Unfortunately, data regarding the timing of prenatal care from these two systems are not comparable. For example, with the 1989 version that represents 2.2 million births, nearly 83 percent of women received first-trimester prenatal care in 2006. Conversely, those states using the 2003 version reported that only 69 percent of women received first-trimester care (Martin and associates, 2009). Although the difference is striking, it merely represents a change in reporting and is not a harbinger of diminished of prenatal care. Indeed, according to the Centers for Disease Control and Prevention (2008a), birth certificate data using the 1989 version show that more than 99 percent of women received some prenatal care in the third trimester.

Since the early 1990s, the largest gains in timely prenatal care have been among minority groups. As shown in Figure 8-2, however, disparity continues. In 2006, African American and Hispanic women were more than twice as likely as non-Hispanic white women to begin prenatal care after the first trimester (Martin and associates, 2009). Obstetrical and medical risk factors or complications identifiable during prenatal care are summarized in Table 8-1. Importantly, many of these complications are *treatable.*

Assessing Adequacy of Prenatal Care

A commonly employed system for measuring prenatal care adequacy is the index of Kessner and colleagues (1973). As shown in Table 8-2, this *Kessner Index* incorporates three items from the birth certificate: length of gestation, timing of the first prenatal visit, and number of visits. It does not, however, measure the quality of care, nor does it consider the relative risk of complications for the mother. Still, the index remains a useful measure of prenatal care adequacy. Using this index, the National Center for Health Statistics concluded that 12 percent of American

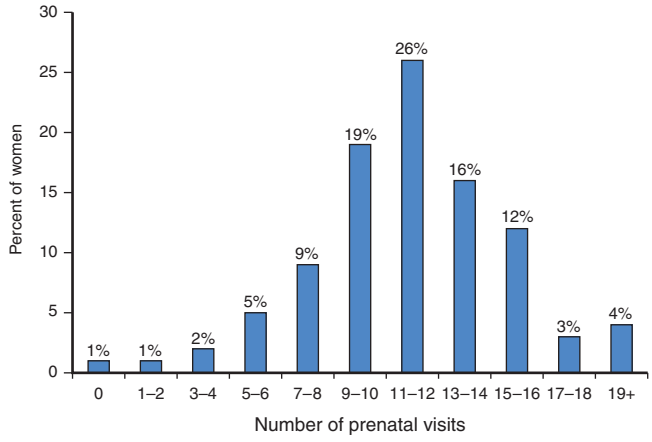

FIGURE 8-1 Frequency distribution of the number of prenatal visits for the United States in 2001. (Adapted from Martin and associates, 2002b.)

women who were delivered in 2000 received inadequate prenatal care (Martin and associates, 2002a).

The Centers for Disease Control and Prevention (2000) analyzed birth certificate data for the years 1989 to 1997 and found that half of women with delayed or no prenatal care wanted to begin care earlier. Reasons for inadequate prenatal care varied by social and ethnic group, age, and method of payment. The most common reason cited was late identification of pregnancy by the patient. The second most commonly cited barrier was lack of money or insurance for such care. The third was inability to obtain an appointment.

Effectiveness of Prenatal Care

Prenatal care designed during the early 1900s was focused on lowering the extremely high maternal mortality rates. Such care undoubtedly contributed to the dramatic decline in maternal mortality rates from 690 per 100,000 births in 1920 to 50 per 100,000 by 1955 (Loudon, 1992). As discussed in Chapter 1 (p. 5), the current low maternal mortality rate of approximately 8 per 100,000 is likely associated with the high utilization of prenatal care. Indeed, in a population-based study from North Carolina, Harper and co-workers (2003) found that the risk of pregnancy-related maternal death was decreased fivefold among recipients of prenatal care.

There are other studies that attest to the efficacy of prenatal care. Herbst and associates (2003) found that no prenatal care was associated with more than a twofold increased risk of preterm birth. Schramm (1992) compared the costs and benefits of prenatal care in 1988 for more than 12,000 Medicaid patients in Missouri. For each $1 spent for prenatal care, there were estimated savings of $1.49 in newborn and postpartum costs. Vintzileos and colleagues (2002a) analyzed National Center for Health Statistics data for 1995 to 1997. They reported that women with prenatal care had an overall stillbirth rate of 2.7 per 1000 compared with 14.1 per 1000 for women without prenatal care—an adjusted relative risk of 3.3 for fetal death. Vintzileos and colleagues (2002b, 2003) later reported that prenatal care was associated with significantly lower rates of preterm births as well as neonatal death associated with several high-risk conditions that included placenta previa, fetal-growth restriction, and postterm pregnancy.

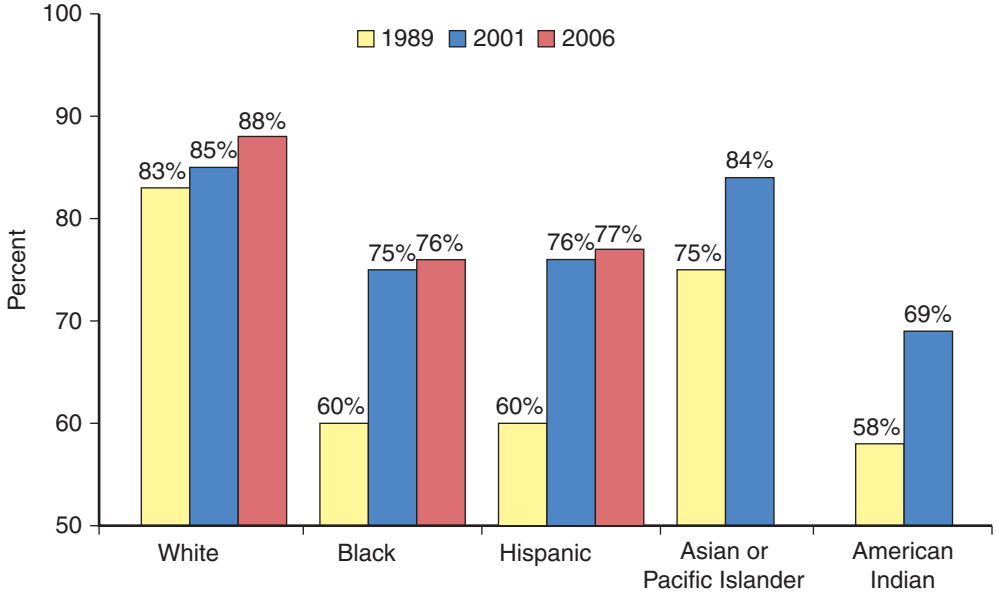

FIGURE 8-2 Percentage of women in the United States with prenatal care beginning in the first trimester by ethnicity in 1989, 2001, and 2006. (Adapted from Martin and associates, 2002b, 2009.)

ORGANIZATION OF PRENATAL CARE

The essence of prenatal care is described by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) as: "A comprehensive antepartum care program involves a coordinated approach to medical care and psychosocial support that optimally begins before conception and extends throughout the antepartum period." This comprehensive program includes: (1) preconceptional care, (2) prompt diagnosis of pregnancy, (3) initial prenatal evaluation, and (4) follow-up prenatal visits.

Preconceptional Care

Because health during pregnancy depends on health before pregnancy, preconceptional care should logically be an integral prelude to prenatal care. As discussed in detail in Chapter 7, a comprehensive preconceptional care program has the potential to assist women by reducing risks, promoting healthy lifestyles, and improving readiness for pregnancy.

TABLE 8-1. Obstetrical and Medical Risk Factors Detected During Prenatal Care in the United States in 2001

Risk Factor	Births	Percent
Total live births	4,025,933	100
Gestational hypertension	150,329	3.7
Diabetes	124,242	3.1
Anemia	99,558	2.5
Hydramnios/oligohydramnios	54,694	1.4
Lung disease	48,246	1.2
Genital herpes	33,560	0.8
Chronic hypertension	32,232	0.8
D (Rh) sensitization	26,933	0.7
Cardiac disease	20,698	0.5
Renal disease	12,045	0.3
Incompetent cervix	11,251	0.3
Hemoglobinopathy	3,141	0.1
Total	616,929	15.3

Data from Martin and associates (2002b).

TABLE 8-2. Kessner Index Criteria

Adequate Prenatal Care

Initial visit in first trimester and:

Weeks		Attended Prenatal Visits
17	and	2 or more
18–21	and	3 or more
22–25	and	4 or more
26–29	and	5 or more
30–31	and	6 or more
32–33	and	7 or more
34–35	and	8 or more
36 or more	and	9 or more

Inadequate Prenatal Care

Initial visit in third trimester or:

Weeks		Attended Prenatal Visits
17–21	and	None
22–29	and	1 or fewer
30–31	and	2 or fewer
32–33	and	3 or fewer
34 or more	and	4 or fewer

Intermediate Care

All other combinations

Diagnosis of Pregnancy

The diagnosis of pregnancy usually begins when a woman presents with symptoms, and possibly a positive home urine pregnancy test result. Typically, such women receive confirmatory testing of urine or blood for human chorionic gonadotropin (hCG). There may be presumptive or diagnostic findings of pregnancy on examination. Sonography is often used, particularly in those cases in which there is question about pregnancy viability or location.

Signs and Symptoms

A number of clinical findings and symptoms may indicate an early pregnancy.

Cessation of Menses. The abrupt cessation of menstruation in a healthy reproductive-aged woman who previously has experienced spontaneous, cyclical, predictable menses is highly suggestive of pregnancy. As discussed in Chapter 3 (p. 44), there is appreciable variation in the length of the ovarian—and thus menstrual—cycle among women, and even in the same woman. Thus, amenorrhea is not a reliable indication of pregnancy until 10 days or more after expected menses onset. When a second menstrual period is missed, the probability of pregnancy is much greater.

Uterine bleeding somewhat suggestive of menstruation occurs occasionally after conception. One or two episodes of bloody discharge, somewhat reminiscent of and sometimes mistaken for menstruation, are not uncommon during the first month of pregnancy. Such episodes are interpreted to be physiological, and likely the consequence of blastocyst implantation.

Changes in Cervical Mucus. Dried cervical mucus examined microscopically has characteristic patterns dependent on the stage of the ovarian cycle and the presence or absence of pregnancy. Mucus crystallization necessary for the production of the fern pattern is dependent on an increased sodium chloride concentration. Cervical mucus is relatively rich in sodium chloride when estrogen, but not progesterone, is being produced. Thus, from approximately the 7th to the 18th day of the cycle, a fern-like pattern is seen (Fig. 8-3).

In contrast, progesterone secretion—even without a reduction in estrogen secretion—acts promptly to lower sodium chloride concentration to levels that prohibit ferning. During pregnancy, progesterone usually exerts a similar effect, even though the amount of estrogen produced is enormous. After approximately the 21st day, a different pattern forms that gives a beaded or cellular appearance (Fig. 8-4). This beaded pattern also is usually encountered during pregnancy. Thus, copious thin mucus with a fern pattern on drying makes early pregnancy unlikely.

Breast Changes. Anatomical changes in the breasts that accompany pregnancy are characteristic during a first pregnancy (see Chap. 5, p. 111). These are less obvious in multiparas, whose breasts may contain a small amount of milky material or colostrum for months or even years after the birth of their last child, especially if the child was breast fed.

Vaginal Mucosa. During pregnancy, the vaginal mucosa usually appears dark bluish- or purplish-red and congested—the

FIGURE 8-3 Photomicrograph of cervical mucus obtained on day 11 of the menstrual cycle. (Used with permission from Stephen W. Glenn on behalf of Dr. James C. Glenn.)

Chadwick sign, popularized by him in 1886. Although presumptive evidence of pregnancy, it is not conclusive.

Skin Changes. Increased pigmentation and changes in appearance of abdominal striae are common to, but not diagnostic of, pregnancy. They may be absent during pregnancy, and they may be seen in women taking estrogen-progestin contraceptives (see Chap. 5, p. 111 and Chap. 56, p. 1185).

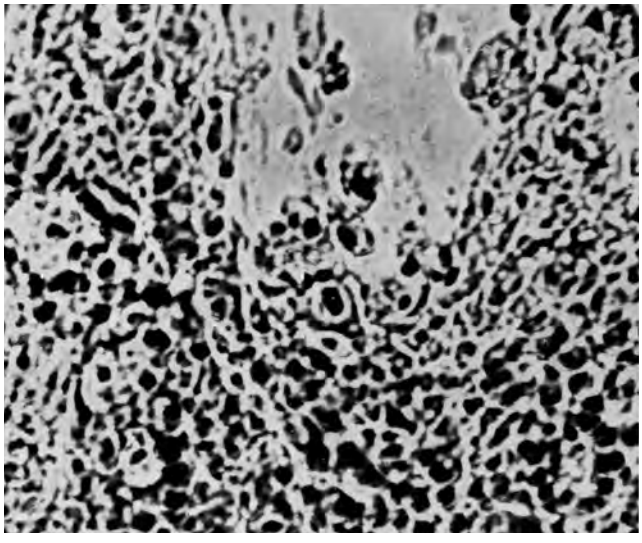

FIGURE 8-4 Photomicrograph of dried cervical mucus obtained from the cervical canal of a woman pregnant at 32 to 33 weeks. The beaded pattern is characteristic of progesterone action on the endocervical gland mucus composition. (Courtesy of Dr. J. C. Ullery.)

Changes in the Uterus. During the first few weeks of pregnancy, the increase in uterine size is limited principally to the anteroposterior diameter. By 12 weeks, the body of the uterus is almost globular with an average diameter of 8 cm. On bimanual examination, it feels doughy or elastic and sometimes becomes exceedingly soft. At 6 to 8 weeks' menstrual age, a firm cervix is felt which contrasts with the now softer fundus and compressible interposed softened isthmus—the *Hegar sign.* The softening at the isthmus may be so marked that the cervix and the body of the uterus seem to be separate organs.

When using a stethoscope for auscultation, the *uterine souffle* may be heard in the later months of pregnancy. This is a soft, blowing sound that is synchronous with the maternal pulse. It is produced by the passage of blood through the dilated uterine vessels and is heard most distinctly near the lower portion of the uterus. In contrast, the *funic souffle* is a sharp, whistling sound that is synchronous with the fetal pulse. It is caused by the rush of blood through the umbilical arteries and may not be heard consistently.

Cervical Changes. There is increased cervical softening as pregnancy advances. Other conditions, such as estrogen–progestin contraceptives, may also cause such softening. As pregnancy progresses, the external cervical os and cervical canal may become sufficiently patulous to admit the fingertip. However, the internal os should remain closed.

Perception of Fetal Movements. Maternal perception of fetal movement may depend on factors such as parity and habitus. In general, after a first successful pregnancy, a woman may first perceive fetal movements between 16 and 18 weeks. A primigravida may not appreciate fetal movements until approximately 2 weeks later (18 to 20 weeks). At approximately 20 weeks, depending on maternal habitus, an examiner can begin to detect fetal movements.

Pregnancy Tests

Detection of hCG in maternal blood and urine provides the basis for endocrine tests of pregnancy. This hormone is a glycoprotein with a high carbohydrate content. The molecule is a heterodimer composed of two dissimilar subunits, designated α and β, which are noncovalently linked (see Chap. 3, p. 63). The α-subunit is identical to those of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and thyroid-stimulating hormone (TSH). HCG prevents involution of the corpus luteum, the principal site of progesterone formation during the first 6 weeks.

Trophoblast cells produce hCG in amounts that increase exponentially following implantation. With a sensitive test, the hormone can be detected in maternal plasma or urine by 8 to 9 days after ovulation. The doubling time of plasma hCG concentration is 1.4 to 2.0 days. As shown in **Figure 8-5**, serum hCG levels increase from the day of implantation and reach peak levels at 60 to 70 days. Thereafter, the concentration declines slowly until a nadir is reached at about 16 weeks.

Measurement of hCG. With the recognition that LH and hCG were composed of both an α- and a β-subunits, but that the β-subunits of each were structurally distinct, antibodies were

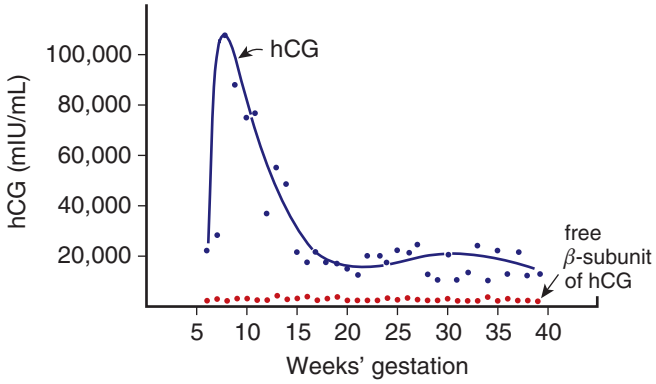

FIGURE 8-5 Mean concentration of human chorionic gonadotropin (hCG) in serum of women throughout normal pregnancy. The free β-subunit of hCG is in low concentration throughout pregnancy. (Data from Ashitaka and colleagues, 1980; Selenkow and co-workers, 1971.)

developed with high specificity for the β-subunit of hCG. This specificity is the basis for its detection, and numerous commercial immunoassays are available for measuring serum and urine levels of hCG. Although each immunoassay detects a slightly different mixture of hormone, its free subunits, or its metabolites, all are appropriate for pregnancy testing (Cole, 1998).

One commonly employed technique is the *sandwich-type immunoassay*. With this test, a monoclonal antibody against the β-subunit is bound to a solid-phase support. The attached antibody is then exposed to and binds hCG in the serum or urine specimen. A second antibody is then added to "sandwich" the bound hCG. In some assays, the second antibody is linked to an enzyme, such as alkaline phosphatase. When substrate for the enzyme is added, a color develops, the intensity of which is proportional to the amount of enzyme and thus to the amount of the second antibody bound. This, in turn, is a function of the amount of hCG in the test sample. The sensitivity for the laboratory detection of hCG in serum is as low as 1.0 mIU/mL using this technique. With extremely sensitive immunoradiometric assays, the detection limit is even lower (Wilcox and associates, 2001).

False-positive hCG test results are rare (Braunstein, 2002). A few women have circulating serum factors that may interact with the hCG antibody. The most common are heterophilic antibodies, which are human antibodies directed against animal-derived antigens used in immunoassays. Thus, women who have worked closely with animals are more likely to develop such antibodies and alternative laboratory techniques are available (American College of Obstetricians and Gynecologists, 2002a).

Home Pregnancy Tests. In 1999, approximately 19 million over-the-counter pregnancy test kits were sold in the United States with sales of almost $230 million (Wilcox and associates, 2001). Bastian and colleagues (1998) evaluated studies of home pregnancy test kits and found that testing done by volunteers achieved a mean 91-percent sensitivity. *Importantly, actual patients obtained only 75-percent sensitivity and a high false-negative result rate.*

Cole and colleagues (2004) also questioned the utility of home testing. They found that a detection limit of 12.5 mIU/ mL would be required to diagnose 95 percent of pregnancies at the time of missed menses. In their study of the accuracy of 18 different home pregnancy tests, they also found that only one brand had this degree of sensitivity. Two other brands gave false-positive or invalid results. In fact, clearly positive results were given by only 44 percent of the brands at an hCG concentration of 100 mIU/mL. A test capable of detecting this level would be expected to identify only about 15 percent of pregnancies at the time of the missed menses.

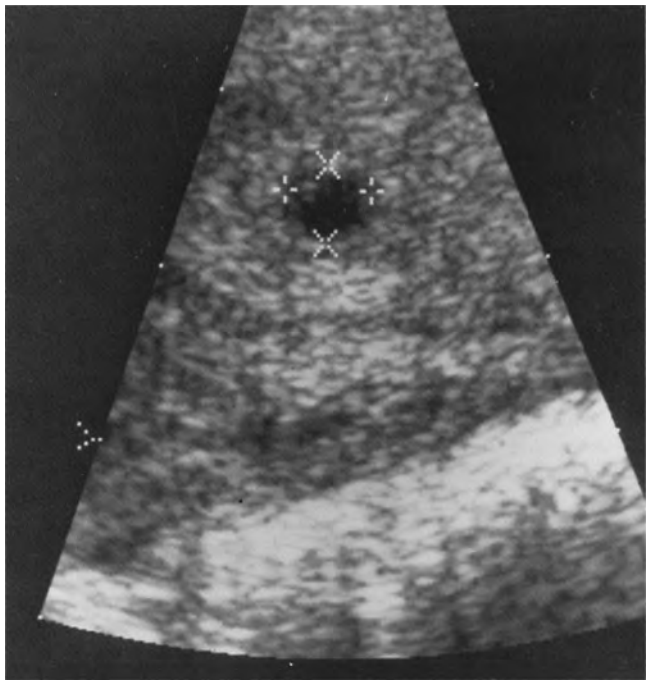

FIGURE 8-6 Abdominal sonogram demonstrating a gestational sac at 4 to 5 weeks' gestational (menstrual) age.

Sonographic Recognition of Pregnancy

The use of transvaginal sonography has revolutionized imaging of early pregnancy and its growth and development. A gestational sac may be demonstrated by abdominal sonography after only 4 to 5 weeks' menstrual age (Fig. 8-6). By 35 days, a normal sac should be visible in all women, and after 6 weeks, heart motion should be seen. Up to 12 weeks, the crown-rump length is predictive of gestational age within 4 days (see Chap. 16, p. 350).

Initial Prenatal Evaluation

Prenatal care should be initiated as soon as there is a reasonable likelihood of pregnancy. The major goals are to:

1. Define the health status of the mother and fetus.
2. Estimate the gestational age.
3. Initiate a plan for continuing obstetrical care.

Typical components of the initial visit are summarized in Table 8-3. The initial plan for subsequent care may range from relatively infrequent routine visits to prompt hospitalization because of serious maternal or fetal disease.

Prenatal Record

Use of a standardized record within a perinatal healthcare system greatly aids antepartum and intrapartum management.

TABLE 8-3. Typical Components of Routine Prenatal Care

		Weeks

HIV serology	Chap. 59, p. 1246	B			
Group B streptococcus culture	Chap. 59, p. 1220				E

[a] First-trimester aneuploidy screening may be offered between 11 and 14 weeks.
HIV = human immunodeficiency virus.
A Performed at 28 weeks, if indicated.
B Test should be offered.
C High-risk women should be retested at the beginning of the third trimester.
D High-risk women should be screened at the first prenatal visit and again in the third trimester.
E Rectovaginal culture should be obtained between 35 and 37 weeks.

Standardizing documentation may allow communication and continuity of care between providers and enable objective measures of care quality to be evaluated over time and across different clinical settings (Gregory and associates, 2006). A prototype is provided by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007).

Definitions. There are several definitions pertinent to establishment of an accurate prenatal record.

- *Nulligravida:* a woman who currently is not pregnant, nor has she ever been pregnant.
- *Gravida:* a woman who currently is pregnant or she has been in the past, irrespective of the pregnancy outcome. With the establishment of the first pregnancy, she becomes a *primigravida,* and with successive pregnancies, a *multigravida.*
- *Nullipara:* a woman who has never completed a pregnancy beyond 20 weeks' gestation. She may or may not have been pregnant or may have had a spontaneous or elective abortion(s) or an ectopic pregnancy.
- *Primipara:* a woman who has been delivered only once of a fetus or fetuses born alive or dead with an estimated length of gestation of 20 or more weeks. In the past, a 500-g birthweight threshold was used to define parity. This threshold is no longer as pertinent because of the survival of infants with birthweights less than 500 g.
- *Multipara:* a woman who has completed two or more pregnancies to 20 weeks or more. Parity is determined by the

number of pregnancies reaching 20 weeks and not by the number of fetuses delivered. *Parity is the same (para 1) for a singleton or multifetal delivery or delivery of a live or stillborn infant.*

In some locales, the obstetrical history is summarized by a series of digits connected by dashes. These refer to the number of term infants, preterm infants, abortuses less than 20 weeks, and children currently alive. For example, a woman who is para 2–1–0–3 has had two term deliveries, one preterm delivery, and no abortuses, and has three living children. Because these are nonconventional, it is helpful to specify the outcome of any pregnancy that did not end normally.

Normal Pregnancy Duration. The mean duration of pregnancy calculated from the first day of the last normal menstrual period is very close to 280 days or 40 weeks. In a study of 427,581 singleton pregnancies from the Swedish Birth Registry, Bergsjø and colleagues (1990) found that the mean duration of pregnancy was 281 days with a standard deviation of 13 days.

It is customary to estimate the expected date of delivery by adding 7 days to the date of the first day of the last normal menstrual period and counting back 3 months—*Naegele's rule*. For example, if the last menstrual period began September 10, the expected date of delivery is June 17. A *gestational age* or *menstrual age* calculated in this way erroneously assumes pregnancy to have begun approximately 2 weeks before ovulation. Clinicians use this gestational age to mark temporal events during pregnancy. In contrast, embryologists and other reproductive biologists more often employ *ovulatory age* or *fertilization age,* both of which are typically 2 weeks shorter. Somewhat related, Bracken and Belanger (1989) tested the accuracy of various "pregnancy wheels" provided by three pharmaceutical companies and found that such devices predicted incorrect delivery dates in 40 to 60 percent of estimates, with a 5-day error being typical.

Trimesters. It has become customary to divide pregnancy into three equal epochs of approximately 3 calendar months. Historically, the first trimester extends through completion of 14 weeks, the second through 28 weeks, and the third includes the 29th through 42nd weeks of pregnancy. Thus, there are three periods of 14 weeks each. Certain major obstetrical problems tend to cluster in each of these time periods. For example, most spontaneous abortions take place during the first trimester, whereas most women with hypertensive disorders due to pregnancy are diagnosed during the third trimester.

In modern obstetrics, the clinical use of trimesters to describe a specific pregnancy is too imprecise. For example, it is inappropriate in cases of uterine hemorrhage to categorize the problem temporally as "third-trimester bleeding." Appropriate management for the mother and her fetus will vary remarkably, depending on whether bleeding begins early or late in the third trimester (see Chap. 35, p. 757). Because precise knowledge of fetal age is imperative for ideal obstetrical management, the clinically appropriate unit is *weeks of gestation completed.* And more recently, clinicians designate gestational age using completed weeks and days, for example, $33^{4/7}$ weeks or 33 + 4, for 33 completed weeks and 4 days.

History

For the most part, the same essentials go into appropriate history-taking from the pregnant woman as elsewhere in medicine. **Detailed information concerning past obstetrical history is crucial because many prior pregnancy complications tend to recur in subsequent pregnancies.**

The *menstrual history* is extremely important. The woman who spontaneously menstruates regularly every 28 days or so is most likely to ovulate at midcycle. Thus, gestational or menstrual age is the number of weeks since the onset of the last menstrual period. If her menstrual cycles were significantly longer than 28 to 30 days, ovulation more likely occurred well beyond 14 days. If the intervals were much longer and irregular, chronic anovulation is likely to have preceded some of the episodes identified as menses. *Without a history of regular, predictable, cyclic, spontaneous menses that suggest ovulatory cycles, accurate dating of pregnancy by history and physical examination is difficult.*

It is also important to ascertain whether or not *steroidal contraceptives* were used before the pregnancy. Because ovulation may not have resumed 2 weeks after the onset of the last withdrawal bleeding and instead may have occurred at an appreciably later and highly variable date, using the time of ovulation for predicting the time of conception in this circumstance may be erroneous. Use of sonography in early pregnancy will clarify gestational age in these situations.

Psychosocial Screening. The American College of Obstetricians and Gynecologists (2006) defines psychosocial risk factors as nonbiomedical factors that affect mental and physical well-being. The College advocates psychosocial screening at least once each trimester to increase the likelihood of identifying important issues and reducing adverse pregnancy outcomes. Screening for barriers to care includes lack of transportation, child care, or family support; unstable housing; unintended pregnancy; communication barriers; nutritional problems; cigarette smoking; substance abuse; depression; and safety concerns that include domestic violence. Such screening is performed regardless of social status, education level, or race and ethnicity. Shown in Table 8-4 is one recommended screening tool.

Cigarette Smoking. Smoking results in unequivocal adverse sequelae for pregnant women and their fetuses (United States Department of Health and Human Services, 2000). Maternal smoking data has been included on the birth certificate since 1989. The number of pregnant women who smoke continues to decline, and from 1990 to 2003, the reported rate decreased from 18 to 13 percent (American College of Obstetricians and Gynecologists, 2005b; Martin and associates, 2009). According to the Centers for Disease Control and Prevention (2007), 13 percent of women admitted to smoking during the last 3 months of pregnancy. Those most likely to smoke were younger and had less education.

Numerous adverse outcomes have been linked to smoking during pregnancy. Potential teratogenic effects are reviewed in Chapter 14 (p. 329). There is a twofold risk of placenta previa, placental abruption, and premature membrane rupture compared with nonsmokers. Further, babies born to women who

TABLE 8-4. Psychosocial Screening Tool

1.	Yes	No	Do you have any problems (job, transportation, etc.) that prevent you from keeping your healthcare appointments?
2.	Yes	No	Do you feel unsafe where you live?
3.	Yes	No	In the past 2 months, have you used any form of tobacco?
4.	Yes	No	In the past 2 months, have you used drugs or alcohol (including beer, wine, or mixed drinks)?
5.	Yes	No	In the past year, have you been threatened, hit, slapped, or kicked by anyone you know?
6.	Yes	No	Has anyone forced you to perform any sexual act that you did not want to do?
7.	On a 1-to-5 scale, how do you rate your current stress level? 1 2 3 4 5 low high		
8.	How many times have you moved in the past 12 months? _____		
9.	If you could change the timing of this pregnancy, would you want it: __ earlier; __ later; __not at all; __ no change.

smoke are approximately 30 percent more likely to be born preterm, weigh on average a half pound less, and are up to three times more likely to die of sudden infant death syndrome (SIDS) than infants born to nonsmokers (Centers for Disease Control and Prevention, 2007). In 2001, the incidence of low-birthweight infants born to American women who smoked during pregnancy was 11.9 percent compared with 7.3 percent born to nonsmokers (Martin and co-workers, 2002b). Finally, risks for spontaneous abortion, fetal death, and fetal digital anomalies are also increased (Man and Chang, 2006).

A number of pathophysiological mechanisms have been proposed to explain these adverse outcomes. They include fetal hypoxia from increased carboxyhemoglobin, reduced uteroplacental blood flow, and direct toxic effects of nicotine and other compounds in smoke (American College of Obstetricians and Gynecologists, 2005b; Jazayeri and colleagues, 1998). Nicotine transfer is so efficient that fetal nicotine exposure is greater than that of the mother (Luck and associates, 1985). Exposed fetuses have decreased heart rate variability, due to impaired autonomic regulation (Zeskind and colleagues, 2006). According to the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007), perinatal mortality rates would be reduced by 5 percent if maternal smoking was eliminated.

Smoking Cessation. The most successful efforts for smoking cessation during pregnancy involve interventions that emphasize how to stop. One example is a 5-step session lasting 15 minutes or less in which the provider: (1) *Asks* about smoking status; (2) *Advises* those who smoke to stop; (3) *Assesses* the willingness to quit within the next 30 days; (4) *Assists* interested patients by providing pregnancy-specific self-help materials; and (5) *Arranges* follow-up visits to track progress (American College of Obstetricians and Gynecologists, 2005b).

Nicotine replacement products have not been sufficiently evaluated to determine their effectiveness and safety in pregnancy. Interdiction is optimal—but not always pragmatic—before conception. Thus, the American College of Obstetricians and Gynecologists (2005b) has concluded that it is reasonable to use nicotine medications during pregnancy if prior nonpharmacological attempts have failed. Wisborg and co-workers (2000) randomly assigned 250 women who smoked at least 10 cigarettes per day to receive a nicotine or a placebo patch beginning after the first trimester. Overall, 26 percent of these women stopped smoking, but there were no significant differences in smoking cessation, birthweight, or preterm delivery between the two groups. Importantly, no serious adverse effects from the patches were reported, but compliance with either treatment was low.

Alcohol Use During Pregnancy. Ethanol is a potent teratogen and can cause fetal alcohol syndrome characterized by growth restriction, facial abnormalities, and central nervous system dysfunction (see Chap. 14, p. 317). Women who are pregnant or considering pregnancy should abstain from using any alcoholic beverages. Such use is substantively underreported on the birth certificate—less than 1 percent of women reported any alcohol use during pregnancy in 2001 (Martin and colleagues, 2002b). But, according to the Centers for Disease Control and Prevention (2002a), approximately 13 percent of pregnant women used alcohol in 1999. Although this was down from 16 percent in 1995, it is unfortunate that rates of binge and frequent drinking during pregnancy have not declined.

Illicit Drug Use. It is estimated that 10 percent of fetuses are exposed to one or more illicit drugs (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2007). Agents may include heroin and other opiates, cocaine, amphetamines, barbiturates, and marijuana. Chronic use of large quantities is harmful to the fetus. Well-documented sequelae include fetal distress, low birthweight, and drug withdrawal soon after birth. Women who use such drugs frequently do not seek prenatal care or if they do, they may not admit to the use of such substances. El-Mohandes and associates (2003) reported that when women who use illicit drugs receive prenatal care, the risks for preterm birth and low birthweight are reduced.

The effects of several illicit drugs are considered in detail in Chapter 14 (p. 326). The American College of Obstetricians and Gynecologists (1999) has reviewed methods for screening women during pregnancy for use of illicit drugs and for alcohol abuse.

Domestic Violence Screening. The term *domestic violence* usually refers to violence against adolescent and adult females within the context of family or intimate relationships. Such violence has been increasingly recognized as a major public health problem (see Chap. 42, p. 936). Unfortunately, most abused women continue to be victimized during pregnancy. With the possible exception of preeclampsia, domestic violence is more prevalent than any major medical condition detectable through routine prenatal screening (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2007). The prevalence during pregnancy is estimated to be between 4 and 8 percent. As discussed in Chapter 42 (p. 936), intimate partner violence is associated with an increased risk of a number of adverse perinatal outcomes including preterm delivery, fetal-growth restriction, and perinatal death.

The American College of Obstetricians and Gynecologists (2006) has provided methods for screening for domestic violence and recommends their use at the first prenatal visit, then again at least once per trimester, and again at the postpartum visit. Webster and Holt (2004) found that a simple, six-question self-report survey is an effective alternative to direct questioning for identifying pregnant women who are experiencing partner violence. Physicians should be familiar with state laws that may require reporting of domestic violence—for example, child abuse is always reportable. Coordination with social services can be invaluable in such cases.

Physical Examination

A thorough, general physical examination should be completed at the initial prenatal encounter. Expected changes in physical examination findings resulting from normal pregnancy are addressed throughout Chapters 2 and 5.

Pelvic Examination. The cervix is visualized employing a speculum lubricated with warm water or water-based lubricant gel. Bluish-red passive hyperemia of the cervix is characteristic, but not of itself diagnostic, of pregnancy. Dilated, occluded cervical glands bulging beneath the ectocervical mucosa—*nabothian cysts*—may be prominent. The cervix is not normally dilated except at the external os. To identify cytological abnormalities, a Pap smear is performed, and specimens for identification of *Chlamydia trachomatis* and *Neisseria gonorrhoeae* are obtained.

Bimanual examination is completed by palpation, with special attention given to the consistency, length, and dilatation of the cervix; to uterine size and any adnexal masses; to the fetal presentation later in pregnancy; to the bony architecture of the pelvis; and to any anomalies of the vagina and perineum. All cervical, vaginal, and vulvar lesions are evaluated further by appropriate use of colposcopy, biopsy, culture, or dark-field examination. The perianal region should be visualized and digital rectal examination performed.

Laboratory Tests

Recommended routine tests at the first prenatal encounter are listed in Table 8-3 and normal ranges for pregnancy are found in the Appendix. The Institute of Medicine recommends universal human immunodeficiency virus (HIV) testing, with patient notification and right of refusal, as a routine part of prenatal care. The Centers for Disease Control and Prevention (2006b) as well as the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) support this recommendation. If a woman declines testing, this should be recorded in the prenatal record. Pregnant women should also be screened for hepatitis B virus. Based on their prospective investigation of 1000 women, Murray and co-workers (2002) concluded that in the absence of hypertension, routine urinalysis beyond the initial prenatal visit was not necessary.

Chlamydial Infection. *Chlamydia trachomatis* is isolated from the cervix in 2 to 13 percent of pregnant women. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) recommend that all women be screened during the first prenatal visit, with additional third-trimester testing for those at increased risk. Risk factors include unmarried status, recent change in sexual partner or multiple concurrent partners, age under 25 years, inner-city residence, history or presence of other sexually transmitted diseases, and little or no prenatal care. Following treatment, repeat testing is recommended in 3 weeks (see Chap. 59, p. 1240). A negative prenatal test for chlamydia or gonorrhea should not preclude postpartum screening (Mahon and associates, 2002).

High-Risk Pregnancies

There are many risk factors that can be identified and given appropriate consideration in pregnancy management. Examples of common risk factors proposed by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) are shown in **Table 8-5**. In addition, **Table 8-6** lists ongoing risk factors for which consultation may be indicated. Some conditions may require the involvement of a maternal-fetal medicine subspecialist, geneticist, pediatrician, anesthesiologist, or other medical specialist in the evaluation, counseling, and care of the woman and her fetus.

Subsequent Prenatal Visits

Subsequent prenatal visits have been traditionally scheduled at intervals of 4 weeks until 28 weeks, and then every 2 weeks until 36 weeks, and weekly thereafter. Women with complicated pregnancies often require return visits at 1- to 2-week intervals. For example, Luke and co-workers (2003) found that a specialized prenatal care program that emphasized nutrition and education and that required return visits every 2 weeks resulted in improved outcomes in twin pregnancies.

In 1986, the Department of Health and Human Services convened an expert panel to review the content of prenatal care. This report was subsequently re-evaluated and revised in 2005 (Gregory and associates, 2006). The panel recommended, among other things, early and continuing risk assessment that

TABLE 8-5. Recommended Consultation for Risk Factors Identified in Early Pregnancy[a]

Medical History and Conditions	
Asthma	
Symptomatic on medication	OBG
Severe (multiple hospitalizations)	MFM
Cardiac disease	
Cyanotic, prior myocardial infarction, aortic stenosis, pulmonary hypertension, Marfan syndrome, prosthetic valve, American Heart Association class II or greater (see Chap. 44, p. 959)	MFM
Other	OBG
Diabetes mellitus	
Class A–C	OBG
Class D or greater	MFM
Drug and alcohol use	OBG
Epilepsy (on medication)	OBG
Family history of genetic problems	
(Down syndrome, Tay-Sachs disease, phenylketonuria)	MFM
Hemoglobinopathy (SS, SC, S-thalassemia)	MFM
Hypertension	
Chronic, with renal or heart disease	MFM
Chronic, without renal or heart disease	OBG
Prior pulmonary embolus or deep vein thrombosis	OBG
Psychiatric illness	OBG
Pulmonary disease	
Severe obstructive or restrictive	MFM
Moderate	OBG
Renal disease	
Chronic, creatinine ≥ 3 mg/dL, ± hypertension	MFM
Chronic, other	OBG
Requirement for prolonged anticoagulation	MFM
Severe systemic disease	MFM
Obstetrical History and Conditions	
Age ≥35 years at delivery	OBG
Cesarean delivery, prior classical or vertical incision	OBG
Incompetent cervix	OBG
Prior fetal structural or chromosomal abnormality	MFM
Prior neonatal death	OBG
Prior fetal death	OBG
Prior preterm delivery or preterm ruptured membranes	OBG
Prior low birthweight (<2500 g)	OBG
Second-trimester pregnancy loss	OBG
Uterine leiomyomas or malformation	OBG
Initial Laboratory Tests	
Human immunodeficiency virus (HIV)	
Symptomatic or low CD4 count	MFM
Other	OBG
CDE (Rh) of other blood group isoimmunization (excluding ABO, Lewis)	MFM
Initial examination condylomata (extensive, covering vulva or vaginal opening)	OBG

is patient specific, with flexibility of clinical visits; health promotion and education, including preconceptional care; medical and psychosocial interventions; standardized documentation; and expanded objectives of prenatal care—to include the health of the family up to 1 year after birth of the infant.

The World Health Organization conducted a multicenter randomized trial with almost 25,000 women comparing routine prenatal care with an experimental model designed to minimize visits (Villar and associates, 2001). In the new model, women were seen once in the first trimester and screened for certain risk factors. Those without any anticipated complications—80 percent of the women screened—were seen again at 26, 32, and 38 weeks. Compared with routine prenatal care, which required a median of eight visits, the new model required a median of only five visits. No disadvantages were found in women with fewer visits, and these findings were consistent with other randomized trials (Clement and co-workers, 1999; McDuffie and colleagues, 1996).

Prenatal Surveillance

At each return visit, steps are taken to determine the well-being of mother and fetus (see Table 8-3). Certain information is considered especially important—an example is assessment of gestational age and accurate measurement of blood pressure (Jones and associates, 2003). Evaluation typically includes:

Fetal
- Heart rate(s)
- Size—current and rate of change
- Amount of amnionic fluid
- Presenting part and station (late in pregnancy)
- Activity

Maternal
- Blood pressure—current and extent of change
- Weight—current and amount of change
- Symptoms—including headache, altered vision, abdominal pain, nausea and vomiting, bleeding, vaginal fluid leakage, and dysuria
- Height in centimeters of uterine fundus from symphysis
- Vaginal examination late in pregnancy often provides valuable information to include:
  1. Confirmation of the presenting part and its station (see Chap. 17, p. 374).
  2. Clinical estimation of pelvic capacity and its general configuration (see Chap. 2, p. 31).
  3. Consistency, effacement, and dilatation of the cervix.

Assessment of Gestational Age

This is one of the most important determinations at prenatal examinations. Precise knowledge of gestational age is important because a number of pregnancy complications may develop for which optimal treatment will depend on fetal age. Fortunately, it is possible to identify gestational age with considerable precision through an appropriately timed, carefully performed clinical examination, coupled with knowledge of the time of onset of the last menstrual period.

Fundal Height. Between 20 and 34 weeks, the height of the uterine fundus measured in centimeters correlates closely with gestational age in weeks (Calvert, 1982; Jimenez, 1983; Quaranta, 1981, and all their associates). The fundal height should be measured as the distance over the abdominal wall from the top of the symphysis pubis to the top of the fundus. *The bladder must be emptied before making the measurement.* For example, Worthen and Bustillo (1980) demonstrated that at 17 to 20 weeks, fundal height

was 3 cm higher with a full bladder. Obesity may also distort this relationship. Unfortunately, using fundal height alone, fetal-growth restriction may be undiagnosed in up to a third of cases (American College of Obstetricians and Gynecologists, 2000).

Fetal Heart Sounds. The fetal heart can first be heard in most women between 16 and 19 weeks when carefully auscultated with a standard nonamplified stethoscope. The ability to hear unamplified fetal heart sounds will depend on factors such as patient size and hearing acuity of the examiner. Herbert and co-workers (1987) reported that the fetal heart was audible by 20 weeks in 80 percent of women. By 21 weeks, audible fetal heart sounds were present in 95 percent, and by 22 weeks they were heard in all. The fetal heart rate now ranges from 110 to 160 bpm and is heard as a double sound resembling the tick of a watch under a pillow. Because the fetus moves freely in amnionic fluid, the site on the maternal abdomen where fetal heart sounds can be heard best will vary.

Instruments incorporating Doppler ultrasound instruments are often used to easily detect fetal heart action, almost always by 10 weeks (see Chap. 18, p. 412). Using real-time sonography with a vaginal transducer, fetal cardiac activity can be seen as early as 5 menstrual weeks.

Sonography. In the United States, about two thirds of women have at least one prenatal sonographic examination (Martin and colleagues, 2005). And within the past decade, many women have an initial sonographic evaluation as part of first-trimester aneuploidy screening, followed by a standard examination in the second trimester to evaluate fetal anatomy. Indications for sonography are reviewed in Chapter 13 (p. 294). The American College of Obstetricians and Gynecologists (2009) has concluded that a physician is not obligated to perform sonography without a specific indication in a low-risk patient, but that if she requests sonography, it is reasonable to honor her request.

Subsequent Laboratory Tests

If initial results were normal, most tests need not be repeated (see Table 8-3). Fetal aneuploidy screening may be performed at 11 to 14 weeks and/or at 15 to 20 weeks, depending on the protocol selected (see Chap. 13, p. 292). Serum screening for neural-tube defects is offered at 15 to 20 weeks (see Chap. 13, p. 287). Hematocrit or hemoglobin determination, along with syphilis serology if it is prevalent in the population, should be repeated at 28 to 32 weeks (Hollier and co-workers, 2003; Kiss and colleagues, 2004). Women who are D (Rh) negative and are unsensitized should have an antibody screening test repeated at 28 to 29 weeks, with administration of anti-D immune globulin if they remain unsensitized.

Cystic fibrosis carrier screening should be offered to couples with a family history of cystic fibrosis and to Caucasian couples of European or Ashkenazi Jewish descent planning a pregnancy or seeking prenatal care. Ideally, screening is performed before conception or during the first or early second trimester. Information about cystic fibrosis screening also should be provided to patients in other racial and ethnic groups who are at lower risk (see Chap. 13, p. 298).

Group B Streptococcal (GBS) Infection. The American College of Obstetricians and Gynecologists (2002c) and the Centers for Disease Control and Prevention (2002b) recommend that vaginal and rectal GBS cultures be obtained in all women between 35 and 37 weeks. Intrapartum antimicrobial prophylaxis is given for those whose cultures are positive. Women with GBS bacteriuria or a previous infant with invasive disease are given empirical intrapartum prophylaxis. These infections are discussed in detail in Chapter 58 (p. 1220).

Gestational Diabetes. All pregnant women should be screened for gestational diabetes mellitus, whether by history, clinical factors, or routine laboratory testing. Although laboratory testing between 24 and 28 weeks is the most sensitive approach, there may be pregnant women at low risk who are less likely to benefit from testing (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2007). Gestational diabetes is discussed in Chapter 52 (p. 1104).

Gonococcal Infection. Risk factors for gonorrhea are similar for those for *Chlamydia*. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) recommend that pregnant women with risk factors or symptoms be tested for *N. gonorrhoeae* at an early prenatal visit and again in the third trimester. Treatment is given for gonorrhea as well as possible coexisting chlamydial infection, as outlined in Chapter 59 (p. 1239).

Special Screening for Genetic Diseases. Selected screening should be offered to couples at increased risk based on family history or the ethnic or racial background (American College of Obstetricians and Gynecologists, 2004c, 2005c). These are discussed further in Chapters 12 (p. 275) and 13 (p. 296). Some examples include testing for Tay-Sachs disease for people of Eastern European Jewish or French Canadian ancestry; β-thalassemia for those of Mediterranean, Southeast Asian, Indian, Pakistani, or African ancestry; α-thalassemia for people of Southeast Asian or African ancestry; and sickle-cell anemia for people of African, Mediterranean, Middle Eastern, Caribbean, Latin American, or Indian descent.

NUTRITION

Recommendations for Weight Gain

For the first half of the 20th century, it was recommended that weight gain during pregnancy be limited to less than 20 lb or 9.1 kg. It was believed that such restriction would prevent gestational hypertension and fetal macrosomia. By the 1970s, however, women were encouraged to gain at least 25 lb or 11.4 kg to prevent preterm birth and fetal-growth restriction, a recommendation supported by subsequent research (Ehrenberg and associates, 2003). In 1990, the Institute of Medicine recommended a weight gain of 25 to 35 lb—11.5 to 16 kg—for women with a normal prepregnancy body mass index (BMI). This index is easily calculated using the chart shown in Figure 43-1 (p. 947). Weight gains recommended by the Institute of Medicine (1990) according to prepregnant BMI categories are shown in Table 8-7. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) have endorsed these guidelines. It is problematic,

TABLE 8-7. Recommended Ranges of Weight Gain During Singleton Gestations Stratified by Prepregnancy Body Mass Index[a]

Weight-for-Height Category		Recommended Total Weight Gain	
Category	BMI	kg	lb
Low	< 19.8	12.5–18	28–40
Normal	19.8–26	11.5–16	25–35
High	26–29	7–11.5	15–25
Obese	> 29	≥ 7	≥ 15

[a] The range for twin pregnancy is 35 to 45 lb (16 to 20 kg). Young adolescents (< 2 years after menarche) and African-American women should strive for gains at the upper end of the range. Shorter women (< 62 in. or < 157 cm) should strive for gains at the lower end of the range.
BMI = body mass index.
From the Institute of Medicine (1990), with permission.

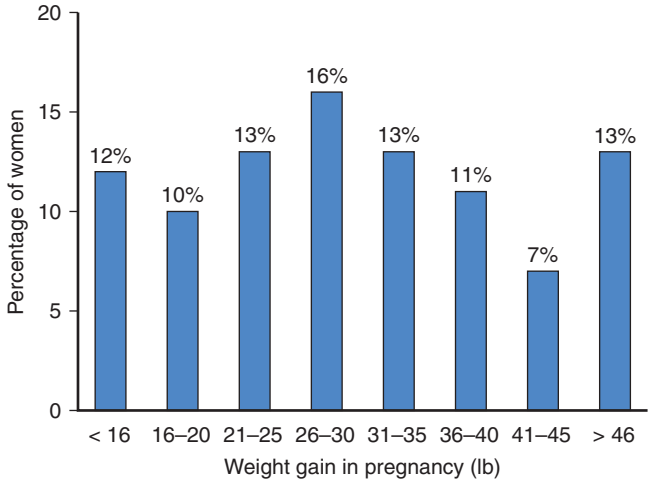

FIGURE 8-7 Maternal weight gains in the United States reported on the birth certificate in 2006. (From Martin and colleagues, 2009.)

however, that in 2003, 46 percent of women had weight gains above these guidelines (Catalano, 2007).

It has been recently emphasized by Catalano (2007) that when the Institute of Medicine guidelines were written, concern was focused on the low-birthweight infant, whereas currently the focus is on the obesity epidemic. This likely explains renewed interest in *lower* weight gains during pregnancy. As discussed in Chapter 43 (p. 949), obesity is associated with significantly increased risks for gestational hypertension, preeclampsia, gestational diabetes, macrosomia, and cesarean delivery. The risk appears "dose related" to prenatal weight gain. In a population-based cohort of more than 120,000 obese pregnant women, Kiel and associates (2007) found that those who gained *less than 15 pounds* had the lowest rates of preeclampsia, large-for-gestational age infants, and cesarean delivery. Among 100,000 women with normal prepregnancy body mass index, DeVader and colleagues (2007) found that those who gained less than 25 pounds during pregnancy had a lower risk for preeclampsia, failed induction, cephalopelvic disproportion, cesarean delivery, and large-for-gestational age infants. This cohort, however, had an increased risk for small-for-gestational age infants.

Overnutrition

There is irrefutable evidence that maternal weight gain during pregnancy influences birthweight. Martin and colleagues (2009) studied this using birth certificate data for 2006. As shown in Figure 8-7, 60 percent of pregnant women gained 26 lb or more. Maternal weight gain had a positive correlation with birthweight, and women with the greatest risk—14 percent—for delivering an infant weighing less than 2500 g were those with weight gains less than 16 lb. Nearly nineteen percent of births to women with such low weight gains were preterm. Cohen and associates (2001) studied more than 4000 pregnant women and concluded that ethnic differences in pregnancy outcomes were not explained by nutritional variations.

Severe Undernutrition

Meaningful studies of nutrition in human pregnancy are exceedingly difficult to design because experimental dietary deficiency is not ethical. In those instances in which severe nutritional deficiencies have been induced as a consequence of social, economic, or political disaster, coincidental events often have created many variables, the effects of which are not amenable to quantification. Some past experiences suggest, however, that in otherwise healthy women, a state of near starvation is required to establish clear differences in pregnancy outcome.

During the severe European winter of 1944–1945, nutritional deprivation of known intensity prevailed in a well-circumscribed area of The Netherlands occupied by the German military (Kyle and Pichard, 2006). At the lowest point during this *Dutch Hunger Winter,* rations reached 450 kcal/day, with generalized rather than selective malnutrition. Smith (1947) analyzed the outcomes of pregnancies that were in progress during this 6-month famine. Median infant birthweights decreased approximately 250 g and rose again after food became available. This indicated that birthweight can be influenced significantly by starvation during later pregnancy. The perinatal mortality rate, however, was not altered, nor was the incidence of malformations significantly increased. Interestingly, the frequency of pregnancy "toxemia" was found to decline.

Evidence of impaired brain development has been obtained in some animal fetuses whose mothers had been subjected to intense dietary deprivation. Subsequent intellectual development was studied by Stein and associates (1972) in young male adults whose mothers had been starved during pregnancy. The comprehensive study was made possible because all males at age 19 underwent compulsory examination for military service. It was concluded that severe dietary deprivation during pregnancy caused no detectable effects on subsequent mental performance.

A number of studies of the long-term consequences to this cohort of children born to nutritionally deprived women have been performed and were recently reviewed by Kyle and Pichard

(2006). Progeny exposed in mid to late pregnancy were lighter, shorter, and thinner at birth, and they had a higher incidence of subsequent diminished glucose tolerance, hypertension, reactive airway disease, dyslipidemia, and coronary artery disease. Early pregnancy exposure was associated with increased obesity in adult women but not men. Early exposure was also associated with increased central nervous system anomalies, schizophrenia, and schizophrenia-spectrum personality disorders.

These observations, as well as others, have led to the concept of *fetal programming* by which adult morbidity and mortality are related to fetal health. Known widely as the *Barker hypothesis*, as promulgated by Barker and colleagues (1989), this concept is discussed in Chapter 38 (p. 853).

Weight Retention after Pregnancy

Not all the weight gained during pregnancy is lost during and immediately after delivery (Hytten, 1991). Schauberger and co-workers (1992) studied prenatal and postpartum weights in 795 Wisconsin women. Their average weight gain was 28.6 lb or 4.8 kg. As shown in **Figure 8-8**, most maternal weight loss was at delivery—approximately 12 lb or 5.5 kg—and in the ensuing 2 weeks thereafter—approximately 9 lb or 4 kg. An additional 5.5 lb or 2.5 kg was lost between 2 weeks and 6 months postpartum. Thus, average total weight loss resulted in an average retained pregnancy weight of 3 lb or 1.4 kg. Overall, the more weight gained during pregnancy, the more that was lost postpartum. Interestingly, there is no relationship between prepregnancy BMI or prenatal weight gain and weight retention (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2005a, 2007). Accruing weight with age—rather than parity—is considered the main factor affecting weight gain over time.

Recommended Dietary Allowances

Periodically, the Food and Nutrition Board of the Institute of Medicine (2008) publishes recommended dietary allowances, including those for pregnant or lactating women. The latest recommendations are summarized in **Table 8-8**. Certain prenatal vitamin–mineral supplements may lead to intakes well in excess of the recommended allowances. Moreover, the use of excessive supplements, which often are self-prescribed, has led to concern about nutrient toxicities during pregnancy. Those with potentially toxic effects include iron, zinc, selenium, and vitamins A, B_6, C, and D. In particular, excessive vitamin A—more than 10,000 IU per day—may be teratogenic (see Chap. 14, p. 324). Vitamin and mineral intake more than twice the recommended daily dietary allowance shown in Table 8-8 should be avoided (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2007).

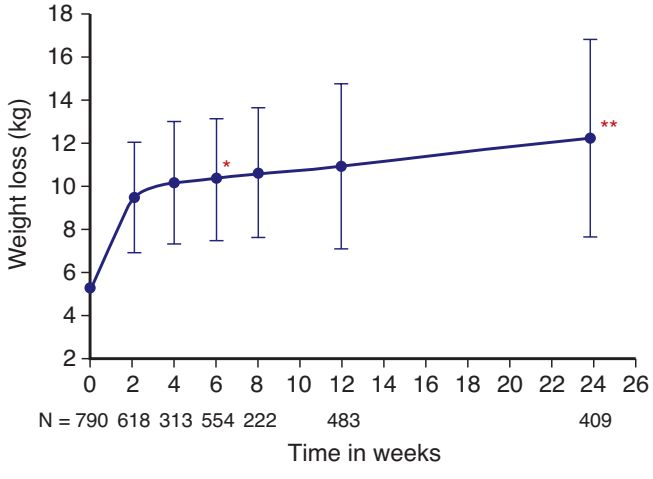

FIGURE 8-8 Cumulative weight loss from last antepartum visit to 6 months' postpartum. *Statistically different from 2-week weight loss, **Statistically different from 6-week weight loss. (From Schauberger and co-workers, 1992, with permission.)

Calories

As shown in **Figure 8-9**, pregnancy requires an additional 80,000 kcal—most are accumulated in the last 20 weeks. To meet this demand, a caloric increase of 100 to 300 kcal per day is recommended during pregnancy (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2007). Calories are necessary for energy, and whenever caloric intake is inadequate, protein is metabolized rather than being spared for its vital role in fetal growth and development. Total physiological requirements during pregnancy are not necessarily the sum of ordinary nonpregnant requirements plus those specific to pregnancy. For example, the additional energy required during pregnancy may be compensated in whole or in part by reduced physical activity (Hytten, 1991).

Protein

To the basic protein needs of the nonpregnant woman are added the demands for growth and remodeling of the fetus, placenta, uterus, and breasts, as well as increased maternal blood volume (see Chap. 5, p. 113). During the second half of pregnancy, approximately 1000 g of protein are deposited, amounting to 5 to 6 g/day (Hytten and Leitch, 1971). The concentrations of most amino acids in maternal plasma fall markedly, including ornithine, glycine, taurine, and proline (Hytten, 1991). Exceptions during pregnancy are glutamic acid and alanine, which rise in concentration.

Preferably, most protein should be supplied from animal sources, such as meat, milk, eggs, cheese, poultry, and fish, because they furnish amino acids in optimal combinations. Milk and dairy products have long been considered nearly ideal sources of nutrients, especially protein and calcium, for pregnant or lactating women. Ingestion of specific fish and methylmercury toxicity are discussed on page 206.

Minerals

The intakes recommended by the Institute of Medicine (2008) for a variety of minerals are presented in Table 8-8. With the exception of iron, practically all diets that supply sufficient calories for appropriate weight gain will contain enough minerals to prevent deficiency if iodized foods are ingested.

Iron. The reasons for substantively increased iron requirements during pregnancy are discussed in Chapter 5 (p. 115). Of the approximately 300 mg of iron transferred to the fetus and

TABLE 8-8. Recommended Daily Dietary Allowances for Adolescent and Adult Pregnant and Lactating Women

	Pregnant		Lactating	
Age (years)	14–18	19–50	14–18	19–50
Fat-soluble vitamins				
Vitamin A	750 μg	770 μg	1200 μg	1300 μg
Vitamin D[a]	5 μg	5 μg	5 μg	5 μg
Vitamin E	15 mg	15mg	19 mg	19 mg
Vitamin K[a]	75 μg	90 μg	75 μg	90 μg
Water-soluble vitamins				
Vitamin C	80 mg	85 mg	115 mg	120 mg
Thiamin	1.4 mg	1.4 mg	1.4 mg	1.4 mg
Riboflavin	1.4 mg	1.4 mg	1.6 mg	1.6 mg
Niacin	18 mg	18 mg	17 mg	17 mg
Vitamin B_6	1.9 mg	1.9 mg	2 mg	2 mg
Folate	600 μg	600 μg	500 μg	500 μg
Vitamin B_{12}	2.6 μg	2.6 μg	2.8 μg	2.8 μg
Minerals				
Calcium[a]	1300 mg	1000 mg	1300 mg	1000 mg
Sodium[a]	1.5 g	1.5 g	1.5 g	1.5 g

Other				
Protein	71 g	71 g	71 g	71 g
Carbohydrate	175 g	175 g	210 g	210 g
Fiber[a]	28 g	28 g	29 g	29 g

[a]Recommendations measured as Adequate Intake (AI).
From the Food and Nutrition Board of the Institute of Medicine (2008).

placenta and the 500 mg incorporated into the expanding maternal hemoglobin mass, nearly all is used after midpregnancy. During that time, iron requirements imposed by pregnancy and maternal excretion total approximately 7 mg per day (Pritchard and Scott, 1970). Few women have sufficient iron stores or dietary iron intake to supply this amount. Thus, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) endorse the recommendation by the National Academy of Sciences that at least 27 mg of ferrous iron supplement be given daily to pregnant women. This amount is contained in most prenatal vitamins.

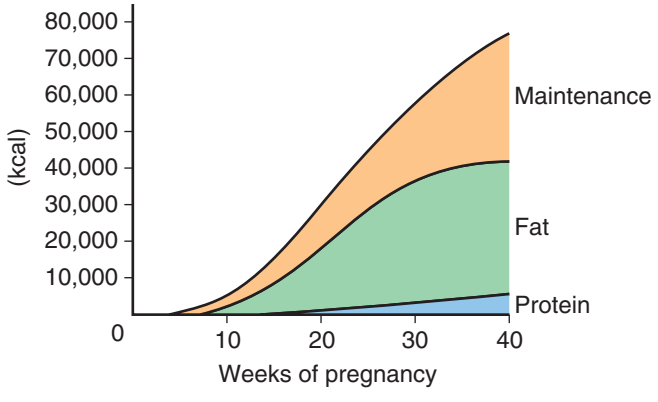

FIGURE 8-9 Cumulative kilocalories required for pregnancy. (From *Clinical Physiology in Obstetrics*, 3rd ed., G Chamberlain and F Broughton-Pipkin (eds). Copyright © 1998 Blackwell Science. Reproduced with permission of Blackwell Publishing Ltd.)

Scott and co-workers (1970) established that as little as 30 mg of elemental iron, supplied as ferrous gluconate, sulfate, or fumarate and taken daily throughout the latter half of pregnancy, provides sufficient iron to meet the requirements of pregnancy and to protect preexisting iron stores. This amount will also provide for iron requirements for lactation. The pregnant woman may benefit from 60 to 100 mg of iron per day if she is large, has twin fetuses, begins supplementation late in pregnancy, takes iron irregularly, or has a somewhat depressed hemoglobin level. The woman who is overtly anemic from iron deficiency responds well to oral supplementation with iron salts (see Chap. 51, p. 1080).

Because iron requirements are slight during the first 4 months of pregnancy, it is *not necessary* to provide supplemental iron during this time. Withholding iron supplementation during the first trimester of pregnancy avoids the risk

of aggravating nausea and vomiting (Gill and associates, 2009). Ingestion of iron at bedtime or on an empty stomach aids absorption and appears to minimize the possibility of an adverse gastrointestinal reaction.

Since 1997, the Food and Drug Administration (FDA) has required that iron preparations containing 30 mg or more of elemental iron per tablet be packaged as individual doses, such as in blister packages. This regulation is targeted at preventing accidental iron poisoning in children.

Calcium. As discussed in Chapter 5 (p. 114), the pregnant woman retains approximately 30 g of calcium, most of which is deposited in the fetus late in pregnancy (Pitkin, 1985). This amount of calcium represents only approximately 2.5 percent of total maternal calcium, most of which is in bone, and which can readily be mobilized for fetal growth. Moreover, Heaney and Skillman (1971) demonstrated increased calcium absorption by the intestine and progressive retention throughout pregnancy. Efforts to prevent preeclampsia using calcium supplementation have not proven efficacious, and it is not recommended for routine use during pregnancy (see Chap. 34, p. 727).

Zinc. Severe zinc deficiency may lead to poor appetite, suboptimal growth, and impaired wound healing. Profound zinc deficiency may cause dwarfism and hypogonadism. It may also lead to a specific skin disorder, *acrodermatitis enteropathica,* as the result of a rare, severe congenital zinc deficiency. Although the level of zinc supplementation that is safe for pregnant women has not been clearly established, recommended daily intake during pregnancy is approximately 12 mg.

Goldenberg and colleagues (1995) randomly assigned 580 indigent women to daily 25-mg zinc supplementation or placebo beginning at midpregnancy. Plasma zinc levels were significantly higher in women who received supplements. Infants born to zinc-supplemented women were slightly larger—mean increase 125 g—and had a slightly larger head circumference—mean 4 mm. Later, Osendarp and colleagues (2001) randomly assigned 420 women in Bangladesh to receive either daily 30-mg zinc supplementation or placebo from 12 to 16 weeks until delivery. Although supplementation did not improve birthweight, low-birthweight infants of mothers who received zinc had reduced risks of acute diarrhea, dysentery, and impetigo. In a follow-up study of these infants at 13 months, zinc supplementation was not found to confer any benefits on developmental outcome (Hamadani and co-workers, 2002).

Iodine. The use of iodized salt and bread products is recommended during pregnancy to offset the increased fetal requirements and maternal renal losses of iodine. Despite this, iodine intake has declined substantially in the past 15 years, and in some areas, it is probably inadequate (see Chap. 53, p. 1133). Interest in increasing dietary iodine was heightened by reports linking subclinical maternal hypothyroidism to adverse pregnancy outcomes and possible neurodevelopmental defects in children studied at age 7 years (Casey and associates, 2004; Haddow and colleagues, 1999). Severe maternal iodine deficiency predisposes offspring to endemic cretinism, characterized by multiple severe neurological defects. In parts of China and Africa where this condition is endemic, iodide supplementation very early in pregnancy prevents some cases of cretinism (Cao and colleagues, 1994).

Magnesium. Deficiency of magnesium as the consequence of pregnancy has not been recognized. Undoubtedly, during prolonged illness with no magnesium intake, the plasma level might become critically low, as it would in the absence of pregnancy. We have observed magnesium deficiency during pregnancy complicated by the consequences of previous intestinal bypass surgery.

Sibai and co-workers (1989) randomly assigned 400 normotensive primigravid women to 365 mg elemental magnesium supplementation or placebo tablets from 13 to 24 weeks. Supplementation did not improve any measures of pregnancy outcome.

Trace Metals. Copper, selenium, chromium, and manganese all have important roles in certain enzyme functions. In general, most are provided by an average diet. A severe geochemical selenium deficiency has been identified in a large area of China. Deficiency is manifested by a frequently fatal cardiomyopathy in young children and women of childbearing age. Conversely, selenium toxicity resulting from oversupplementation also has been observed. There is no reported need to supplement selenium in American women.

Potassium. The concentration of potassium in maternal plasma decreases by approximately 0.5 mEq/L by midpregnancy (Brown and colleagues, 1986). Potassium deficiency develops in the same circumstances as when a woman is not pregnant.

Fluoride. There is no evidence that supplemental fluoride during pregnancy is beneficial (Institute of Medicine, 1990). Maheshwari and co-workers (1983) found that fluoride metabolism is not altered appreciably during pregnancy. Horowitz and Heifetz (1967) concluded that there were no additional benefits from maternal ingestion of fluoridated water if the offspring ingested such water from birth.

Sa Roriz Fonteles and associates (2005) studied microdrill biopsies of deciduous teeth and concluded that prenatal fluoride provided no additional fluoride uptake compared with postnatal fluoride alone. Supplemental fluoride ingested by lactating women does not increase the fluoride concentration in breast milk (Ekstrand and colleagues, 1981).

Vitamins

The increased requirements for most vitamins during pregnancy shown in Table 8-8 usually are supplied by any general diet that provides adequate calories and protein. The exception is folic acid during times of unusual requirements, such as pregnancy complicated by protracted vomiting, hemolytic anemia, or multiple fetuses. That said, in impoverished countries, routine multivitamin supplementation reduced the incidence of low-birthweight and growth-restricted fetuses, but did not alter preterm delivery or perinatal mortality rates (Fawzi and colleagues, 2007).

Folic Acid. The Centers for Disease Control and Prevention (2004) estimated that the number of pregnancies affected by

neural-tube defects has decreased from 4000 pregnancies per year to approximately 3000 per year since mandatory fortification of cereal products with folic acid in 1998. Perhaps more than half of all neural-tube defects can be prevented with daily intake of 400 μg of folic acid throughout the periconceptional period (Centers for Disease Control and Prevention, 1999). Putting 140 μg of folic acid into each 100 g of grain products may increase the folic acid intake of the average American woman of childbearing age by 100 μg per day. Because nutritional sources alone are insufficient, however, folic acid supplementation is still recommended (American College of Obstetricians and Gynecologists, 2003b). Using data from 15 international registries, Botto and associates (2006) demonstrated a significant reduction in neural-tube defects only in countries with folic acid *fortification* programs, but no decrease in areas with supplementation recommendations alone.

A woman with a prior child with a neural-tube defect can reduce the 2- to 5-percent recurrence risk by more than 70 percent with daily 4-mg folic acid supplements the month before conception and during the first trimester. As emphasized by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007), this dose should be consumed as a separate supplement, that is, not as multivitamin tablets, to avoid excessive intake of fat-soluble vitamins. Unfortunately, surveys continue to suggest that many women, especially among minorities, remain unaware of the recommendations regarding folic acid supplementation (Perlow, 2001; Rinsky-Eng and Miller, 2002). This important relationship between folic acid deficiency and neural-tube defects is further discussed in Chapter 13 (p. 288).

Vitamin A. Dietary intake of vitamin A in the United States appears to be adequate, and routine supplementation during pregnancy is not recommended by the American College of Obstetricians and Gynecologists (1998b). Conversely, there is an association of birth defects with very high doses during pregnancy—10,000 to 50,000 IU daily. These malformations are similar to those produced by the vitamin A derivative isotretinoin—*Accutane*—which is a potent teratogen (see Chap. 14, p. 324). Beta-carotene, the precursor of vitamin A found in fruits and vegetables, has not been shown to produce vitamin A toxicity.

Vitamin A deficiency is an endemic nutrition problem in the developing world. West (2003) estimates that worldwide, 6 million pregnant women suffer from night blindness secondary to vitamin A deficiency. In 736 third-trimester Indian women, Radhika and colleagues (2002) found overt deficiency manifested as night blindness in 3 percent. Another 27 percent had subclinical vitamin A deficiency defined as a serum retinol concentration below 20 μg/dL. Vitamin A deficiency, whether overt or subclinical, was associated with an increased risk of anemia and spontaneous preterm birth.

Vitamin B_{12}. Maternal plasma vitamin B_{12} levels decrease in normal pregnancy and result mostly from reduced plasma levels of carrier proteins—*transcobalamins* (see Chap. 51, p. 1082 and Appendix). Vitamin B_{12} occurs naturally only in foods of animal origin, and strict vegetarians may give birth to infants whose B_{12} stores are low. Likewise, because breast milk of a vegetarian mother contains little vitamin B_{12}, the deficiency may become profound in the breast-fed infant (Higginbottom and associates, 1978). Excessive ingestion of vitamin C also can lead to a functional deficiency of vitamin B_{12}. Although its role is still controversial, low levels of vitamin B_{12} preconceptionally, similar to folate, may increase the risk of neural-tube defects (Molloy and co-workers, 2009; Thompson and colleagues, 2009).

Vitamin B_6—Pyridoxine. Limited clinical trials in pregnant women have failed to demonstrate any benefits of vitamin B_6 supplements (Thaver and associates, 2006). For women at high risk for inadequate nutrition—for example, substance abusers, adolescents, and those with multifetal gestations—a daily 2-mg supplement is recommended. Vitamin B_6, when combined with the antihistamine *doxylamine,* has been found helpful in many cases of nausea and vomiting of pregnancy (Boskovic and associates, 2003; Staroselsky and associates, 2007).

Vitamin C. The recommended dietary allowance for vitamin C during pregnancy is 80 to 85 mg/day—about 20 percent more than when nonpregnant (see Table 8-8). A reasonable diet should readily provide this amount. The maternal plasma level declines during pregnancy, whereas the cord level is higher, a phenomenon observed with most water-soluble vitamins.

Pragmatic Nutritional Surveillance

Although the science of nutrition continues in its perpetual struggle to identify the ideal amounts of protein, calories, vitamins, and minerals for the pregnant woman and her fetus, those directly responsible for their care may best discharge their duties as follows:

1. In general, advise the pregnant woman to eat what she wants in amounts she desires and salted to taste.
2. Ensure that there is ample food available in the case of socioeconomically deprived women.
3. Monitor weight gain, with a goal of approximately 25 to 35 lb in women with a normal BMI.
4. Periodically explore food intake by dietary recall to discover the occasional nutritionally absurd diet.
5. Give tablets of simple iron salts that provide at least 27 mg of iron daily. Give folate supplementation before and in the early weeks of pregnancy.
6. Recheck the hematocrit or hemoglobin concentration at 28 to 32 weeks to detect any significant decrease.

COMMON CONCERNS

Employment

More than half of the children in the United States are born to working mothers. Federal law prohibits employers from excluding women from job categories on the basis that they are or might become pregnant (Annas, 1991). The Family Medical Leave Act requires that covered employers must grant up to 12 workweeks of unpaid leave to an employee for the birth and care of a newborn child (United States Department of Labor, 2008). In the absence of complications, most women can continue to work until the onset of labor (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2007).

Some types of work, however, may increase pregnancy complication risks. Mozurkewich and colleagues (2000) reviewed 29 studies that involved more than 160,000 pregnancies. With physically demanding work, women had a 20- to 60-percent increase in rates of preterm birth, fetal-growth restriction, or gestational hypertension. In a prospective study of more than 900 healthy nulliparas, Higgins and associates (2002) found that women who worked had a fivefold risk of preeclampsia. Newman and colleagues (2001) reported outcomes in 2929 women with singleton pregnancies studied by the Maternal–Fetal Medicine Units Network. Occupational fatigue—estimated by the number of hours standing, intensity of physical and mental demands, and environmental stressors—was associated with an increased risk of preterm membrane rupture. For women reporting the highest degrees of fatigue, the risk was 7.4 percent.

Thus, any occupation that subjects the pregnant woman to severe physical strain should be avoided. Ideally, no work or play should be continued to the extent that undue fatigue develops. Adequate periods of rest should be provided. It seems prudent to advise women with previous pregnancy complications that are at risk to recur—for example, preterm birth—to minimize physical work.

Exercise

In general, pregnant women do not need to limit exercise, provided they do not become excessively fatigued or risk injury. Clapp and associates (2000) randomly assigned 46 pregnant women who did not exercise regularly to either no exercise or to weight-bearing exercise beginning at 8 weeks. Exercise consisted of treadmill running, step aerobics, or stair stepper use for 20 minutes three to five times each week. They did this throughout pregnancy at an intensity between 55 and 60 percent of the preconceptional maximum aerobic capacity. Both placental size and birthweight were significantly greater in the exercise group. Duncombe and co-workers (2006) reported similar findings in 148 women. In contrast, Magann and colleagues (2002) prospectively analyzed exercise behavior in 750 healthy women and found that working women who exercised had smaller infants, more dysfunctional labors, and more frequent upper respiratory infections.

The American College of Obstetricians and Gynecologists (2002b) advises a thorough clinical evaluation be conducted before recommending an exercise program. In the absence of contraindications listed in **Table 8-9**, pregnant women should be encouraged to engage in regular, moderate-intensity physical activity 30 minutes or more a day. Each activity should be reviewed individually for its potential risk. Activities with a high risk of falling or abdominal trauma should be avoided. Similarly, scuba diving should be avoided because the fetus is at an increased risk for decompression sickness.

In the setting of certain pregnancy complications, it is wise to abstain from exercise and even limit physical activity. For example, some women with hypertensive disorders caused by pregnancy may benefit from being sedentary (see Chap. 34, p. 729), as may women with preterm labor, placenta previa, or multifetal gestation (see Chap. 39, p. 880); those suspected of having a growth-restricted fetus (see Chap. 38, p. 852); or those with severe cardiac or pulmonary disease (see Chap. 44, p. 958).

TABLE 8-9. Absolute and Relative Contraindications to Aerobic Exercise During Pregnancy

Absolute Contraindications
• Hemodynamically significant heart disease
• Restrictive lung disease
• Incompetent cervix/cerclage
• Multifetal gestation at risk for preterm labor
• Persistent second- or third-trimester bleeding
• Placenta previa after 26 weeks
• Preterm labor during the current pregnancy
• Ruptured membranes
• Preeclampsia/pregnancy-induced hypertension
Relative Contraindications
• Severe anemia
• Unevaluated maternal cardiac arrhythmia
• Chronic bronchitis
• Poorly controlled type 1 diabetes
• Extreme morbid obesity
• Extreme underweight (BMI <12)
• History of extremely sedentary lifestyle
• Fetal-growth restriction in current pregnancy
• Poorly controlled hypertension
• Orthopedic limitations
• Poorly controlled seizure disorder
• Poorly controlled hyperthyroidism
• Heavy smoker

Reprinted, with permission, from Exercise during pregnancy and the postpartum period. ACOG Committee Opinion No. 267. American College of Obstetricians and Gynecologists. *Obstet Gyn* 2002; 99:171-173.

Fish Consumption

Fish are an excellent source of protein, are low in saturated fats, and contain omega-3 fatty acids. Because nearly all fish and shellfish contain trace amounts of mercury, pregnant and lactating women are advised to avoid specific types of fish with potentially high methylmercury levels. These include shark, swordfish, king mackerel, and tile fish. It is further recommended that pregnant women ingest no more than 12 ounces or two servings of canned tuna per week and no more than 6 ounces of albacore or "white" tuna (U.S. Environmental Protection Agency, 2008). If the mercury content of locally caught fish is unknown, then overall fish consumption should be limited to 6 ounces per week. The recent ALSPAC study—Avon Longitudinal Study of Parents and Children, however, reported beneficial effects on pregnancy outcomes in women who consumed 340 g or more of seafood weekly (Hibbeln and co-workers, 2007).

Travel

Automobile Travel

The American College of Obstetricians and Gynecologists (1998a) has formulated guidelines for use of automobile passenger restraints during pregnancy (see Chap. 42, p. 937).

Women should be encouraged to wear properly positioned three-point restraints throughout pregnancy while riding in automobiles. The lap belt portion of the restraining belt should be placed under the abdomen and across her upper thighs. The belt should be comfortably snug. The shoulder belt also should be snugly positioned between the breasts. Available information suggests that airbags should not be disabled for the pregnant woman (American College of Obstetricians and Gynecologists, 1998a).

Air Travel

In general, air travel by the healthy woman has no harmful effect on pregnancy (Aerospace Medical Association, 2003). Travel in properly pressurized aircraft offers no unusual risk. Thus, in the absence of obstetrical or medical complications, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2004a, 2007) have concluded that pregnant women can safely fly up to 36 weeks. It is recommended that pregnant women observe the same precautions for air travel as the general population, including periodic movement of the lower extremities, ambulation at least hourly, and use of seatbelts while seated. A significant risk with travel, especially international travel, is acquisition of infectious diseases or developing a complication remote from adequate facilities (Ryan and associates, 2002).

Coitus

It is generally accepted that in healthy pregnant women, sexual intercourse usually is not harmful. Whenever abortion or preterm labor threatens, however, coitus should be avoided. Nearly 10,000 women enrolled in a prospective investigation by the Vaginal Infection and Prematurity Study Group were interviewed regarding sexual activity (Read and Klebanoff, 1993). They reported a decreased frequency of sexual intercourse with advancing gestation. By 36 weeks, 72 percent had intercourse less than once weekly. According to Bartellas and colleagues (2000), the decrease is attributed to decreased desire in 58 percent and fear of harm to the pregnancy in 48 percent.

Intercourse late in pregnancy specifically has not been found to be harmful. Grudzinskas and co-workers (1979) found no association between gestational age at delivery and the frequency of coitus during the last 4 weeks of pregnancy. Sayle and colleagues (2001) found no increased—and actually a decreased—risk of delivery within 2 weeks of intercourse. Tan and co-workers (2007) studied women scheduled for nonurgent labor induction and found that spontaneous labor ensued in half of each group who had and did not have intercourse.

Oral-vaginal intercourse is occasionally hazardous. Aronson and Nelson (1967) described a fatal air embolism late in pregnancy as a result of air blown into the vagina during cunnilingus. Other near-fatal cases have been described (Bernhardt and associates, 1988).

Dental Care

Examination of the teeth should be included in the prenatal examination, and good dental hygiene is encouraged. Periodontal disease has been linked to preterm labor (see Chap. 36, p. 812). Unfortunately, its treatment improves dental health but does not prevent preterm birth (Michalowicz and co-workers, 2006). Dental caries are not aggravated by pregnancy. Importantly, pregnancy is not a contraindication to dental treatment including dental radiographs (Giglio and associates, 2009).

Immunization

Current recommendations for immunizations during pregnancy are summarized in **Table 8-10**. Over the past decade, well-publicized concerns regarding childhood exposure to the thimerosal preservative in some vaccines led to parental prohibition. These results have proven groundless, but controversy continues (Sugarman, 2007; Thompson and co-workers, 2007; Tozzi and associates, 2009). Thus, they are recommended for use in pregnancy. The American College of Obstetricians and Gynecologists (2003a) stresses that current information on the safety of vaccines given during pregnancy is subject to change and can be verified from the Centers for Disease Control and Prevention website at http://www.cdc.gov/vaccines.

All women who will be pregnant during the influenza season should be offered vaccination, regardless of their stage of pregnancy. Those with underlying medical conditions that increase the risk for complications should be offered the vaccine before flu season starts (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2007). Recently, Zaman and co-workers (2008) showed that prenatal maternal vaccination reduced influenza incidence in the first 6 months by 63 percent in infants born to these women. Moreover, it reduced all febrile respiratory illnesses in these children by a third.

Women who are susceptible to rubella during pregnancy should receive MMR—measles-mumps-rubella—vaccination postpartum. Although this vaccine is not recommended during pregnancy, congenital rubella syndrome has never resulted from its inadvertent use. There is no contraindication to MMR vaccination while breast feeding (American College of Obstetricians and Gynecologists, 2002d).

Biological Warfare and Vaccines

The tragic events of September 11, 2001, and the ongoing threat of bioterrorism require familiarity with smallpox and anthrax vaccines during pregnancy. The smallpox vaccine is made with live attenuated vaccinia virus related to smallpox and to cowpox viruses. Fetal vaccinia infection is rare, but it may result in abortion, stillbirth, or neonatal death. Thus, in nonemergency circumstances, vaccination is contraindicated during pregnancy and in women who might become pregnant within 28 days of vaccination (Centers for Disease Control and Prevention, 2006a). If, however, vaccination is inadvertently performed in early pregnancy, this is not grounds for termination (Suarez and Hankins, 2002). If the pregnant woman is at risk because of exposure to smallpox—either as a direct victim of a bioterrorist attack or as a close contact of an individual case—the risks from clinical smallpox substantially outweigh any potential risk from vaccination (Suarez and Hankins, 2002).

Anthrax vaccination has been limited principally to individuals who are occupationally exposed, such as special veterinarians, laboratory workers, and members of the armed forces. The vaccine contains no live virus and thus would not be

TABLE 8-10. Recommendations for Immunization During Pregnancy

Immunobiological Agent	Indications for Immunization During Pregnancy	Dose Schedule	Comments
Live Attenuated Virus Vaccines			
Measles	Contraindicated—see immune globulins	Single dose SC, preferably as MMR[a]	Vaccinate susceptible women postpartum. Breast feeding is not a contraindication
Mumps	Contraindicated	Single dose SC, preferably as MMR	Vaccinate susceptible women postpartum
Rubella	Contraindicated, but congenital rubella syndrome has never been described after vaccine	Single dose SC, preferably as MMR	Teratogenicity of vaccine is theoretical and not confirmed to date; vaccinate susceptible women postpartum
Poliomyelitis Oral = live attenuated; injection = enhanced-potency inactivated virus	Not routinely recommended for women in the United States, except women at increased risk of exposure[b]	Primary: Two doses of enhanced-potency inactivated virus SC at 4–8 week intervals and a 3rd dose 6–12 months after 2nd dose Immediate protection: One dose oral polio vaccine (in outbreak setting)	Vaccine indicated for susceptible women traveling in endemic areas or in other high-risk situations
Yellow fever	Travel to high-risk areas	Single dose SC	Limited theoretical risk outweighed by risk of yellow fever
Varicella	Contraindicated, but no adverse outcomes reported in pregnancy	Two doses needed: 2nd dose given 4–8 weeks after 1st dose	Teratogenicity of vaccine is theoretical. Vaccination of susceptible women should be considered postpartum
Smallpox (vaccinia)	Contraindicated in pregnant women and in their household contacts	One dose SC, multiple pricks with lancet	Only vaccine known to cause fetal harm
Other			
Influenza	All pregnant women, regardless of trimester during flu season (Nov.-Mar.)	One dose IM every year	Inactivated virus vaccine
Rabies	Indications for prophylaxis not altered by pregnancy; each case considered individually	Public health authorities to be consulted for indications, dosage, and route of administration	Killed-virus vaccine
Hepatitis B	Pre-exposure and postexposure for women at risk of infection	Three-dose series IM at 0, 1, and 6 months	Used with hepatitis B immune globulin for some exposures. Exposed newborn needs birth-dose vaccination and immune globulin as soon as possible. All infants should receive birth dose of vaccine
Hepatitis A	Pre-exposure and postexposure if at risk (international travel)	Two-dose schedule IM, 6 months apart	Inactivated virus
Inactivated Bacterial Vaccines			
Pneumococcus	Indications not altered by pregnancy. Recommended for women with asplenia; metabolic, renal, cardiac, or pulmonary diseases; immunosuppression; or smokers	In adults, one dose only; consider repeat dose in 6 years for high-risk women	Polyvalent polysaccharide vaccine

(*continued*)

TABLE 8-10. Recommendations for Immunization During Pregnancy (*Continued*)

Immunobiological Agent	Indications for Immunization During Pregnancy	Dose Schedule	Comments
Inactivated Bacterial Vaccines			
Meningococcus	Indications not altered by pregnancy; vaccination recommended in unusual outbreaks	One dose; tetravalent vaccine	Antimicrobial prophylaxis if significant exposure
Typhoid	Not recommended routinely except for close, continued exposure or travel to endemic areas	Killed Primary: 2 injections IM 4 weeks apart Booster: One dose; schedule not yet determined	Killed, injectable vaccine or live attenuated oral vaccine. Oral vaccine preferred
Anthrax	See text	Six-dose primary vaccination, then annual booster vaccination	Preparation from cell-free filtrate of *B. anthracis*. No dead or live bacteria. Teratogenicity of vaccine theoretical
Toxoids			
Tetanus-diphtheria	Lack of primary series, or no booster within past 10 years	Primary: Two doses IM at 1–2 month interval with 3rd dose 6–12 months after the 2nd Booster: Single dose IM every 10 years after completion of primary series	Combined tetanus-diphtheria toxoids preferred: adult tetanus-diphtheria formulation. Updating immune status should be part of antepartum care
Specific Immune Globulins			
Hepatitis B	Postexposure prophylaxis	Depends on exposure (see Chap. 50, p. 1069)	Usually given with hepatitis B virus vaccine; exposed newborn needs immediate prophylaxis
Rabies	Postexposure prophylaxis	Half dose at injury site, half dose in deltoid	Used in conjunction with rabies killed-virus vaccine
Tetanus	Postexposure prophylaxis	One dose IM	Used in conjunction with tetanus toxoid
Varicella	Should be considered for exposed pregnant women to protect against maternal, not congenital, infection	One dose IM within 96 hours of exposure	Indicated also for newborns or women who developed varicella within 4 days before delivery or 2 days following delivery
Standard Immune Globulins			
Hepatitis A Hepatitis A virus vaccine should be used with hepatitis A immune globulin	Postexposure prophylaxis and high risk	0.02 mL/kg IM in one dose	Immune globulin should be given as soon as possible and within 2 weeks of exposure; infants born to women who are incubating the virus or are acutely ill at delivery should receive one dose of 0.5 mL as soon as possible after birth

[a] Two doses necessary for students entering institutions of higher education, newly hired medical personnel, and travel abroad.
[b] Inactivated polio vaccine recommended for nonimmunized adults at increased risk.
ID = intradermally; IM = intramuscularly; MMR = measles, mumps, rubella; PO = orally: and SC = subcutaneously.
Adapted from the Centers for Disease Control and Prevention, Recommendations of the Advisory Committee on Immunization Practices, 2003, 2005, 2006a, 2008b.

expected to pose significant risk to the fetus. Wiesen and Littell (2002) studied the reproductive outcomes of 385 women in the United States Army who became pregnant after vaccination and reported no adverse effects on fertility or pregnancy outcome.

Smallpox, anthrax, and other infections related to bioterrorism are discussed in Chapter 58 (p. 1230).

Caffeine

In 1980, the FDA advised pregnant women to limit caffeine intake. The Fourth International Caffeine Workshop concluded shortly thereafter that there was no evidence that caffeine had increased teratogenic or reproductive risks (Dews and colleagues, 1984). Caffeine is not a teratogen for small laboratory animals, but if given in massive doses it potentiates mutagenic effects of radiation and some chemicals. When infused intravenously into sheep, caffeine decreases uterine blood flow by 5 to 10 percent (Conover and colleagues, 1983).

Whether adverse outcomes may be related to caffeine consumption is somewhat controversial. In a case-control study, Klebanoff and co-workers (1999) measured paraxanthine, a biological serum marker of caffeine consumption, in 487 women with spontaneous abortions and in 2087 controls. Only extremely high levels, equivalent to more than 5 cups of coffee per day, were associated with abortion. Clausson and associates (2002) found no association of moderate caffeine consumption of less than 500 mg daily with low birthweight, fetal-growth restriction, or preterm delivery. Bech and associates (2007) randomly assigned more than 1200 pregnant women who drank at least three cups of coffee per day to caffeinated versus decaffeinated coffee. They found no difference in birthweight or gestational age at delivery between groups. However, the CARE study (2008) included 2635 low-risk pregnancies and found that the odds ratio for fetal-growth restriction was increased to approximately 1.4 among those whose daily caffeine consumption exceeded 200 mg throughout pregnancy compared with those who consumed less than 100 mg daily. The American Dietetic Association (2002) recommends that caffeine intake during pregnancy be limited to less than 300 mg daily, or approximately three, 5-oz cups of percolated coffee.

Nausea and Vomiting

These are common complaints during the first half of pregnancy. Nausea and vomiting of varying severity usually commence between the first and second missed menstrual period and continue until 14 to 16 weeks. Although nausea and vomiting tend to be worse in the morning—thus erroneously termed *morning sickness,* they frequently continue throughout the day. Lacroix and co-workers (2000) found that nausea and vomiting were reported by three fourths of pregnant women and lasted an average of 35 days. Half had relief by 14 weeks, and 90 percent by 22 weeks. In 80 percent of the women, nausea lasted all day. It was frequently described to have a character and intensity similar to that experienced by patients undergoing cancer chemotherapy.

Seldom is the treatment of nausea and vomiting of pregnancy so successful that the affected expectant mother is afforded complete relief. Fortunately, the unpleasantness and discomfort usually can be minimized. Eating small meals at more frequent intervals but stopping short of satiation is valuable. Borrelli and colleagues (2005) did a systematic literature search and reported that the herbal remedy, ginger, was likely effective. Mild symptoms usually respond to vitamin B_6 given along with doxylamine, but some women require phenothiazine or H_1-receptor blocker antiemetics (American College of Obstetricians and Gynecologists, 2004b). In some women, vomiting may be so severe that dehydration, electrolyte and acid–base disturbances, and starvation ketosis become serious problems. This is termed *hyperemesis gravidarum,* and its management is described in Chapter 49 (p. 1050).

Backache

Low back pain to some extent is reported in nearly 70 percent of pregnant women (Wang and colleagues, 2004). Minor degrees follow excessive strain or fatigue and excessive bending, lifting, or walking. Orvieto and associates (1994) studied 449 women and reported that back pain increased with duration of gestation. Prior low back pain and obesity were risk factors.

Back pain can be reduced by having women squat rather than bend over when reaching down, providing back support with a pillow when sitting down, and avoiding high-heeled shoes. Severe back pain should not be attributed simply to pregnancy until a thorough orthopedic examination has been conducted. Muscular spasm and tenderness, which often are classified clinically as acute strain or fibrositis, respond well to analgesics, heat, and rest. As discussed in Chapter 53, some women with severe back and hip pain may have *pregnancy-associated osteoporosis* (Dunne and colleagues, 1993). Severe pain also has other uncommon causes, such as disc disease, vertebral osteoarthritis, or septic arthritis (Smith and associates, 2008).

Norén and co-workers (2002) studied the long-term outcomes of 231 women who had some type of back pain during pregnancy. Residual pain 3 years after delivery was reported by approximately 20 percent. Women with combined lumbar back and posterior pelvic pain were at greatest risk for disability, which was attributed to impaired back extensor and hip abductor muscle functions (see Chap. 30, p. 656).

Varicosities

These enlarged veins generally result from congenital predisposition and are exaggerated by prolonged standing, pregnancy, and advancing age. Usually varicosities become more prominent as pregnancy advances, as weight increases, and as the length of time spent upright is prolonged. As discussed in Chapter 5 (p. 119), femoral venous pressure increases appreciably as pregnancy advances. The symptoms produced by varicosities vary from cosmetic blemishes and mild discomfort at the end of the day to severe discomfort that requires prolonged rest with elevated feet.

Treatment is generally limited to periodic rest with leg elevation, elastic stocking use, or both. Surgical correction during pregnancy

generally is not advised, although occasionally the symptoms may be so severe that injection, ligation, or even stripping of the veins is necessary. Vulvar varicosities may be aided by application of a foam rubber pad suspended across the vulva by a belt. Rarely, large varicosities may rupture, resulting in profuse hemorrhage.

Hemorrhoids

Varicosities of the rectal veins may first appear during pregnancy because of increased venous pressure. More often, pregnancy causes an exacerbation or a recurrence of previous hemorrhoids. Pain and swelling usually are relieved by topically applied anesthetics, warm soaks, and stool-softening agents. Thrombosis of an external hemorrhoid can cause considerable pain, but the clot usually can be evacuated by incising the vein wall under topical anesthesia.

Heartburn

This symptom is one of the most common complaints of pregnant women and is caused by reflux of gastric contents into the lower esophagus. The increased frequency of regurgitation during pregnancy most likely results from the upward displacement and compression of the stomach by the uterus, combined with relaxation of the lower esophageal sphincter (see Chap. 5, p. 125). In most pregnant women, symptoms are mild and are relieved by a regimen of more frequent but smaller meals and avoidance of bending over or lying flat. Antacids may provide considerable relief. Aluminum hydroxide, magnesium trisilicate, or magnesium hydroxide alone or in combination are given. Management for symptoms that do not respond to these simple measures is discussed in Chapter 49 (p. 1052).

Pica

The cravings of pregnant women for strange foods are termed pica. At times, nonfoods such as ice—pagophagia, starch—amylophagia, or clay—geophagia may predominate. This desire has been considered by some to be triggered by severe iron deficiency. Although some women crave these items, and although the craving usually is ameliorated after correction of iron deficiency, not all pregnant women with pica are necessarily iron deficient. Indeed, if strange "foods" dominate the diet, iron deficiency will be aggravated or will develop eventually.

Patel and colleagues (2004) from the University of Alabama at Birmingham prospectively completed a dietary inventory on more than 3000 women during the second trimester. The prevalence of pica was 4 percent. The most common nonfood items ingested were starch in 64 percent, dirt in 14 percent, sourdough in 9 percent, and ice in 5 percent. The prevalence of anemia was 15 percent in women with pica compared with 6 percent in those without it. Interestingly, the rate of spontaneous preterm birth at less than 35 weeks was twice as high in women with pica.

Ptyalism

Women during pregnancy are occasionally distressed by profuse salivation. Although usually unexplained, the cause of such ptyalism sometimes appears to be stimulation of the salivary glands by the ingestion of starch.

Sleeping and Fatigue

Beginning early in pregnancy, many women experience fatigue and need increased amounts of sleep. This likely is due to the soporific effect of progesterone(s). Moreover, *sleep efficiency* is diminished because REM sleep is decreased and non-REM sleep prolonged (Pien and Schwab, 2004). Fatigue and nonrestful sleep may be exacerbated by morning sickness. By the late second trimester, total nocturnal sleep duration is decreased, and women usually begin to complain of sleep disturbances. Approximately half of women begin snoring (Izci and associates, 2005). By the third trimester, nearly all women have altered sleep. Although total nocturnal sleep time is similar to nonpregnancy, sleep efficiency is perturbed because REM sleep is decreased. Daytime naps and mild sedatives at bedtime such as diphenhydramine (Benadryl) are usually helpful.

Leukorrhea

Pregnant women commonly develop increased vaginal discharge, which in many instances is not pathological. Increased mucus secretion by cervical glands in response to hyperestrogenemia is undoubtedly a contributing factor. Occasionally, troublesome leukorrhea is the result of vulvovaginal infection. The majority of these in adult women are caused by bacterial vaginosis, candidiasis, or trichomoniasis (Eckert, 2006). These vulvovaginal infections are reviewed in Chapter 59 (p. 1246).

Cord Blood Banking

In the past 20 years, umbilical cord blood transplantation has been successfully performed more than 7000 times to treat hematopoietic cancers and a variety of genetic conditions in children and adults (Moise, 2005). There are two types of cord blood banks. Public banks promote allogenic donation, for use by a related or unrelated recipient, similar to blood product donation. Whereas private banks were initially developed to store stem cells for future autologous use, these banks charge fees for initial processing and annual storage. The American College of Obstetricians and Gynecologists (2008) has concluded that if a woman requests information on umbilical cord banking, information regarding advantages and disadvantages of public versus private banking should be disclosed. Some states have passed legislation that requires physicians to inform patients about cord blood banking options. Importantly, few transplants have been performed by using cord blood stored in the absence of a known indication in the recipient (Thornley and associates, 2009). The likelihood that cord blood would be used for the donor couple's child or family member is considered remote—at most, approximately 1 in 2700 individuals (American College of Obstetricians and Gynecologists, 2008). It is recommended that directed donation be considered when an immediate family member carries the diagnosis of a specific condition known to be treatable by hematopoietic transplantation.

CHAPTER 9

Abortion

SPONTANEOUS ABORTION 215
RECURRENT MISCARRIAGE 224
INDUCED ABORTION 226
CONTRACEPTION FOLLOWING MISCARRIAGE OR ABORTION 234

The word *abortion* derives from the Latin *aboriri*—to miscarry. According to the New Shorter Oxford Dictionary (2002), abortion is premature birth before a live birth is possible, and in this sense it is synonymous with miscarriage. It also means an induced pregnancy termination to destroy the fetus. Although both terms are used interchangeably in a medical context, popular use of the word *abortion* by laypersons implies a deliberate pregnancy termination. Thus, many prefer *miscarriage* to refer to spontaneous fetal loss before viability. To add to confusion, widespread use of sonography and measurement of serum human chorionic gonadotropin levels allow identification of extremely early pregnancies along with terms to describe these. Some examples are *early pregnancy loss* or *early pregnancy failure*. Throughout this book, we employ all of these at one time or another.

The duration of pregnancy is also used to define and classify abortions for statistical and legal purposes (see Chap. 1, p. 3). For example, the National Center for Health Statistics, the Centers for Disease Control and Prevention, and the World Health Organization define *abortion* as pregnancy termination prior to 20 weeks' gestation or with a fetus born weighing less than 500 g. Despite this, definitions vary widely according to state laws.

SPONTANEOUS ABORTION

More than 80 percent of spontaneous abortions are in the first 12 weeks. As shown in **Figure 9-1**, at least half result from chromosomal anomalies. There also appears to be a 1.5 male:female gender ratio in early abortuses (Benirschke and Kaufmann, 2000). After the first trimester, both the abortion rate and the incidence of chromosomal anomalies decrease.

Hemorrhage into the decidua basalis, with adjacent tissue necrosis, usually accompanies early miscarriage. In these cases, the ovum detaches, and this stimulates uterine contractions that result in expulsion. When a gestational sac is opened, fluid is commonly found surrounding a small macerated fetus, or alternatively, there is no fetus—the so-called *blighted ovum*.

Incidence

The prevalence of spontaneous abortion varies according to diligence used in its identification. For example, Wilcox and colleagues (1988) studied 221 healthy women through 707 menstrual cycles. They found that 31 percent of pregnancies were lost after implantation. Importantly, using highly specific assays for minute concentrations of maternal serum β-human chorionic gonadotropin (β-hCG), two thirds of these early losses were designated as *clinically silent*.

A number of factors influence the spontaneous abortion rate, but it is not known at this time if those that are clinically silent are affected by some of these. For example, clinically apparent miscarriage increases with parity as well as with maternal and paternal age (Gracia, 2005; Warburton, 1964; Wilson, 1986, and all their colleagues). The frequency doubles from 12 percent in women younger than 20 years to 26 percent in those older than 40 years. For the same comparison of paternal ages, the frequency increases from 12 to 20 percent. But again, it is not known if clinically silent miscarriages are similarly affected by age and parity.

Although mechanisms responsible for abortion are not always apparent, during the first 3 months of pregnancy, death of the embryo or fetus nearly always precedes spontaneous expulsion. Thus, finding the cause of early abortion involves ascertaining the cause of fetal death. In later losses, the fetus usually

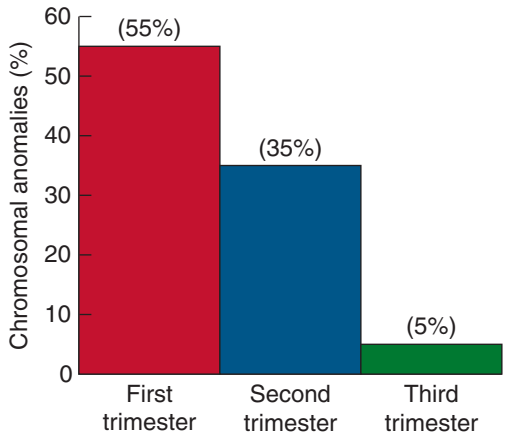

FIGURE 9-1 Frequency of chromosomal anomalies in abortuses and stillbirths during each trimester. Approximate percentages for each group are shown. (Data from Eiben, 1990; Fantel, 1980; Warburton, 1980, and all their colleagues.)

does not die before expulsion, and other explanations are sought.

Fetal Factors

Early spontaneous abortions commonly display a developmental abnormality of the zygote, embryo, fetus, or at times, the placenta. Of 1000 spontaneous abortions analyzed by Hertig and Sheldon (1943), half had a degenerated or absent embryo—the *blighted ovum* described previously. In 50 to 60 percent of spontaneously aborted embryos and early fetuses, abnormalities in chromosomal numbers account for most wastage (Table 9-1). Chromosomal errors become less common with advancing pregnancy and are found in approximately a third of second-trimester losses but in only 5 percent of third-trimester stillbirths (see Chap. 29, p. 630).

Aneuploid Abortion

Approximately 95 percent of chromosomal abnormalities are caused by maternal gametogenesis errors, whereas 5 percent are due to paternal errors (Jacobs and Hassold, 1980). Those found most commonly in abortuses are listed in Table 9-1.

Autosomal trisomy is the most frequently identified chromosomal anomaly with first-trimester miscarriages. Although most trisomies result from *isolated nondisjunction*, balanced structural chromosomal rearrangements are present in one partner in 2 to 4 percent of couples with recurrent miscarriage (American College of Obstetricians and Gynecologists, 2001). Autosomal trisomies for all except chromosome number 1 have been identified in abortuses, and those with autosomes 13, 16, 18, 21, and 22 are most common. Bianco and colleagues (2006) recently described that a previous miscarriage increased the risk of a subsequent fetal aneuploidy from a baseline risk of 1.39 percent to 1.67 percent in almost 47,000 women. Two or three previous miscarriages increased this to 1.84 and 2.18 percent, respectively.

Monosomy X (45,X) is the single most common specific chromosomal abnormality. These cause Turner syndrome, which usually results in abortion and much less frequently in live-born females (Chap. 12, p. 270). Conversely, *autosomal monosomy* is rare and incompatible with life.

Triploidy is often associated with hydropic placental (molar) degeneration (Chap. 11, p. 258). Incomplete (partial) hydatidiform moles may be triploid or trisomic for only chromosome 16. Although these fetuses frequently abort early, the few carried longer are all grossly malformed. Advanced maternal and paternal age does not increase the incidence of triploidy.

Tetraploid abortuses are rarely live born and are most often aborted early in gestation.

Chromosomal structural abnormalities infrequently cause abortion. Some infants who are live born with a balanced translocation may appear normal as discussed on page 224.

Euploid Abortion

Chromosomally normal fetuses tend to abort later in gestation than those with aneuploidy. For example, although 75 percent of aneuploid abortions occurred before 8 weeks, euploid abortions peaked at approximately 13 weeks (Kajii, 1980). The incidence of euploid abortions increases dramatically after maternal age exceeds 35 years (Stein and co-workers, 1980).

TABLE 9-1. Chromosomal Findings in Abortuses

	Incidence in Percent		
Chromosomal Studies	Kajii et al. (1980)	Eiben et al. (1990)	Simpson (1980)
Normal (euploid)			
46,XY and 46,XX	46	51	54
Abnormal (aneuploid)			
Autosomal trisomy	31	31	22
Monosomy X (45,X)	10	5	9
Triploidy	7	6	8
Tetraploidy	2	4	3
Structural anomaly	2	2	2
Double or triple trisomy	2	0.9	0.7

Maternal Factors

The causes of euploid abortions are poorly understood, although a variety of medical disorders, environmental conditions, and developmental abnormalities have been implicated. The well-known influence of maternal age was discussed above.

Infections

According to the American College of Obstetricians and Gynecologists (2001), infections are an uncommon cause of early abortion. Even in their study of insulin-dependent diabetic women—presumably more susceptible to infection—Simpson and co-workers (1996) found no evidence of infection-induced miscarriage.

A number of specific infections have been studied. For example, although *Brucella abortus* and *Campylobacter fetus* cause abortion in cattle, they do not do so in humans (Sauerwein and associates, 1993). There is also no evidence that either *Listeria monocytogenes* or *Chlamydia trachomatis* stimulate abortions in humans (Feist, 1999; Osser, 1996; Paukku, 1999, and all their colleagues). In a prospective study, infection with herpes simplex virus in early pregnancy also did not increase the incidence (Brown and co-workers, 1997). Evidence that *Toxoplasma gondii* causes abortion in humans remains inconclusive.

Data concerning a link between some other infections and increased abortion are conflicting. For example, Quinn and co-workers (1983a, b) provided serological evidence that supports a role for *Mycoplasma hominis* and *Ureaplasma urealyticum*. Conversely, Temmerman and associates (1992) found no link between genital mycoplasma and spontaneous abortion. They did find abortion to be independently associated with serological evidence of syphilis and HIV-1 infection, and with vaginal colonization with group B streptococci. In contrast, van Benthem and associates (2000) reported that women had the same risk for spontaneous abortion before and after they had developed HIV infection. Oakeshott and associates (2002) reported an association between second, but not first-trimester miscarriage and *bacterial vaginosis* (see Chap. 59, p. 1246).

Chronic Debilitating Diseases

Early abortions are rarely secondary to chronic wasting diseases such as tuberculosis or carcinomatosis. Celiac sprue, however, has been reported to cause both male and female infertility and recurrent abortions (Sher and colleagues, 1994).

Endocrine Abnormalities

Hypothyroidism. Severe iodine deficiency may be associated with miscarriages (Castañeda and co-workers, 2002). Thyroid hormone deficiency is common in women, it is usually caused by an autoimmune disorder, but any effects of hypothyroidism on early pregnancy loss have not been adequately studied. Thyroid autoantibodies alone have been associated with an increased incidence of miscarriage (Abramson and Stagnaro-Green, 2001; Poppe and colleagues, 2008). As discussed on page 226, the data are less convincing that women with *recurrent miscarriage* have a greater incidence of antithyroid antibodies than normal controls.

Diabetes Mellitus

Spontaneous abortion and major congenital malformation rates are both increased in women with insulin-dependent diabetes. The risk appears related to the degree of metabolic control in early pregnancy. In a prospective study, Mills and associates (1988) reported that excellent glucose control within 21 days of conception resulted in a miscarriage rate similar to that in non-diabetic controls. Poor glucose control, however, resulted in a markedly increased abortion rate. Overt diabetes is a cause of recurrent pregnancy loss, and Craig and co-workers (2002) have reported a higher incidence of insulin resistance in these women. This is discussed further on page 226.

Nutrition

Dietary deficiency of any one nutrient or moderate deficiency of all nutrients does not appear to be an important cause of abortion. Even at the extreme, hyperemesis gravidarum with significant weight loss is rarely followed by miscarriage. In one study, Maconochie and associates (2007) found a reduced risk in women who ate fresh fruit and vegetables daily.

Drug Use and Environmental Factors

A variety of different agents have been reported to be associated with an increased incidence of abortion.

Tobacco. Smoking has been linked with an increased risk for euploid abortion (Kline and co-workers, 1980). Two studies suggested that the abortion risk increased in a linear fashion with cigarettes smoked per day (Armstrong and colleagues, 1992; Chatenoud and associates, 1998). Subsequent studies, however, failed to support this association (Maconochie, 2007; Rasch, 2003; Wisborg, 2003, and all their co-workers).

Alcohol. Both spontaneous abortion and fetal anomalies may result from frequent alcohol use during the first 8 weeks of pregnancy (Floyd and co-workers, 1999). The risk seems to be related to both frequency and dose (Armstrong and associates, 1992). A low level of alcohol consumption during pregnancy was not associated with a significant risk for abortion (Kesmodel and associates, 2002; Maconochie and co-workers, 2007).

Caffeine. Armstrong and associates (1992) reported that women who consumed at least five cups of coffee per day had a slightly increased abortion risk, and that above this threshold, the risk correlated linearly. Similarly, Cnattingius and colleagues (2000) observed a significantly increased abortion risk only in women who consumed at least 500 mg of caffeine daily—roughly equivalent to five cups of coffee. Klebanoff and associates (1999) reported that pregnant women in whom levels of the caffeine metabolite paraxanthine were extremely elevated had a twofold risk for miscarriage. They concluded that moderate caffeine consumption was unlikely to cause spontaneous abortion.

Radiation. In therapeutic doses given to treat malignancy, radiation is certainly an abortifacient (see Chap. 41, p. 915). Although lower doses are less toxic, the human dose to effect abortion is not precisely known. According to Brent (1999),

exposure to less than five rads does not increase the risk for miscarriage.

Contraceptives. Oral contraceptives or spermicidal agents used in contraceptive creams and jellies are not associated with an increased miscarriage rate. When intrauterine devices fail to prevent pregnancy, however, the risk of abortion, and specifically septic abortion, increases substantively (see Chap. 32, p. 685).

Environmental Toxins. Accurately assessing the relationship between environmental exposures and miscarriage poses challenges. There may be difficulties in measuring the intensity and duration of exposure, and there is little information to conclusively indict or absolve any specific agent. Some studies include those by Barlow and Sullivan (1982), who found that arsenic, lead, formaldehyde, benzene, and ethylene oxide possibly cause miscarriages. Video display terminals and exposure to their accompanying electromagnetic fields do not adversely affect miscarriage rates (Schnorr and associates, 1991). Similarly, no effects were found with occupational exposure to ultrasound (Taskinen and colleagues, 1990). An increased risk of miscarriage has been described for dental assistants exposed to 3 or more hours of nitrous oxide per day in offices without gas-scavenging equipment (Rowland and co-workers, 1995). Before the use of such equipment, Boivin (1997) concluded that women occupationally exposed to anesthetic gases had an increased risk for miscarriage. In another meta-analysis, Dranitsaris and colleagues (2005) identified a small incremental risk for spontaneous abortion in female staff who worked with cytotoxic chemotherapeutic drugs.

Immunological Factors

A number of immune-mediated disorders are associated with early pregnancy loss. Many tend to be repetitive, and they are considered with recurrent miscarriage (p. 225).

Inherited Thrombophilias

Some genetic disorders of blood coagulation may increase the risk of both arterial and venous thrombosis. The better studied thrombophilias are caused by mutations of the genes for factor V Leiden, prothrombin, antithrombin, proteins C and S, and methylene tetrahydrofolate reductase (hyperhomocysteinemia). Because these are most commonly associated with recurrent miscarriage, they are considered on page 225.

Maternal Surgery

Uncomplicated abdominal or pelvic surgery performed during early pregnancy does not appear to increase the risk for abortion. Ovarian tumors are generally removed without interfering with pregnancy (see Chap. 40, p. 904). An important exception involves early removal of the corpus luteum or the ovary in which the corpus luteum resides. If performed prior to 10 weeks' gestation, supplemental progesterone is indicated. If between 8 and 10 weeks, then only one injection of intramuscular 17-hydroxyprogesterone caproate, 150 mg, is required immediately after surgery. If the corpus luteum is excised between 6 to 8 weeks, then two additional doses should be given one and two weeks after the first.

Trauma

Presumably, major abdominal trauma can precipitate abortion, however, this is unusual. Any effects of minor trauma are difficult to ascertain. In general, trauma contributes minimally to the incidence of abortion (see Chap. 42, p. 936).

Uterine Defects

Acquired Uterine Defects. Large and multiple uterine leiomyomas are common, and they may cause miscarriage. In most instances, their location is more important than their size (see Chap. 40, p. 901). Uterine synechiae—*Asherman syndrome*—usually result from destruction of large areas of endometrium by curettage. A hysterosalpingogram may show characteristic multiple filling defects, but hysteroscopy is more accurate for diagnosis. With subsequent pregnancy, the amount of remaining endometrium may be insufficient to support the pregnancy, and abortion may ensue.

Developmental Uterine Defects. Abnormal müllerian duct formation or fusion defects may develop spontaneously or may follow in utero exposure to diethylstilbestrol (DES) (see Chap. 40, p. 897). Although they can cause midpregnancy loss and other preterm birth and pregnancy complications, it is controversial whether uterine defects cause early miscarriage. As discussed on page 224, corrective procedures to prevent abortion, if done at all, should be performed as a last resort and with a full understanding that they may not be effective (American College of Obstetricians and Gynecologists, 2001).

Incompetent Cervix

This describes a discrete obstetrical entity characterized by painless cervical dilatation in the second trimester. It can be followed by prolapse and ballooning of membranes into the vagina, and ultimately, expulsion of an immature fetus. Unless effectively treated, this sequence may repeat in future pregnancies.

Unfortunately, women with pregnancies that abort in the second trimester often have histories and clinical findings that make it difficult to distinguish true cervical incompetence from other causes of midtrimester pregnancy loss. MacNaughton and colleagues (1993) studied almost 1300 women with nonclassical histories of cervical incompetence. In a randomized trial with the primary outcome of delivery before 33 weeks, cerclage was found to be beneficial, albeit marginally. Specifically, 13 percent of women in the cerclage group delivered prior to 33 weeks compared with 17 percent in the noncerclage group. Said another way, for every 25 cerclage procedures, one birth before 33 weeks was prevented.

Recently, interest has been focused on the use of transvaginal sonography to identify cervical incompetence. Some features—primarily cervical length—when measured at midpregnancy, may predict preterm delivery. Another is termed *funneling*—ballooning of the membranes into a dilated internal os, but with a closed external os (Owen and associates, 2003).

The clinical relevance of these cervical changes is not entirely clear. Three randomized cerclage trials that studied such women reported conflicting results. Rust and colleagues (2001) randomized 113 women with a cervical length of less than 25 mm

or with substantive funneling to undergo either cerclage or expectant management. The incidence of preterm birth was 35 percent in the cerclage group and 36 percent in the control group. In a second study, To and colleagues (2004) randomly assigned 253 women to cerclage placement and reported that the risk of early preterm birth was not significantly reduced. The third study by Althuisius and colleagues (2001) randomized only 35 women, but results suggested that cerclage might be beneficial. At least at this time, the use of sonography to diagnose cervical incompetence is not recommended.

Etiology. Although the cause of cervical incompetence is obscure, previous trauma to the cervix such as dilatation and curettage, conization, cauterization, or amputation has been implicated. In a population-based Norwegian cohort study of more than 15,000 women who had undergone cervical conization, Albrechtsen and colleagues (2008) reported a fourfold risk of pregnancy loss before 24 weeks. Chasen and associates (2005) reported that neither prior dilatation and evacuation (D&E) nor dilatation and extraction (D&X) after 20 weeks increased the likelihood of an incompetent cervix. In other instances, abnormal cervical development, including that following exposure to DES in utero, may play a role (see Chap. 40, p. 897).

Evaluation and Treatment. Once confirmed, classical cervical incompetence is treated with cerclage, which surgically reinforces a weak cervix by some type of purse-string suturing. Bleeding, uterine contractions, or ruptured membranes are usually contraindications to cerclage. Sonography is performed to confirm a living fetus and to exclude major fetal anomalies. Cervical specimens are tested for gonorrhea and chlamydial infection, and these and other obvious cervical infections are treated. For at least a week before and after surgery, sexual intercourse is prohibited.

Cerclage ideally is performed prophylactically before cervical dilatation. In some cases, this is not possible, and *rescue cerclage* is performed emergently after the cervix is found to be dilated or effaced. Elective cerclage generally is performed between 12 and 16 weeks, but there is debate as to how late emergency cerclage should be performed. The conundrum is that the more advanced the pregnancy, the greater the risk that surgical intervention will stimulate preterm labor or membrane rupture. Although this is not evidence based, we usually do not perform cerclage after approximately 23 weeks, however, others recommend placement even later (Caruso and associates, 2000; Terkildsen and colleagues, 2003).

In a 10-year review of 75 women undergoing emergency cerclage procedures, Chasen and Silverman (1998) reported that 65 percent were delivered at 28 weeks or later, and half delivered after 36 weeks. Importantly, only 44 percent of those with bulging membranes at the time of cerclage reached 28 weeks. Caruso and associates (2000) reported their experience with emergency cerclage in 23 women from 17 to 27 weeks who had a dilated cervix and protruding membranes. Because only 11 live-born infants resulted, they concluded that success was unpredictable. Based on their 20-year experience with 116 women, Terkildsen and colleagues (2003) reported that nulliparas and those with bulging membranes were significantly more likely to be delivered before 28 weeks. Cerclage after 22 weeks, however, was associated with a better chance of delivery beyond 28 weeks.

If the clinical indication for cerclage is questionable, these women may be advised to decrease physical activity and abstain from intercourse. Most receive cervical examinations each week or every 2 weeks to assess effacement and dilatation. Unfortunately, rapid effacement and dilatation can develop despite such precautions (Witter, 1984).

Cerclage Procedures. Two types of vaginal operations are commonly used during pregnancy. The more simple procedure developed by McDonald (1963) is shown in **Figure 9-2**. The more complicated operation is a modification of the original procedure described by Shirodkar (1955) and shown in **Figure 9-3**. Compared with historical controls, women with classical histories of cervical incompetence have success rates approaching 85 to 90 percent when either technique is performed prophylactically (Caspi and associates, 1990; Kuhn and Pepperell, 1977). For these reasons, most practitioners reserve the modified Shirodkar procedure for women with a previous failure of the McDonald cerclage or those with structural cervical abnormalities.

During emergency cerclage, replacing the prolapsed amnionic sac back into the uterus will usually aid suture placement (Locatelli and associates, 1999). Tilting the operating table head down may be beneficial. And filling the bladder with 600 mL of saline through an indwelling Foley catheter usually will help to reduce prolapsing membranes. Unfortunately, this maneuver also can carry the cervix cephalad, away from the operating field. Some advocate placing a Foley catheter with a 30-mL balloon through the cervix and inflating the balloon to deflect the amnionic sac cephalad. The balloon is then deflated gradually as the cerclage suture is tightened.

Transabdominal cerclage with the suture placed at the uterine isthmus is used in some cases of severe anatomical defects of the cervix or cases of prior transvaginal cerclage failure (Cammarano and colleagues, 1995; Gibb and Salaria, 1995). In a review of 14 retrospective reports, Zaveri and associates (2002) concluded that when a prior transvaginal cerclage failed to prevent preterm delivery, the risk of perinatal death or delivery prior to 24 weeks following transabdominal cerclage (6 percent) was only slightly lower than the risk following repeat transvaginal cerclage (13 percent). Importantly, 3 percent of women who underwent transabdominal cerclage had serious operative complications, whereas there were none in women in the transvaginal group. Although transabdominal cerclage has been performed through the laparoscope, it generally requires laparotomy for initial suture placement and subsequent laparotomy for removal of the suture, for delivery of the fetus, or both.

Complications. Charles and Edward (1981) identified complications, especially infection, to be less frequent when elective cerclage was performed by 18 weeks. In the trial by MacNaughton and colleagues (1993), membrane rupture complicated only 1 of more than 600 procedures done before 19 weeks. Cerclage

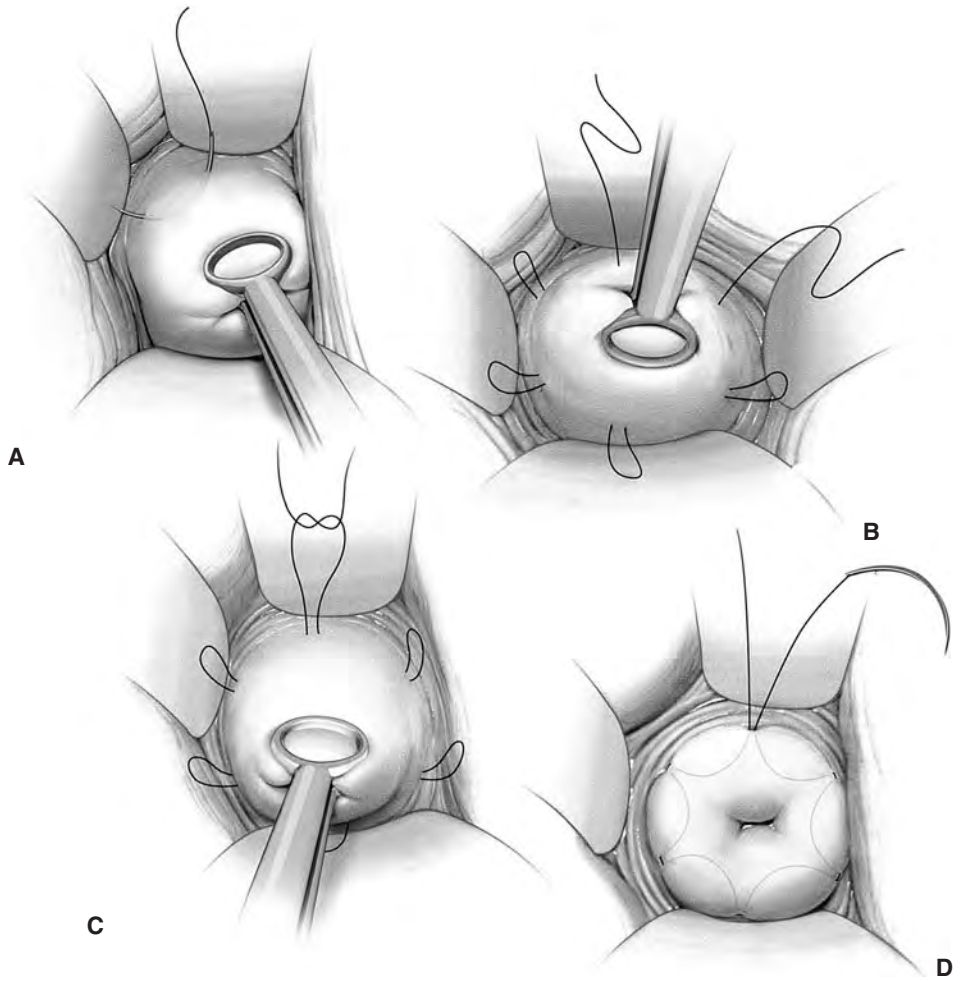

FIGURE 9-2 McDonald cerclage procedure for incompetent cervix. **A.** Start of the cerclage procedure with a number 2 monofilament suture being placed in the body of the cervix very near the level of the internal os. **B.** Continuation of suture placement in the body of the cervix so as to encircle the os. **C.** Completion of encirclement. **D.** The suture is tightened around the cervical canal sufficiently to reduce the diameter of the canal to 5 to 10 mm, and then the suture is tied. The effect of the suture placement on the cervical canal is apparent. A second suture placed somewhat higher may be of value if the first is not in close proximity to the internal os.

was associated with higher rates of subsequent hospitalization and tocolysis, as well as a doubling of the incidence of puerperal fever—6 percent versus 3 percent. Thomason and co-workers (1982) found that perioperative antimicrobial prophylaxis failed to prevent most infection, and tocolytics failed to arrest most labor. With clinical infection, the suture should be cut, and labor induced or augmented if necessary. Similarly, if signs of imminent abortion or delivery develop, the suture should be released at once. Failure to do so may enable vigorous uterine contractions to tear the uterus or cervix.

Membrane rupture during suture placement or within the first 48 hours following surgery is considered by some to be an indication for cerclage removal. Kuhn and Pepperell (1977) reported that rupture in the absence of labor increased the likelihood of serious fetal or maternal infection if the suture was left in situ and delivery was delayed. Still, the range of management options includes observation, removal of the cerclage and observation, or removal of the cerclage and labor induction (Barth, 1995). Insufficient data limit firm recommendations, and the optimal management remains controversial (O'Connor and associates, 1999).

Following the modified Shirodkar operation, the suture may be left in place, and cesarean delivery performed. Conversely, it may be removed, and vaginal delivery permitted.

Paternal Factors

Little is known about paternal factors in the genesis of miscarriage. Certainly, chromosomal abnormalities in sperm have been associated with abortion (Carrell and co-workers, 2003).

Clinical Classification of Spontaneous Abortion

Spontaneous abortion can be classified clinically a number of ways. Commonly used subgroups include threatened, inevitable, incomplete, and missed abortion. *Septic abortion* is the condition when the products of conception and uterus are infected. Finally, *recurrent miscarriage*—also termed *recurrent pregnancy loss*—describes consecutive early losses with implied similar etiology.

Threatened Abortion

The clinical diagnosis of *threatened abortion* is presumed when a bloody vaginal discharge or bleeding appears through a closed cervical os during the first half of pregnancy. These develop in 20 to 25 percent of women during early gestation and may persist for days or weeks. Approximately half of these pregnancies will abort, although the risk is substantially lower if fetal cardiac activity is visualized (Tongsong and colleagues, 1995).

Eddleman and associates (2006) designed an individualized risk assessment model for spontaneous pregnancy loss in more than 35,000 pregnancies. By far, bleeding during the current pregnancy was the most predictive risk factor for pregnancy loss. Even if abortion does not follow early bleeding, these fetuses are at increased risk for preterm delivery, low birthweight, and perinatal death (Johns and Jauniaux, 2006; Weiss and associates, 2002). Fortunately, the risk of a malformed surviving infant does not appear to be increased. Maternal risks include antepartum hemorrhage, manual removal

of the placenta, and cesarean delivery (Wijesiriwardana and coworkers, 2006).

One physiological cause of bleeding occurs near the time of expected menses—*implantation bleeding*. Cervical lesions commonly bleed in early pregnancy, especially after intercourse. Cervical polyps and decidual reaction also tend to bleed in early gestation. Bleeding from these benign sources is not accompanied by lower abdominal pain and low backache.

With miscarriage, bleeding usually begins first, and cramping abdominal pain follows a few hours to several days later. The pain may present as anterior and clearly rhythmic cramps; as a persistent low backache, associated with a feeling of pelvic pressure; or as a dull, midline, suprapubic discomfort. Whichever form the pain takes, the combination of bleeding and pain predicts a poor prognosis for pregnancy continuation.

Because ectopic pregnancy, ovarian torsion, and the other types of abortion may mimic threatened abortion, women with early pregnancy bleeding and pain should be evaluated. With persistent or heavy bleeding, a hematocrit is performed, and if there is significant anemia or hypovolemia, then pregnancy evacuation is usually indicated.

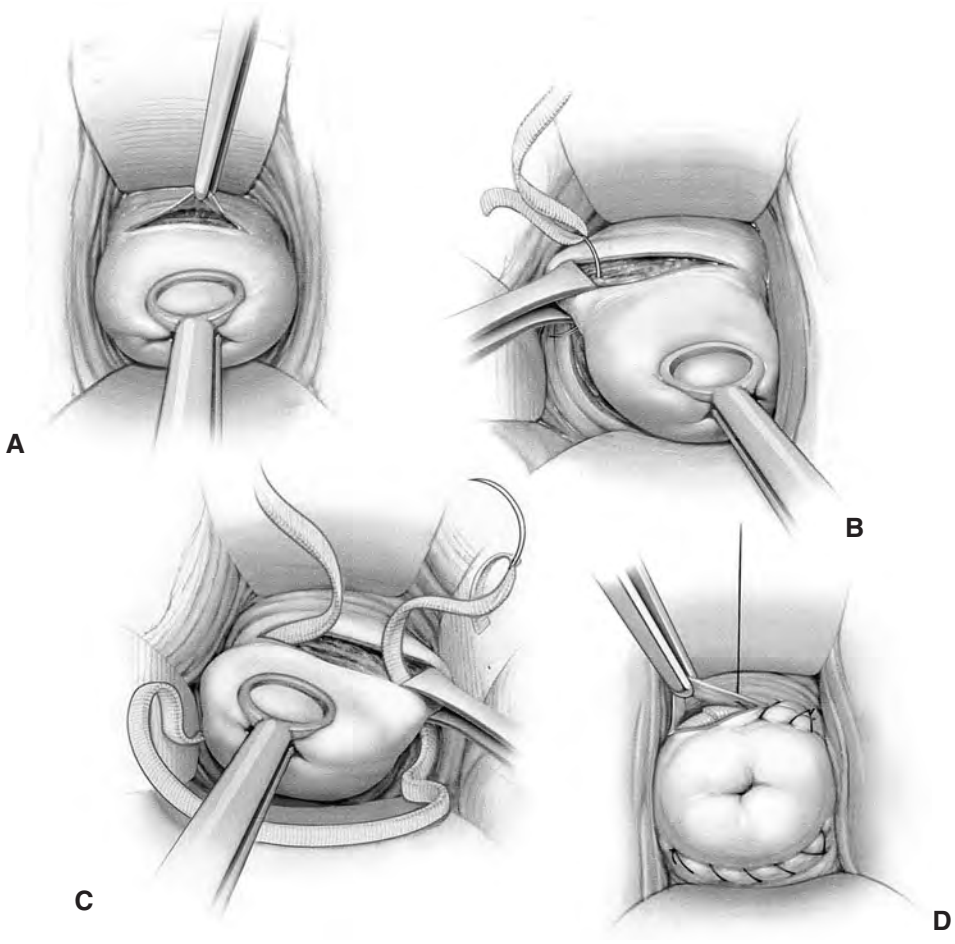

FIGURE 9-3 Modified Shirodkar cerclage for incompetent cervix. **A.** A transverse incision is made in the mucosa overlying the anterior cervix, and the bladder is pushed cephalad. **B.** A 5-mm Mersiline tape on a Mayo needle is passed anteriorly to posteriorly. **C.** The tape is then directed posteriorly to anteriorly on the other side of the cervix. Allis clamps placed so as to bunch the cervical tissue to diminish the distance the needle must travel submucosally facilitate placement of the tape. **D.** The tape is snugly tied anteriorly, after ensuring that all slack has been taken up. The cervical mucosa is then closed with continuous stitches of chromic suture to bury the anterior knot.

There are no effective therapies for threatened abortion. Bed rest, although often prescribed, does not alter its course. Acetaminophen-based analgesia may be given for discomfort. Typically, transvaginal sonography, serial serum quantitative human chorionic gonadotropin (hCG), and serum progesterone levels, used alone or in combination, are analyzed to ascertain if the fetus is alive and within the uterus. Because they are not 100-percent accurate to confirm fetal death, repeat evaluations may be necessary.

Ectopic pregnancy should always be considered in the differential diagnosis of threatened abortion. In one report, Condous and colleagues (2005) described 152 women with heavy bleeding who were diagnosed to have a completed miscarriage and an endometrial thickness < 15 mm. Almost 6 percent of these women were found to have an ectopic pregnancy on further evaluation.

It is imperative to recognize an early ectopic pregnancy before tubal rupture develops. Thus, for women with abnormal bleeding or pelvic pain who have low serum β-hCG levels, an extrauterine pregnancy must be differentiated from a normal uterine pregnancy or an early miscarriage (Chap. 10, p. 243). Barnhart and colleagues (2004a) have provided data concerning composite serum β-hCG disappearance curves in women with early miscarriage (Fig. 9-4). They also provided similar data for symptomatic women with a normal early pregnancy (Barnhart and associates, 2004b).

Anti-D Immunoglobulin

The D-negative woman is given anti-D immunoglobulin following miscarriage because as many as 5 percent become isoimmunized without it. This practice is controversial with threatened abortion because it lacks evidence-based support (American College of Obstetricians and Gynecologists, 1999; Weissman and associates, 2002).

Inevitable Abortion

Gross rupture of the membranes, evidenced by leaking amnionic fluid in the presence of cervical dilatation, signals almost certain abortion. Commonly, either uterine contractions begin

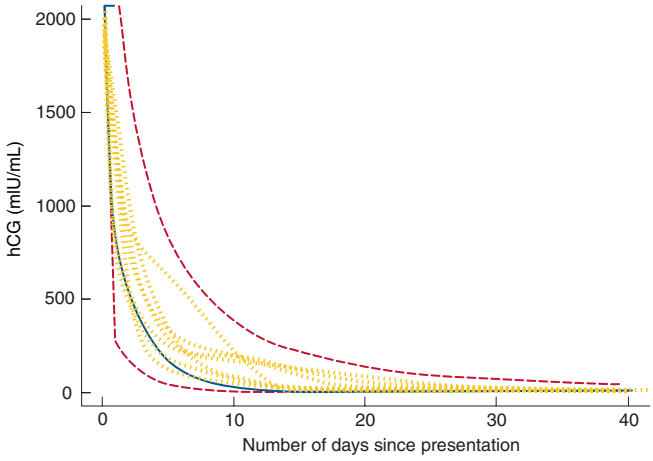

FIGURE 9-4 Composite curve describing decline in serial serum β-hCG values starting at a level of 2000 mIU/mL following early spontaneous miscarriage. The yellow dotted lines are individual patients. The solid blue line is the predicted curve based on the summary of all data, and the two red dashed lines represent the 95-percent confidence intervals. (From Barnhart, 2004a, with permission.)

promptly to cause miscarriage, or infection develops. Rarely, a gush of vaginal fluid during the first half of pregnancy is without serious consequence. If not emanating from the bladder, the fluid may have collected previously between the amnion and chorion. Because of this possibility, if a sudden discharge of fluid in early pregnancy occurs before pain, fever, or bleeding, then diminished activity with observation is reasonable. After 48 hours, if no additional amnionic fluid has escaped and if there is no bleeding, pain, or fever, then a woman may resume her usual activities except for any form of vaginal penetration. If, however, the gush of fluid is accompanied or followed by bleeding, pain, or fever, abortion should be considered inevitable, and the uterus emptied.

Incomplete Abortion

Bleeding ensues when the placenta, in whole or in part, detaches from the uterus. During *incomplete abortion*, the internal cervical os opens and allows passage of blood. The fetus and placenta may remain entirely in utero or may partially extrude through the dilated os. Before 10 weeks, the fetus and placenta are commonly expelled together, but later they are delivered separately. In some women, additional cervical dilatation is necessary before curettage is performed. In many cases, retained placental tissue simply lies loosely in the cervical canal, allowing easy extraction from an exposed external os with ring forceps. Suction curettage, as described later, effectively evacuates the uterus. In clinically stable women, expectant management of an incomplete abortion can also be a reasonable option (Blohm and colleagues, 2003).

Hemorrhage from incomplete abortion of a more advanced pregnancy is occasionally severe but rarely fatal. Therefore, in women with more advanced pregnancies or with heavy bleeding, evacuation is promptly performed. If there is fever, appropriate antibiotics are given before curettage.

Missed Abortion—Early Pregnancy Failure

The term *missed abortion* is contemporaneously imprecise because it was defined many decades before the advent of immunological pregnancy tests and sonography. It was used to describe dead products of conception that were retained for days, weeks, or even months in the uterus with a closed cervical os. Because spontaneous miscarriages are almost always preceded by embryofetal death, most were correctly referred to as "missed." In the typical instance, early pregnancy appears to be normal, with amenorrhea, nausea and vomiting, breast changes, and uterine growth. After embryonic death, there may or may not be vaginal bleeding or other symptoms of threatened abortion.

With sonography, confirmation of an anembryonic gestation or of fetal or embryonic death is possible (**Fig. 9-5**). Many women choose medical or surgical termination at the time of diagnosis. If the pregnancy is not terminated and if miscarriage does not follow for days or weeks, uterine size remains unchanged, and then gradually becomes smaller. Mammary changes usually regress, and women often lose a few pounds. Many women have no symptoms during this period except persistent amenorrhea. If the missed abortion terminates spontaneously, and most do, the process of expulsion is the same as in any abortion.

Septic Abortion

Maternal deaths associated with septic criminal abortions are rare in the United States. Occasionally, however, miscarriage and elective abortion may be complicated by severe infections (Barrett and co-workers, 2002; Fjerstad and associates, 2009). Endomyometritis is the most common manifestation of postabortal infection, but parametritis, peritonitis, septicemia, and even endocarditis occasionally develop (Vartian and Septimus, 1991). Treatment of infection includes prompt administration of intravenous broad-spectrum antibiotics followed by uterine evacuation. With severe sepsis syndrome, acute respiratory syndrome or disseminated intravascular coagulopathy may develop, and supportive care is essential (see Chap. 42, p. 932).

TABLE 9-2. Some Randomized Controlled Studies for Management of Early Pregnancy Loss

Study	Type of Abortion	Treatment Arms	Outcomes
Blohm et al (2005)	"Signs of miscarriage" (n = 126)	1. Placebo 2. PGE_1, 400 μg vaginally	54% completed at 7 days 81% completed at 7 days; more pain, more analgesia
Trinder et al (2006)	Incomplete or missed SAB (n = 1200)	1. Expectant 2. PGE_1, 800 μg vaginally ± 200 mg mifepristone 3. Suction curettage	50% curettage 2% transfusions 38% curettage 1% transfusions 5% repeat curettage
Zhang et al (2005)	Pregnancy failure[a] (n = 652)	1. PGE_1, 800 μg vaginally 2. Vacuum aspiration	71% completed at 3 days; 84% by 8 days;16% failure 97% successful
Weeks et al (2005)	Incomplete SAB (n = 312)	1. PGE_1, 600 μg vaginally 2. Vacuum aspiration	96% success, 1% complications 92% success, 10% complications
Dao et al (2007)	Incomplete SAB (n = 447)	1. PGE_1, 600 μg orally 2. Vacuum aspiration	95% completed 99% completed
Shwekerela et al (2007)	Incomplete SAB (n = 300)	1. PGE_1, 600 μg orally 2. Vacuum aspiration	99% completed 100% completed

[a]Includes anembryonic gestation, embryonic or fetal death, or incomplete or inevitable SAB.
PGE_1 = prostaglandin E_1; SAB = spontaneous abortion

In the past, criminal abortions and neglected incomplete abortions became infected by otherwise nonvirulent vaginal commensural bacteria such as *Clostridium perfringens.* These almost disappeared after abortion was legalized. However, in 2005, the Centers for Disease Control and Prevention reported four deaths associated with medical abortion from toxic shock syndrome caused by *Clostridium sordellii* infection. Fischer and colleagues (2005) detailed these infections and described clinical manifestations that began within 1 week after the medically induced abortion. The hallmark was severe endothelial injury with capillary leakage and hemoconcentration, hypotension, and profound leukocytosis. Since that time, Cohen and associates (2007) reported four other cases—two with *C. sordellii* and two with *C. perfringens*—that developed following spontaneous or induced abortions. Two were fatal. Daif and associates (2009) described a case of necrotizing fasciitis and toxic shock syndrome caused by group A streptococcal infection after elective medical abortion.

Management

With embryofetal death now easy to verify with current sonographic technology, management can be more individualized. Expectant, medical, and surgical management are all reasonable options unless there is serious bleeding or infection. Surgical treatment is definitive and predictable, but is invasive and not necessary for all women. Expectant and medical management may obviate curettage, but are associated with unpredictable bleeding, and some women will need unscheduled surgery. For example, in the observational study of Luise and colleagues (2002), 81 percent of almost 1100 women with suspected first-trimester miscarriage reported spontaneous resolution.

A number of randomized studies have been done to evaluate these methods. In many cases, however, the studies themselves are not comparable because different criteria were used for inclusion, and various protocols were employed. For example, emptying the uterus with medical therapy for early pregnancy failure has a higher success rate in those with vaginal bleeding compared with women with a more "intact" gestation (Creinin and colleagues, 2006). From the studies listed in **Table 9-2**, some generalizations can be made:

1. Success is dependent on the type of early pregnancy failure.
2. With spontaneous incomplete abortion, expectant management results in spontaneous completion in approximately half of cases.
3. For early pregnancy failure, otherwise not further defined, PGE_1 given orally or vaginally is effective in approximately 85 percent for completed abortion within 7 days.
4. Curettage is a quick resolution that is almost 100-percent successful in completing early pregnancy failures.

Thus, there are several management options that can be selected by the woman and her gynecologist. Of course, with dangerous hemorrhage or infection, prompt completion of abortion—either medically or surgically—is warranted.

RECURRENT MISCARRIAGE

This is also referred to as *recurrent spontaneous abortion* and *recurrent pregnancy loss.* It is classically defined as three or more consecutive pregnancy losses at 20 weeks or less or with fetal weights less than 500 grams. Most women with recurrent miscarriage have embryonic or early fetal loss, and the minority of losses are after 14 weeks. Although the definition includes three or more miscarriages, many agree that evaluation should at least be considered following two consecutive losses. This is because the risk of subsequent loss after two successive miscarriages is similar to that following three losses—approximately 30 percent (Harger and associates, 1983). Remarkably, the chance for successful pregnancy may approach 50 percent even after six losses (Poland and co-workers, 1977; Warburton and Fraser, 1964).

Recurrent miscarriage should be distinguished from sporadic pregnancy loss described in the previous section. Sporadic loss implies that intervening pregnancies have resulted in healthy infants. Others distinguish *primary recurrent miscarriage*—no successful pregnancies—from *secondary recurrent miscarriage*—one prior live birth—as the latter group does not reach a risk of subsequent loss of 32 percent until after three miscarriages. Thus, it is reasonable to delay evaluation of secondary recurrent loss until three consecutive losses (Poland and co-workers, 1977).

The causes of recurrent miscarriage parallel those of sporadic miscarriage, although the relative incidence differs between the two categories. For example, first-trimester losses with recurrent miscarriage have a significantly lower incidence of genetic anomalies (Sullivan and colleagues, 2004). In one series, normal karyotypes were identified in half of recurrent miscarriages but only a fourth of sporadic losses. The timing of the pregnancy losses may provide a clue to their cause. By way of another example, genetic factors most frequently result in early embryonic losses, whereas autoimmune or anatomical abnormalities are more likely to result in second-trimester losses (Schust and Hill, 2002).

Parental Chromosomal Abnormalities

Although these account for only 2 to 4 percent of recurrent losses, karyotypic evaluation of both parents remains a critical part of evaluation. Therapel and colleagues (1985) summarized data from 79 studies of couples with two or more miscarriages. These included 8208 women and 7834 men, and chromosomal abnormalities were detected in 2.9 percent—a fivefold greater incidence than for the general population. The ratio of female-to-male abnormalities was approximately 2:1. Balanced reciprocal translocations accounted for 50 percent of identified abnormalities; Robertsonian translocations for 24 percent; X chromosome mosaicism such as 47,XXY—*Klinefelter syndrome*—for 12 percent; and inversions and a variety of other anomalies comprised the remainder. Conversely, Hogge and associates (2007) reported that recurrent pregnancy loss is not associated with skewed X-inactivation—*transcriptional silencing.*

Inheritance of translocation syndromes is discussed in detail in Chapter 12 (p. 273). Briefly, if one parent carries a balanced translocation, the karyotype of a resultant pregnancy may be normal, the same balanced translocation, or an unbalanced translocation. Balanced translocations are likely to cause subsequent recurrent miscarriage in the offspring. An unbalanced translocation may produce a miscarriage, fetal anomaly, or stillbirth. Overall, however, the prognosis is good. Franssen and colleagues (2006) studied 247 couples with a balanced translocation and reported that almost 85 percent had at least one healthy infant. Thus, a history of second-trimester loss or fetal anomaly should raise the suspicion that an abnormal chromosome pattern is present in one parent. Couples with an abnormal karyotype should be offered preimplantation genetic counseling (Chap. 12, p. 301).

Routine karyotyping of products of conception is costly, may not accurately reflect the fetal karyotype, and we do not recommend it. That said, some recommend routine chromosomal analysis following a second consecutive miscarriage (Stephenson, 2006).

Anatomical Factors

A number of genital tract anatomical abnormalities have been implicated in recurrent miscarriage. According to Devi Wold and colleagues (2006), 15 percent of women with three or more consecutive miscarriages have a congenital or acquired uterine anomaly. These essentially are the same as those associated with all miscarriages and are discussed on page 218. They are also discussed in detail in Chapter 40 (p. 890). They include acquired uterine abnormalities such as intrauterine synechiae-*Asherman syndrome*, leiomyomas, and cervical incompetence. Developmental defects include septate, bicornuate, and unicornuate uterus as well as uterine didelphys. Also included are abnormalities associated with in utero exposure to DES.

The frequency of these anomalies in women with recurrent miscarriage varies widely depending on depth of evaluation and criteria set for abnormalcy. Salim and colleagues (2003) described nearly 2500 women who were screened for developmental uterine anomalies using three-dimensional sonography. Anomalies were identified in 24 percent of women with recurrent miscarriage, but in only 5 percent of normal controls. In other studies of women with recurrent miscarriage, the prevalence of uterine anomalies has been estimated to be only 7 to 15 percent (Ashton and co-workers, 1988; Makino and associates, 1992).

Treatment

As discussed on page 218, the evidence is not robust to link these anatomical anomalies with early pregnancy loss. It is therefore difficult to prove that their correction improves pregnancy outcome (American College of Obstetricians and Gynecologists, 2001). There are retrospective studies to support correction with some anomalies. Saygili-Yilmaz and colleagues (2003) reviewed pregnancy outcomes following hysteroscopic metroplasty in women who had a septate uterus and more than two prior miscarriages. In 59 such women, the incidence of miscarriage decreased from 96 to 10 percent following surgery, and term pregnancies increased from none to 70 percent (Saygili-Yilmaz and associates, 2002).

For uterine synechiae, hysteroscopic lysis is preferable to curettage. Katz and colleagues (1996) reported 90 women with synechiae who had at least two prior miscarriages or preterm perinatal deaths or both. With adhesiolysis, miscarriage rates decreased from 79 to 22 percent, and term pregnancies increased from 18 to 69 percent. Other studies have reported similar outcomes (Al-Inany, 2001; Goldenberg and associates, 1995).

As discussed in Chapter 40 (p. 903), it is controversial whether submucous myomas cause recurrent miscarriage more than infrequently. If symptomatic, most agree that submucosal and intracavitary fibroids should be excised. In studies of women undergoing in vitro fertilization, pregnancy outcomes were adversely affected by submucosal myomas, but not by those that were subserosal or intramural and less than 5 to 7 cm (Jun and co-workers, 2001; Ramzy and colleagues, 1998).

Immunological Factors

In their analysis of published studies, Yetman and Kutteh (1996) determined that 15 percent of more than 1000 women with recurrent miscarriage had recognized autoimmune factors. Two primary pathophysiological models are the *autoimmune theory*—immunity against self, and the *alloimmune theory*—immunity against another person.

Autoimmune Factors

Miscarriages are more common in women with systemic lupus erythematosus (Warren and Silver, 2004). Many of these women have antiphospholipid antibodies, which are a family of autoantibodies that bind to negatively charged phospholipids, phospholipids-binding proteins, or a combination of the two (Branch and Khamashta, 2003; Carp and colleagues, 2008). They also are found in women without lupus. Indeed, in up to 5 percent of normal pregnant women, lupus anticoagulant (LAC) and anticardiolipin antibody (ACA) have been linked with excessive pregnancy wastage. Instead of causing miscarriage, they more likely are found with fetal death after midpregnancy. Because of this, fetal death is one criterion for diagnosis of the *antiphospholipid syndrome* (American College of Obstetricians and Gynecologists, 2005a). These are discussed in Chapter 47 (p. 1017) and listed in Table 47-3 (p. 1018). This is the only autoimmune condition that can be correlated with adverse pregnancy outcome. Women with both a history of early fetal loss and high antibody levels may have a 70-percent miscarriage recurrence rate (Dudley and Branch, 1991). Antibodies to β_2-glycoprotein may be especially problematic, but not those to phosphatidyl serine (Alijotas-Reig and colleagues, 2008, 2009).

In a prospective study of 860 women screened for anticardiolipin antibody in the first trimester, Yasuda and colleagues (1995) reported that 7 percent tested positive. Miscarriage developed in 25 percent of the antibody-positive group, compared with only 10 percent of the negative group. In another study, however, Simpson and associates (1998) found no association between early pregnancy loss and the presence of either anticardiolipin antibody or lupus anticoagulant.

Treatment. There are treatment regimens for antiphospholipid syndrome that increase live birth rates. Kutteh (1996) randomized 50 affected women to receive either low-dose aspirin alone or low-dose aspirin plus heparin. Women who received both aspirin and heparin had a significantly greater percentage of viable infants—80 versus 44 percent, respectively. Rai and colleagues (1997) reported a 77-percent live-birth rate in women randomized to be given low-dose aspirin plus low-dose unfractionated heparin therapy—5000 units twice daily—versus 42 percent with aspirin alone. In contrast, Farquharson and associates (2002) reported a 72-percent live-birth rate using low-dose aspirin alone, which was similar to a 78-percent rate in women given low-dose aspirin plus low-dose low-molecular weight heparin.

As emphasized by Branch and Khamashta (2003), the discrepant reports are confusing, and therapeutic guidelines are blurred. The American College of Obstetricians and Gynecologists (2005a) recommends low-dose aspirin—81 mg orally per day, along with unfractionated heparin—5000 units subcutaneously, twice daily. This therapy, begun when pregnancy is diagnosed, is continued until delivery. Although this treatment may improve overall pregnancy success, these women remain at high risk for preterm labor, prematurely ruptured membranes, fetal-growth restriction, preeclampsia, and placental abruption (Backos and colleagues, 1999; Rai and co-workers, 1997).

In addition to IgG and IgM anticardiolipin antibodies, there are antibody idiotypes directed to a large number of lipids (Bick and Baker, 2006). Their measurement is expensive, frequently poorly controlled, and of uncertain relevance in the diagnosis of recurrent miscarriage. Results are likewise inconclusive regarding testing for other antibodies including rheumatoid factor, antinuclear antibodies, and antithyroid antibodies.

Alloimmune Factors

It is suggested that normal pregnancy requires the formation of blocking factors that prevent maternal rejection of foreign fetal antigens that are paternally derived. A woman will not produce these serum blocking factors if she has human leukocyte antigens (HLAs) similar to those of her husband. Other alloimmune disorders have been posited to cause recurrent miscarriage, including altered natural killer (NK) cell activity and increased lymphocytotoxic antibodies. A variety of therapies to correct these disorders have been suggested, including the use of paternal-cell immunization, third-party donor leukocytes, trophoblast membrane infusion, and intravenous immunoglobulin. Most of these have not withstood rigorous scrutiny, some are potentially harmful, and thus we agree with Scott (2003) that immunotherapy cannot be recommended. One possible exception is intravenous immunoglobulin therapy for secondary recurrent miscarriage—women with recurrent early pregnancy losses following one previously successful birth (Hutton and associates, 2007).

Inherited Thrombophilias

These are genetically determined abnormal clotting factors that can cause pathological thrombosis from an imbalance between clotting and anticoagulation pathways. These are discussed in detail in Chapter 47, and their action is shown in Figure 47-1 (p. 1016). The most widely studied include resistance to activated protein C (aPC) caused by the *factor V Leiden mutation* or another; decreased or absent *antithrombin III* activity; the *prothrombin gene* mutation; and mutation in the gene for *methylene tetrahydrofolate reductase* that causes elevated serum levels of homocysteine—hyperhomocysteinemia.

Carp and associates (2002) and Adelberg and Kuller (2002) cast doubt on the importance of inherited thrombophilias in early miscarriage. As placental perfusion is minimal in very early pregnancy, thrombophilias may have greater clinical implications in later pregnancy. In a meta-analysis of 31 studies by Rey and colleagues (2003), recurrent miscarriage was most closely associated with the factor V Leiden and prothrombin gene mutation. The subject was recently reviewed by Kutteh and Triplett (2006) as well as Bick and Baker (2006). After their Cochrane Database review, Kaandorp and co-workers (2009) concluded that women with recurrent miscarriage and thrombophilia do not benefit from aspirin or heparin therapy.

Endocrinological Factors

Studies evaluating the relationship between various endocrinological abnormalities have been inconsistent and have generally been underpowered (American College of Obstetricians and Gynecologists, 2001). According to Arredondo and Noble (2006), 8 to 12 percent of recurrent miscarriages are the result of endocrine factors.

Progesterone Deficiency

Also termed *luteal phase defect*, insufficient progesterone secretion by the corpus luteum or placenta has been suggested to cause miscarriage. Deficient progesterone production, however, may be the consequence rather than the cause of early pregnancy failure (Salem and associates, 1984). Diagnostic criteria and efficacy of therapy for this proposed disorder require validation (American College of Obstetricians and Gynecologists, 2001). If the corpus luteum is removed surgically, such as for an ovarian tumor, progesterone replacement is indicated in pregnancies less than 8 to 10 weeks (p. 218).

Polycystic Ovarian Syndrome

Because of oligo- or anovulation, these women are subfertile. When pregnant, there also may be an increased risk for miscarriage, but this is controversial (Cocksedge and associates, 2008). Two possible mechanisms that have been suggested are elevations in luteinizing hormone (LH) and direct effects of hyperinsulinemia on ovarian function. If the elevated LH concentration causes miscarriage, then its inhibition during a gonadotropin ovulation induction cycle might decrease miscarriage rates. In the controlled trial by Clifford and co-workers (1996), however, this did not improve pregnancy outcome. The data implicating hyperinsulinemia in pregnancy loss are somewhat stronger. In two studies, miscarriage rates were decreased with metformin treatment before and during pregnancy (Glueck and associates, 2002; Jakubowicz and colleagues, 2002). Continuing metformin throughout pregnancy has been shown to also significantly reduce the incidence of insulin-requiring gestational diabetes as well as fetal-growth restriction.

Diabetes Mellitus

Spontaneous abortion and major congenital malformation rates are both increased in women with insulin-dependent diabetes (see Chap. 7, p. 175). This risk is also related to the degree of metabolic control in early pregnancy. Similar to women with polycystic ovary syndrome, some women with recurrent miscarriage have been reported to have increased insulin resistance (Craig and associates, 2002). Pregnancy loss from poorly controlled diabetes is substantively lowered with optimal metabolic control (see Chap. 52. p. 1114).

Hypothyroidism

Severe iodine deficiency is associated with excessive early pregnancy loss (p. 217). Thyroid hormone deficiency from an autoimmune cause is common in women, but any effects it has on miscarriage have not been adequately studied. And although thyroid autoantibodies are associated with an increased incidence of spontaneous abortion, their role in recurrent miscarriage is less convincing (Abramson and Stagnaro-Green, 2001; Lakasing and Williamson, 2005). In a study of 870 women with recurrent miscarriage, Rushworth and colleagues (2000) reported that those with antithyroid antibodies were just as likely to achieve a live birth as those without antibodies.

Because it is not clear that thyroid disease causes recurrent miscarriage, the American College of Obstetricians and Gynecologists (2001) concludes that there is no indication for screening asymptomatic women. Conversely, overt hypothyroidism may be difficult to detect clinically, testing is inexpensive, and treatment is highly effective. Thus, we recommend thyroid-stimulating hormone (TSH) screening for women with recurrent miscarriage.

Infections

Very few infections are firmly proven to cause early pregnancy loss (p. 217). Moreover, if any of those infections are associated with miscarriage, they are even less likely to cause recurrent miscarriage because maternal antibodies usually develop with the primary infection.

Evaluation and Management

The timing and extent of evaluation of women with recurrent miscarriage is based on maternal age, coexistent infertility, symptoms, and the level of anxiety. With otherwise normal findings, we perform a modicum of tests to include parental karyotyping, uterine cavity evaluation, and testing for antiphospholipid antibody syndrome. Approximately half of couples with recurrent miscarriage will have no explanatory findings. Nevertheless, their prognosis is reasonable. The meta-analysis by Jeng and colleagues (1995) of randomized, prospective studies of couples with unexplained recurrent miscarriage determined that 60 to 70 percent had a successful subsequent pregnancy with no treatment.

INDUCED ABORTION

An induced abortion is the medical or surgical termination of pregnancy before the time of fetal viability. In 2005, a total of 1.22 million legal abortions were reported to the Centers for Disease Control and Prevention (Gamble and colleagues, 2008). The total has decreased each year since 2002, but this at least partially results from clinics inconsistently reporting

medically induced abortions (Strauss and colleagues, 2007). The *abortion ratio* was 238 abortions per 1000 live births, and the *abortion rate* was 16 per 1000 women aged 15 to 44 years. Half of these women were 24 years or younger, 80 percent were unmarried, and 53 percent were Caucasian. Approximately 60 percent of abortions were performed during the first 8 weeks, and 88 percent during the first 12 weeks of pregnancy.

Classification

Therapeutic Abortion

There are a number of diverse medical and surgical disorders that are indications for termination of pregnancy. Examples include persistent cardiac decompensation, especially with fixed pulmonary hypertension, advanced hypertensive vascular disease or diabetes, and malignancy. In cases of rape or incest, most consider termination reasonable. The most common indication currently is to prevent birth of a fetus with a significant anatomical, metabolic, or mental deformity. The seriousness of fetal deformities is wide ranging and frequently defies social, legal, or political classification.

Elective (Voluntary) Abortion

The interruption of pregnancy before viability at the request of the woman, but not for medical reasons, is usually termed *elective* or *voluntary abortion*. These procedures comprise most abortions done today, and according to the National Vital Statistics Reports, approximately one pregnancy is electively terminated for every four live births in the United States (Ventura and colleagues, 2008). The Executive Board of the American College of Obstetricians and Gynecologists (2004) supports the legal right of women to obtain an abortion prior to fetal viability and considers this a medical matter between a woman and her physician.

Abortion in the United States

In 1973, the United States Supreme Court legalized abortion. Until then, only therapeutic abortions could be performed legally in most states. The most common legal definition of therapeutic abortion until then was termination of pregnancy before fetal viability for the purpose of saving the life of the mother. A few states extended their laws to read "to prevent serious or permanent bodily injury to the mother" or "to preserve the life or health of the woman." Some states allowed abortion if a pregnancy was likely to result in the birth of an infant with grave malformations.

The legality of elective abortion was established by the Supreme Court in the case of *Roe v. Wade*. The Court defined the extent to which states might regulate abortion:

1. For the stage prior to approximately the end of the first trimester, the abortion decision and the procedure must be left to the medical judgment of the attending physician.
2. For the stage subsequent to approximately the end of the first trimester, the State, in promoting its interest in the health of the mother, may, if it chooses, regulate the abortion procedures in ways that are reasonably related to maternal health.
3. For the stage subsequent to viability, the State, in promoting its interest in the potential of human life, may, if it chooses, regulate, and even proscribe abortion, except where necessary, in appropriate medical judgment, for the preservation of the life or health of the mother.

Since 1973, several other Supreme Court decisions merit citation. Borgmann and Jones (2000) have extensively reviewed these legal issues. These appellate cases originated with legislation, both state and national, that was introduced or enacted to regulate or dismantle the three provisions listed above. In general, these attempts were unsuccessful until 1989. At that time, the Supreme Court ruled in the case of *Webster v. Reproductive Health Services* that states could place restrictions interfering with provision of abortion services on such items as waiting periods, specific informed consent requirements, parental/spousal notification, and hospital requirements. Based upon this decision, there are now numerous individual state restrictions that limit choice and access to abortion services. In one example, the decision to enforce parental notification in Texas in 2000 was associated with decreased abortion rates but simultaneously increased unintended births among 17-year-olds (Joyce and associates, 2006).

Another recent choice-limiting decision is the federal law banning the poorly defined *partial birth abortion*. This law is under challenge on several fronts. The Supreme Court in 2007 voted 5 to 4 to uphold the Partial-Birth Abortion Ban Act of 2003 in its review of *Gonzales v. Carhart* from Nebraska. This was followed by editorials in the *New England Journal of Medicine* lamenting more governmental intrusion into medical practice as well as "chipping away at women's rights" described by Justice Ginsburg in her dissenting opinion (Charo, 2007; Greene, 2007). Their opinions are in line with that of the American College of Obstetricians and Gynecologists (2004) that states: *The intervention of legislative bodies into medical decision making is inappropriate, ill advised, and dangerous.*

Counseling before Elective Abortion

Three choices available to a woman considering an abortion include continued pregnancy with its risks and parental responsibilities; continued pregnancy with its risks and responsibilities of arranged adoption; or the choice of abortion with its risks. Knowledgeable and compassionate counselors should objectively describe and provide information about these choices so that a woman or couple can make an informed decision.

Techniques for Early Abortion

Abortion can be performed either medically or surgically by several techniques shown in **Table 9-3**. Distinctive clinical features of each technique are shown in **Table 9-4**. Paul and colleagues (1999) summarized in detail many abortion techniques. A first-trimester pregnancy may be removed surgically by uterine curettage or by a number of medical regimens.

TABLE 9-3. Abortion Techniques

Surgical Techniques
- Cervical dilatation followed by uterine evacuation
  - Curettage
  - Vacuum aspiration (suction curettage)
  - Dilatation and evacuation (D&E)
  - Dilatation and extraction (D&X)
- Menstrual aspiration
- Laparotomy
  - Hysterotomy
  - Hysterectomy

Medical Techniques
- Intravenous oxytocin
- Intra-amnionic hyperosmotic fluid
  - 20-percent saline
  - 30-percent urea
- Prostaglandins E_2, $F_{2\alpha}$, E_1, and analogues
  - Intra-amnionic injection
  - Extraovular injection
  - Vaginal insertion
  - Parenteral injection
  - Oral ingestion
- Antiprogesterones—RU 486 (mifepristone) and epostane
- Methotrexate—intramuscular and oral
- Various combinations of the above

Residency Training in Abortion Techniques

Because of its inherent controversial aspects, abortion training for residents in obstetrics and gynecology has been both championed and assailed. The American College of Obstetricians and Gynecologists (2009) supports abortion training for residents. In some programs, such as the University of California at San Francisco, a special 6-week abortion-training elective for housestaff was implemented in 1980. From 1998 through 2003, 40 residents completed training and none opted out of the rotation (Steinauer and co-workers, 2005b). Other programs, such as ours at Parkland Memorial Hospital, teach residents the technical aspects of abortion by management of early missed abortions as well as pregnancy interruption for fetal death, severe fetal anomalies, and maternal medical or surgical disorders. According to Eastwood and colleagues (2006), only 10 percent of programs provide no training in elective abortion.

Because of these differences, influenced by political and moral convictions, the American College of Obstetricians and Gynecologists (2004) respects the need and responsibility of healthcare providers to determine their individual positions based on personal beliefs. Certainly, physicians trained to care for women must be familiar with various abortion techniques so that complications can be managed or referrals made for suitable care (Steinauer and associates, 2005a).

Surgical Abortion

A pregnancy may be removed surgically through an appropriately dilated cervix or transabdominally by either hysterotomy or hysterectomy. In the absence of maternal systemic disease, abortion procedures do not require hospitalization. When abortion is performed outside a hospital setting, capabilities for cardiopulmonary resuscitation and for immediate transfer to a hospital must be available.

Dilatation and Curettage (D&C)

Transcervical approaches to surgical abortion require first dilating the cervix and then evacuating the pregnancy by mechanically scraping out the contents—sharp curettage, by suctioning out the contents—suction curettage, or both. Vacuum aspiration, the most common form of suction curettage, requires a rigid cannula attached to an electric-powered vacuum source (MacIsaac and Darney, 2000; Masch and Roman, 2005). Alternatively, manual vacuum aspiration uses a similar cannula that attaches to a handheld syringe for its vacuum source (Goldberg and associates, 2004). The likelihood of complications increases after the first trimester. These include uterine perforation, cervical laceration, hemorrhage, incomplete removal of the fetus and placenta, and infections. Accordingly, sharp or suction curettage should be performed before 14 to 15 weeks.

Evidence supports that antimicrobial prophylaxis should be provided to all women undergoing a transcervical surgical abortion. Based on their review of 11 randomized trials, Sawaya and associates (1996) concluded that antimicrobials decreased the risk of infection by approximately 40 percent. No one regimen

TABLE 9-4. Features of Medical and Surgical Abortion

Medical Abortion	Surgical Abortion
Usually avoids invasive procedure	Involves invasive procedure
Usually avoids anesthesia	Allows use of sedation if desired
Requires two or more visits	Usually requires one visit
Days to weeks to complete	Complete in a predictable period of time
Available during early pregnancy	Available during early pregnancy
High success rate (~95 percent)	High success rate (99 percent)
Bleeding moderate to heavy for short time	Bleeding commonly perceived as light
Requires follow-up to ensure completion of abortion	Does not require follow-up in all cases
Requires patient participation throughout a multistep process	Patient participation in a single-step process

Reprinted, with permission, from American College of Obstetricians and Gynecologists. Medical management of abortion. ACOG Practice Bulletin 67. Washington, DC: ACOG; 2005

appears superior. One convenient, inexpensive, and effective regimen is doxycycline, 100 mg orally twice daily for 7 days (Fjerstad and associates, 2009).

Dilatation and Evacuation (D&E)

Beginning at 16 weeks, fetal size and structure dictate use of this technique. Wide mechanical cervical dilatation, achieved with metal or hygroscopic dilators, precedes mechanical destruction and evacuation of fetal parts. With complete removal of the fetus, a large-bore vacuum curette is used to remove the placenta and remaining tissue.

Dilatation and Extraction (D&X)

This is similar to dilatation and evacuation except that suction evacuation of the intracranial contents after delivery of the fetal body through the dilated cervix aids extraction and minimizes uterine or cervical injury from instruments or fetal bones. In political parlance, this procedure has been termed *partial birth abortion,* discussed on page 227.

Hygroscopic Dilators. Trauma from mechanical dilatation can be minimized by using devices that slowly dilate the cervix (Fig. 9-6). These devices, called *hygroscopic dilators*, draw water from cervical tissues and expand, gradually dilating the cervix. One type of hygroscopic dilators originates from the stems of *Laminaria digitata* or *Laminaria japonica*, a brown seaweed. The stems are cut, peeled, shaped, dried, sterilized, and packaged according to size-small, 3 to 5 mm in diameter; medium, 6 to 8 mm; and large, 8 to 10 mm. The strongly hygroscopic laminaria presumably act by drawing water from proteoglycan complexes, causing the complexes to dissociate, and thereby allowing the cervix to soften and dilate.

Synthetic hygroscopic dilators, such as Lamicel and Dilapan-S, are also available. Lamicel is a slender, rod-shaped polyvinyl acetal sponge impregnated with anhydrous magnesium sulfate. Dilapan-S is an acrylic-based hydrogel rod. In 1995, Dilapan was removed from the U.S. market because of concerns over device fragmentation. It was reintroduced following Food and Drug Administration approval of a new device design (Food and Drug Administration, 2008).

To insert hygroscopic dilators, the cervix is cleansed with povidone-iodine solution and is grasped anteriorly with a tenaculum. A hygroscopic dilator of the appropriate size is then inserted using a uterine packing forceps so that the tip rests at the level of the internal os (see Fig. 9-6). After 4 to 6 hours, the laminaria will have swollen and dilated the cervix sufficiently to allow easier mechanical dilatation and curettage. Cramping frequently accompanies expansion of the laminaria.

An interesting dilemma is presented by the woman who has a hygroscopic dilator placed overnight in preparation for elective abortion, but who then changes her mind. Schneider and associates (1991) described this in first-trimester and 14 second-trimester pregnancies. Four patients returned to their original decision and aborted their pregnancies. Of the remaining 17, there were 14 term deliveries, two preterm deliveries, and one spontaneous abortion 2 weeks later. None of the women suffered infectious morbidity, including three untreated women whose cervical cultures were positive for chlamydia. In spite of this generally reassuring report, an attitude of irrevocability with regard to dilator placement and abortion seems prudent.

Prostaglandins. As an alternative to hygroscopic dilators, various prostaglandin preparations may be placed into the posterior vaginal fornix to aid subsequent dilatation. MacIsaac and colleagues (1999) randomized women to receive 400 μg of misoprostol placed vaginally 4 hours before first-trimester abortion versus laminaria placement. Misoprostol effected equal or greater dilatation, caused less pain on insertion, and produced similar side effects. It is important to emphasize that this 400-μg dose is far in excess of oral or vaginal dosing for labor induction (see Chap. 22, p. 503).

Technique for Dilatation and Curettage

After bimanual examination is performed to determine the size and orientation of the uterus, a speculum is inserted, and the cervix is swabbed with povidone-iodine or equivalent solution. The anterior cervical lip is grasped with a toothed tenaculum. The cervix, vagina, and uterus are richly supplied by nerves of Frankenhäuser plexus, which lies within connective tissue lateral to the

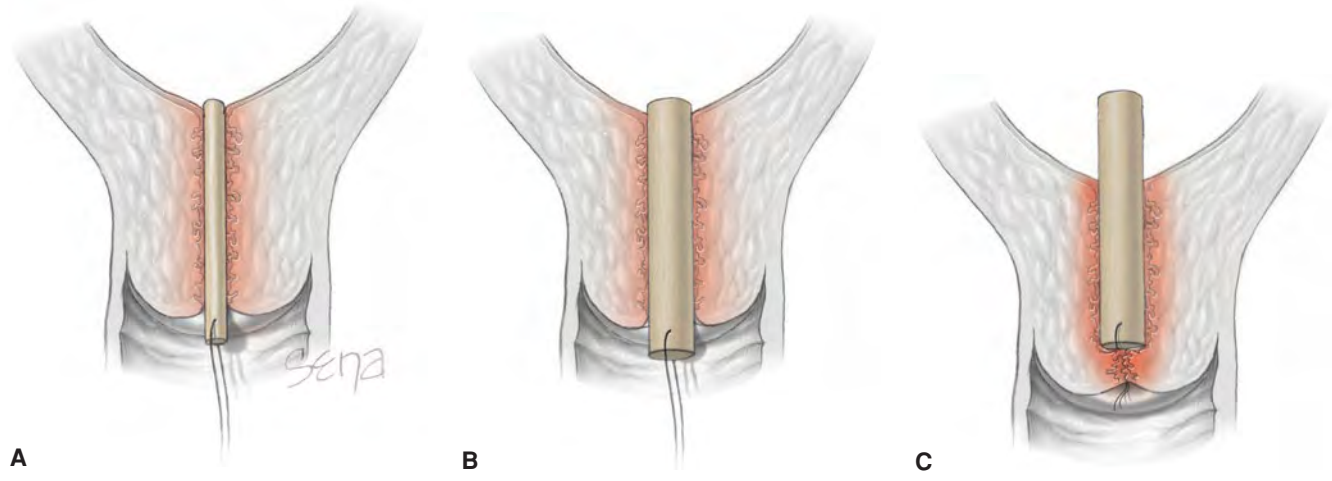

FIGURE 9-6 Insertion of laminaria prior to dilatation and curettage. **A.** Laminaria immediately after being appropriately placed with its upper end just through the internal os. **B.** Several hours later the laminaria is now swollen, and the cervix is dilated and softened. **C.** Laminaria inserted too far through the internal os; the laminaria may rupture the membranes.

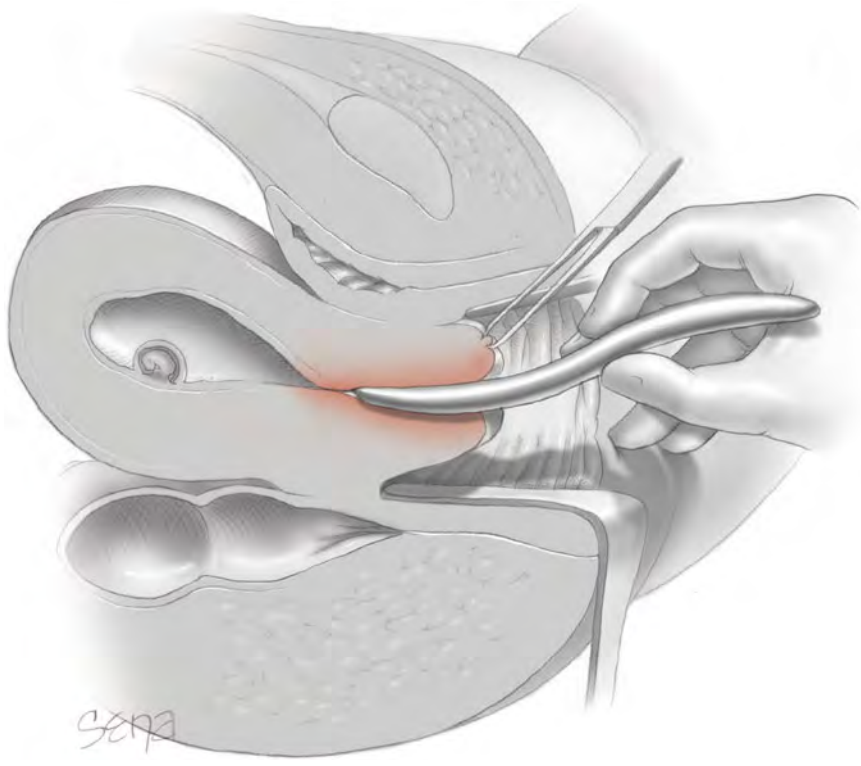

FIGURE 9-7 Dilatation of cervix with a Hegar dilator. Note that the fourth and fifth fingers rest against the perineum and buttocks, lateral to the vagina. This maneuver is an important safety measure because if the cervix relaxes abruptly, these fingers prevent a sudden and uncontrolled thrust of the dilator, a common cause of uterine perforation.

uterosacral ligaments. Thus, paracervical injections are most effective if placed immediately lateral to the insertion of the uterosacral ligaments into the uterus. A local anesthetic, such as 5 mL of 1 or 2-percent lidocaine, may be injected at 4 and 8 o'clock at the cervical base. Mankowski and associates (2009) reported that an intracervical block with 5-mL aliquots of 1-percent lidocaine injected at 12, 3, 6, and 9 o'clock were equally as effective. Dilute vasopressin may be added to the local anesthetic to decrease blood loss (Keder, 2003).

If required, the cervix is further dilated with Hegar, Hank, or Pratt dilators until a suction cannula of the appropriate diameter can be inserted. Choosing the most appropriately sized cannula balances competing factors: small cannulas carry the risk of retained intrauterine tissue postoperatively, whereas large cannulas risk cervical injury and more discomfort. The fourth and fifth fingers of the hand introducing the dilator should rest on the perineum and buttocks as the dilator is pushed through the internal os (Fig. 9-7). This technique minimizes forceful dilatation and provides a safeguard against uterine perforation. Uterine sounding measures the depth and inclination of the uterine cavity prior to cannula insertion. The suction cannula is moved toward the fundus and then back toward the os and is turned circumferentially to cover the entire surface of the uterine cavity (Fig. 9-8). When no more tissue is aspirated, a gentle sharp curettage should follow to remove any remaining placental or fetal fragments (Fig. 9-9).

Because the uterus is characteristically perforated on the insertion of any instrument, manipulations should be carried out with the thumb and forefinger only (Fig. 9-7). If beyond 16 weeks' gestation, the fetus is extracted, usually in parts, using Sopher forceps and other destructive instruments. Risks include uterine perforation, cervical laceration, and uterine bleeding due to the larger fetus and placenta and to the thinner uterine walls. Morbidity can be minimized if: (1) the cervix is adequately dilated before attempting to remove the products of conception, (2) instruments are introduced into the uterus and manipulated without force, and (3) all tissue is removed.

Complications. The incidence of uterine perforation associated with dilatation and curettage for elective abortion varies. Two important determinants are the skill of the clinician and the position of the uterus. The likelihood of perforation is greater if the uterus is retroverted. Accidental uterine perforation usually is recognized easily when the instrument passes without resistance deep into the pelvis. Observation may be sufficient if the uterine perforation is small, as when produced by a uterine sound or narrow dilator.

Although possible, Chen and colleagues (2008) reported no uterine scar separation in 78 women with prior cesarean delivery or myomectomy who then underwent medical or surgical abortion for early pregnancy failure.

Considerable intra-abdominal damage can be caused by instruments, especially suction and sharp curettes, passed through a uterine defect into the peritoneal cavity (Keegan and Forkowitz, 1982). In this circumstance, laparotomy to examine the abdominal contents is often the safest course of action. Depending on the circumstances, laparoscopy may be substituted. Unrecognized bowel injury can cause severe peritonitis and sepsis (Kambiss and associates, 2000).

Some women may develop cervical incompetence or uterine synechiae following dilatation and curettage. Rarely, abortion performed by curettage on more advanced pregnancies may induce sudden, severe consumptive coagulopathy, which can prove fatal. Those contemplating abortion should understand the potential for these rare but serious complications.

If prophylactic antimicrobials are given as described on page 228, pelvic sepsis is decreased by 40 to 90 percent, depending whether the procedure is surgical or medical. Most infections that develop respond readily to appropriate antimicrobial treatment (see Chap. 31, p. 662). Rarely, infections such as bacterial endocarditis will develop, but they can be fatal (Jeppson and associates, 2008).

Menstrual Aspiration

Aspiration of the endometrial cavity can be completed using a flexible 5- or 6-mm Karman cannula that is attached to a

syringe. When completed within 1 to 3 weeks after a missed menstrual period, this has been referred to as *menstrual extraction, menstrual induction, instant period, traumatic abortion, and mini-abortion.* At this early stage of gestation, pregnancy can be misdiagnosed, an implanted zygote can be missed by the curette, ectopic pregnancy can be unrecognized, or infrequently, a uterus can be perforated. Even so, Paul and associates (2002) reported a 98-percent success rate in more than 1000 women who underwent this procedure. A positive pregnancy test result will eliminate a needless procedure on a nonpregnant woman whose period has been delayed for other reasons.

To identify placenta in the aspirate, MacIsaac and Darney (2000) recommend that the syringe contents be rinsed in a strainer to remove blood, then placed in a clear plastic container with saline, and examined with back lighting. Placental tissue macroscopically appears soft, fluffy, and feathery. A magnifying lens, colposcope, or microscope also can improve visualization.

Manual Vacuum Aspiration

This office-based procedure is similar to menstrual aspiration but is used for early pregnancy failures as well as elective termination up to 12 weeks. Masch and Roman (2005) recommend that pregnancy terminations in the office with this method be limited to 10 weeks or less. Certainly, blood loss rises sharply between 10 and 12 weeks (Westfall and colleagues, 1998).

The procedure uses a hand-operated 60-mL syringe and cannula. A vacuum is created in the syringe and attached to the cannula, which is inserted transcervically into the uterus. The vacuum is activated and produces up to 60 mm Hg suction. Although complications are similar to other surgical methods, they are not increased (Goldberg and associates, 2004).

With pregnancies less than 8 weeks, no cervical preparation is required. After this time, some recommend either osmotic dilators placed the day before or misoprostol given 2 to 4 hours before the procedure. A paracervical block, with or without intravenous sedation, or conscious sedation is used for anesthesia.

Laparotomy

In a few circumstances, abdominal hysterotomy or hysterectomy for abortion is preferable to either curettage or medical

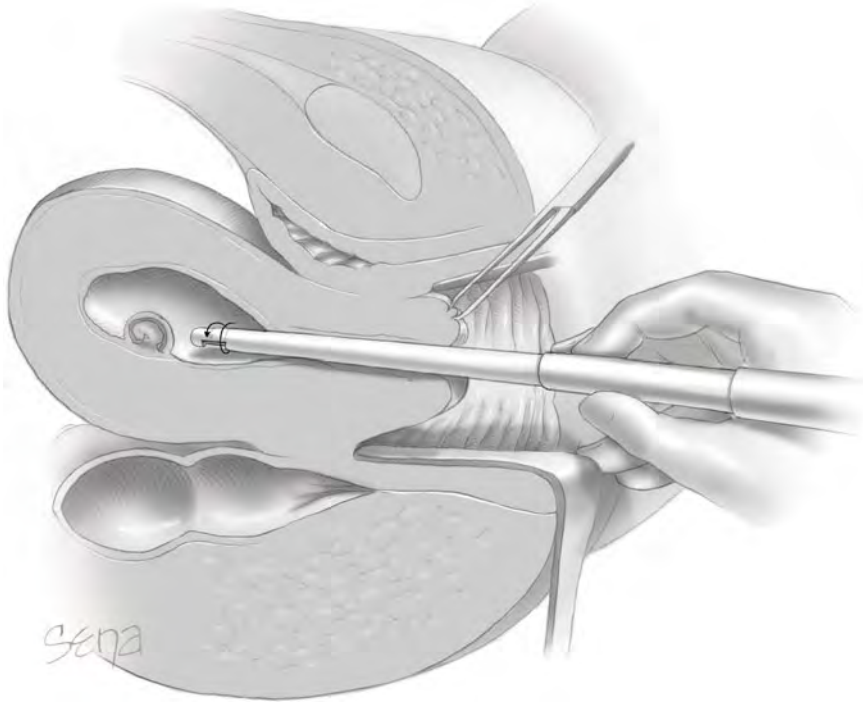

FIGURE 9-8 A suction curette is advanced to the uterine fundus and then back to the internal os. During its insertion and retraction, the curette is simultaneously rotated 360° several times to remove tissue circumferentially from the uterine walls.

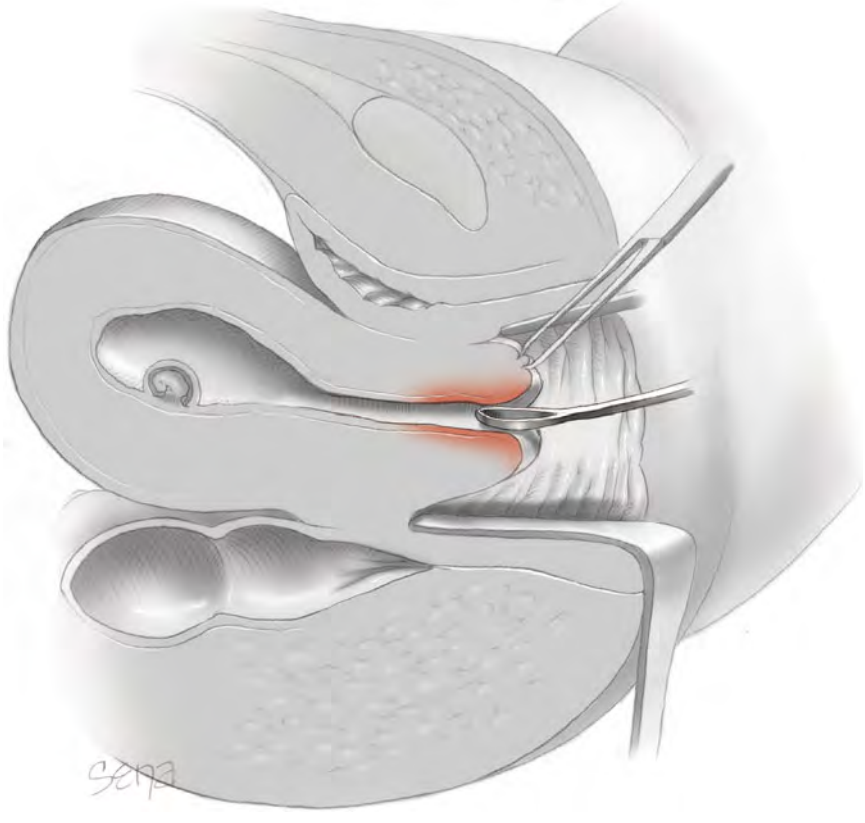

FIGURE 9-9 Introduction of a sharp curette. The instrument is held with the thumb and forefinger. In the upward movement of the curette, only the strength of these two fingers should be used.

induction. If significant uterine disease is present, hysterectomy may provide ideal treatment. Either hysterotomy with tubal ligation or on occasion, hysterectomy may be indicated for women who desire pregnancy termination and sterilization. At times, a failed medical induction during the second trimester may necessitate hysterotomy or hysterectomy.

Medical Abortion

Throughout history, many naturally occurring substances have been tried as abortifacients. In many cases, serious systemic illness or even death has resulted rather than abortion. Even today, only a few effective, safe abortifacient drugs are used.

According to the American College of Obstetricians and Gynecologists (2005b), outpatient medical abortion is an acceptable alternative to surgical abortion in appropriately selected women with pregnancies less than 49 days menstrual age. Beyond this point, the available data, although less robust, support surgical abortion as a preferable method of early abortion.

Three medications for early medical abortion have been widely studied and used: the antiprogestin *mifepristone*; the antimetabolite *methotrexate*; and the prostaglandin *misoprostol*. These agents cause abortion by increasing uterine contractility either by reversing the progesterone-induced inhibition of contractions—mifepristone and methotrexate or by stimulating the myometrium directly—misoprostol. In addition, mifepristone causes cervical collagen degradation, possibly because of increased expression of matrix metalloproteinase-2 (Clark and associates, 2006).

A variety of dosing schemes that have been proven effective are shown in Table 9-5. Mifepristone or methotrexate are administered initially, and followed after a specified time by misoprostol. Guest and associates (2007) randomized 450 women to be given 200 mg mifepristone orally followed by 800 μg misoprostol vaginally either 6 hours later or 36 to 48 hours later. When given at 36 to 48 hours, the success rate was 96 percent compared with 89 percent for the 6-hour group ($p < .05$). As discussed on page 223, at least for "pregnancy failures"—anembryonic gestation, embryonic or fetal death, and incomplete or inevitable abortion—800 μg misoprostol given vaginally as a sole agent was effective in causing complete expulsion by day 8 in 84-percent of women treated (Zhang and colleagues, 2005). Recently, Fjerstad and associates (2009) compared septic complications in more than 225,000 women undergoing a medical abortion. After changing the route of administration from vaginal to buccal misoprostol, along with providing 7-day postprocedure doxycycline prophylaxis, they documented a 93-percent decreased serious infection rate—from 0.93 per 1000 to 0.06 per 1000. Finally, both methotrexate and misoprostol are teratogens, and their use thus requires a commitment on the part of both a woman and her caregiver to complete the abortion.

Contraindications to medical abortion have evolved from the exclusion criteria of various medical abortion trials. In addition to specific allergies to the medicines, they have included an in situ intrauterine device, severe anemia, coagulopathy or anticoagulant use, and significant medical conditions such as active liver disease, cardiovascular disease, and uncontrolled seizure disorders. Additionally, because misoprostol can lower glucocorticoid activity, women with adrenal disease or with disorders requiring glucocorticoid therapy should be excluded (American College of Obstetricians and Gynecologists, 2005b). A modified methotrexate dose should be given with caution—if at all—in women with renal insufficiency (Kelly and associates, 2006). Women contemplating medical abortion should receive thorough counseling of both medical and surgical approaches.

TABLE 9-5. Regimens for Medical Termination of Early Pregnancy

Mifepristone/Misoprostol

[a]Mifepristone, 100-600 mg orally followed by:
[b]Misoprostol, 200-600 μg orally or 800 μg vaginally in multiple doses over 6-72 hours.

Methotrexate/Misoprostol

[c]Methotrexate, 50 mg/m^2 intramuscularly or orally followed by:
[d]Misoprostol, 800 μg vaginally in 3-7 days. Repeat if needed 1 week after methotrexate initially given.

Misoprostol alone

800 μg vaginally, repeated for up to three doses.

[a]Doses of 200 versus 600 mg similarly effective.
[b]Oral route may be less effective and with more nausea and diarrhea. May be given sublingually, or buccally. Postprocedure pelvic infection significantly higher with vaginal versus oral route. Possibly more effective when given at 36-48 hours instead of at 6 hours.
[c]Efficacy similar for routes of administration.
[d]Similar efficacy when given on day 3 versus day 5.
Data from the American College of Obstetricians and Gynecologists (2005); Borgatta (2001); Bracken (2007); Chen (2008); Creinin (2001, 2007); Fjerstad (2009); Guest (2007); Hamoda (2005); Schaff (2000); Shannon (2006); von Hertzen (2007); Wiebe (1999, 2002); Winikoff (2008), and all their colleagues.

With the mifepristone regimen, according to the package labeling, misoprostol is to be provider administered. Afterwards the woman typically remains in the office for 4 hours, and if the pregnancy appears to have been expelled, she is examined to confirm expulsion. If during observation, the pregnancy does not appear to have been expelled, a pelvic examination is performed prior to discharge, and the woman is reappointed for 1 to 2 weeks. At this later appointment, if clinical examination or sonographic evaluation fails to confirm completed abortion, a suction procedure usually is done.

In regimens employing methotrexate, women are typically seen at least 24 hours after misoprostol, and approximately 7 days after methotrexate administration, at which time a sonographic examination is performed. If the pregnancy persists, another dose of misoprostol is given, and the woman is seen again in 1 week if fetal cardiac activity is present or in 4 weeks if there is no fetal cardiac activity. If by the second visit, abortion has not occurred, it is usually completed by suction curettage.

Bleeding and cramping with medical termination can be significantly worse than symptoms experienced with menses. Adequate pain medication, usually including a narcotic, should be provided. According to the American College of Obstetricians and Gynecologists (2005b), soaking two pads or more per hour

for at least 2 hours is a threshold at which the woman should be instructed to contact her provider, who can determine whether she needs to be seen.

Early medical abortion is highly effective—90 to 98 percent of women will not require surgical intervention (Kahn and co-workers, 2000). According to Hausknecht (2003), there were only 139 complications reported to the manufacturer with mifepristone when given with misoprostol to 80,000 women for medical abortion.

Unnecessary surgical intervention in women undergoing medical abortion can be avoided if sonographic results are interpreted appropriately. Specifically, if no gestational sac is present, in the absence of heavy bleeding, intervention in most women is unnecessary. This is true even when, as is common, the uterus contains sonographically evident debris.

Second-Trimester Abortion

Invasive means of second-trimester medical abortion have long been available, and some are listed in Table 9-3. In the past 25 years, however, the ability to safely and effectively accomplish noninvasive second-trimester abortion has evolved considerably. Principal among these noninvasive methods are high-dose intravenous oxytocin and vaginal prostaglandin administration, including prostaglandin E_2 suppositories and prostaglandin E_1 (misoprostol) pills. Regardless of method, hygroscopic dilator placement as shown in Figure 9-6 will shorten the duration (Goldberg and colleagues, 2005).

Oxytocin

Given as a single agent in high doses, oxytocin will effect second-trimester abortion in 80 to 90 percent of cases. For more than 15 years, the regimen shown in Table 9-6 has been used with a high degree of safety and effectiveness at the University of Alabama. By mixing the oxytocin in an isotonic solution such as normal saline, and avoiding excessive administration of dilute intravenous solutions, we have not observed hyponatremia or water intoxication.

TABLE 9-6. Concentrated Oxytocin Protocol for Mid-trimester Abortion

50 units oxytocin in 500 mL of normal saline infused over 3 hr; 1-hr diuresis (no oxytocin)
100 units oxytocin in 500 mL of normal saline infused over 3 hr; 1-hr diuresis (no oxytocin)
150 units oxytocin in 500 mL of normal saline infused over 3 hr; 1-hr diuresis (no oxytocin)
200 units oxytocin in 500 mL of normal saline infused over 3 hr; 1-hr diuresis (no oxytocin)
250 units oxytocin in 500 mL of normal saline infused over 3 hr; 1-hr diuresis (no oxytocin)
300 units oxytocin in 500 mL of normal saline infused over 3 hr; 1-hr diuresis (no oxytocin)

Modified from Ramsey and Owen (2000), with permission

Prostaglandin E_2

Suppositories of 20 mg prostaglandin E_2 placed in the posterior vaginal fornix are a simple and effective means of effecting second-trimester abortion. This method is not more effective than high-dose oxytocin, and it causes more frequent side effects such as nausea, vomiting, fever, and diarrhea (Owen and associates, 1992). If prostaglandin E_2 is used, an antiemetic such as metoclopramide, an antipyretic such as acetaminophen, and an antidiarrheal such as diphenoxylate/atropine are given either to prevent or to treat symptoms.

Prostaglandin E_1

Misoprostol can be used easily and inexpensively as a single agent for second-trimester pregnancy termination. In their randomized trial, Ramsey and co-workers (2004) administered misoprostol, 600 μg vaginally followed by 400 μg every 4 hours. They reported that this effected abortion significantly faster than concentrated oxytocin given in combination with prostaglandin E_2—median time to abortion 12 versus 17 hours, respectively. Misoprostol achieved abortion within 24 hours in 95 percent of women compared with 85 percent in the other group. Importantly, only 2 percent of women in the misoprostol group required curettage for retained placenta compared with 15 percent in the oxytocin/prostaglandin E_2 group. Kapp and co-workers (2007) reported that mifepristone, 200 mg given 1 day before misoprostol, reduced median time to expulsion from 18 to 10 hours compared with a placebo group.

The outcome of medically induced second-trimester abortion after a previous cesarean delivery has been the subject of several reports. Although some early reports were discouraging, recent evidence is not so pessimistic. Systematic reviews by Berghella and colleagues (2009) as well as Goyal (2009) found that the risk of uterine rupture in these women given misoprostol was only about 0.3 to 0.4 percent

Consequences of Elective Abortion

Maternal Mortality

Legally induced abortion, performed by trained gynecologists, especially when performed during the first 2 months of pregnancy, has a mortality rate of less than 1 per 100,000 procedures (Grimes, 2006; Strauss and colleagues, 2007). Early abortions are safer, and the relative risk of dying as the consequence of abortion approximately doubles for each 2 weeks after 8 weeks' gestation. The Centers for Disease Control and Prevention recorded seven deaths related to legal abortion in 2004 (Gamble and associates, 2008). According to Horon (2005), such deaths are underreported.

Impact on Future Pregnancies

In a scholarly review of the impact of elective abortion on subsequent pregnancy outcome, Hogue (1986) summarized data from more than 200 publications. Data relating abortion to subsequent pregnancy outcome are observational and therefore subject to bias and uncontrolled confounding factors. All studies on this topic must be interpreted with these limitations in mind. That

TABLE 9-7. Outcomes in Next Pregnancy in 16,883 Women Who Had Either a Surgically or Medically Induced First-Trimester Abortion

	Incidence (Percent)[a]	
Pregnancy Outcome	Surgical	Medical
Ectopic pregnancy	2.3	2.4
Miscarriage	12.7	12.2
Preterm delivery	6.7	5.4
Birthweight <2500 g	5.1	4.0

[a]All comparisons $p > .05$.
Data from Virk and colleagues (2007).

said, fertility does not appear to be diminished by an elective abortion. Moreover, most studies indicate that vacuum aspiration does not increase the subsequent incidence of second-trimester spontaneous abortion or preterm delivery. The case-control French EPIPAGE study, however, found a 1.5-fold increased incidence of very preterm delivery—22 to 32 weeks—in women with a history of induced abortion (Moreau and colleagues, 2005). Subsequent ectopic pregnancies are not increased. Multiple sharp curettage abortion procedures may increase the subsequent risk of placenta previa, whereas vacuum aspiration procedures likely do not (Johnson and associates, 2003). In their recent meticulous systematic review, Swingle and co-workers (2009) found a significantly increased risk of preterm birth—OR 1.32—after either spontaneous or induced abortions.

The large population study from Denmark indicated that subsequent pregnancy outcomes are similar following medical and surgical methods of induced abortions. Using the Danish Abortion Registry of 30,349 procedures done from 1999 through 2004, Virk and colleagues (2007) provided data from 16,883 women who had a subsequent pregnancy through 2005. The results listed in Table 9-7 show very similar pregnancy outcomes.

CONTRACEPTION FOLLOWING MISCARRIAGE OR ABORTION

Ovulation may resume as early as 2 weeks after an early pregnancy is terminated, whether spontaneously or induced. Lahteenmaki and Luukkainen (1978) detected surges of luteinizing hormone (LH) 16 to 22 days after abortion in 15 of 18 women studied. Plasma progesterone levels, which had plummeted after the abortion, increased soon after LH surges. These hormonal events agree with histological changes observed in endometrial biopsies (Boyd and Holmstrom, 1972). **Therefore, if pregnancy is to be prevented, effective contraception should be initiated soon after abortion.** Reeves and associates (2007) have computed a lower unintended pregnancy rate in women who desire an intrauterine device if it is inserted at the time of pregnancy termination. Madden and Westhoff (2009) have shown similar benefits with depot medroxyprogesterone acetate (DMPA). Choices for contraception are discussed in Chapter 32.

CHAPTER 10

Ectopic Pregnancy

GENERAL CONSIDERATIONS 238
TUBAL PREGNANCY 240
ABDOMINAL PREGNANCY 249
OVARIAN PREGNANCY 251
CERVICAL PREGNANCY 251
CESAREAN SCAR PREGNANCY 253
OTHER SITES OF ECTOPIC PREGNANCY 254

The blastocyst normally implants in the endometrial lining of the uterine cavity. Implantation anywhere else is considered an ectopic pregnancy. It is derived from the Greek *ektopos*—out of place. According to the American College of Obstetricians and Gynecologists (2008), 2 percent of all first-trimester pregnancies in the United States are ectopic, and these account for 6 percent of all pregnancy-related deaths. The risk of death from an extrauterine pregnancy is greater than that for pregnancy that either results in a live birth or is intentionally terminated. Moreover, the chance for a subsequent successful pregnancy is reduced after an ectopic pregnancy. With earlier diagnosis, however, both maternal survival and conservation of reproductive capacity are enhanced.

GENERAL CONSIDERATIONS

Classification

Nearly 95 percent of ectopic pregnancies are implanted in the various segments of the fallopian tubes (Fig. 10-1). Of these, most are ampullary implantations. The remaining 5 percent implant in the ovary, peritoneal cavity, or within the cervix. More recently, cesarean scar pregnancies are reported to be more common than in the past. Occasionally, and usually with assisted reproductive technologies (ART), multifetal pregnancies implant simultaneously with either both ectopic, or one ectopic and the other intrauterine.

Risk Factors

Prior tubal damage, either from a previous ectopic pregnancy or from tubal surgery to relieve infertility or for sterilization, confers the highest risk for ectopic pregnancy (Table 10-1). After one previous ectopic pregnancy, the chance of another is approximately 10 percent (Ankum and colleagues, 1996; Skjeldestad and co-workers, 1998). Infertility, per se, as well as the use of ART to overcome it, is associated with substantively increased risks for ectopic pregnancy (Clayton and colleagues, 2006). The Society for Assisted Reproductive Technology and the American Society for Reproductive Medicine (2007) reported outcomes from more than 108,000 cycles performed in 2001. Ectopic pregnancy rates were 4.3 percent following zygote intrafallopian transfer (ZIFT) but only 1.8 percent with in vitro fertilization (IVF). And "atypical" implantations—cornual, abdominal, cervical, ovarian, and heterotopic pregnancy—are more common following ART procedures. Prior tubal infection or other sexually transmitted diseases are also common risk factors. And so is smoking, which may be a surrogate marker for these infections because of high-risk behavior (Saraiya and co-workers, 1998). Peritubal adhesions subsequent to salpingitis, postabortal or puerperal infection, appendicitis, or endometriosis may increase the risk for tubal pregnancy. One episode of salpingitis can be followed by a subsequent ectopic pregnancy in up to 9 percent of women (Centers for Disease Control and Prevention, 2007).

Failed Contraception

With any form of contraceptive, the *absolute* number of ectopic pregnancies is decreased because pregnancy occurs less often. In some contraceptive failures, however, the relative number of

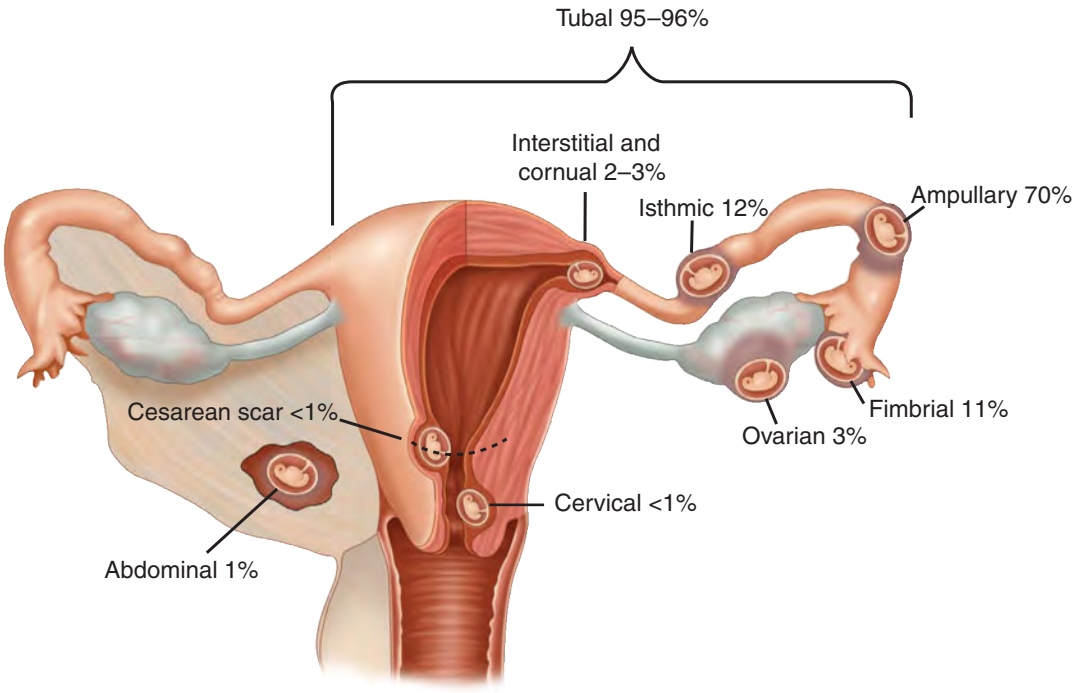

FIGURE 10-1 Sites of implantation of 1800 ectopic pregnancies from a 10-year population-based study. (Data from Callen, 2000; Bouyer and colleagues, 2003.)

ectopic pregnancies is increased. Examples include some forms of tubal sterilization, intrauterine devices, high-dose estrogen emergency contraception, and progestin-only minipills (Ory, 1981; Sivin, 1991).

Epidemiology

According to the Centers for Disease Control and Prevention (1995), the rate of ectopic pregnancies continued to increase in the United States through the 1990s (Fig. 10-2). Thereafter, because of the increasing use of medical outpatient treatment, reliable data on the actual number of ectopic pregnancies are not available after 1990. That said, the 1.9-percent rate in 1992 is similar to that of 2.1 percent in more than 125,000 pregnancies reported from Kaiser Permanente of North California from 1997 to 2000 (Van Den Eeden and colleagues, 2005).

TABLE 10-1. Some Reported Risk Factors for Ectopic Pregnancy

Risk Factor	Relative Risk
Previous ectopic pregnancy	3–13
Tubal corrective surgery	4
Tubal sterilization	9
Intrauterine device	1–4.2
Documented tubal pathology	3.8–21
Infertility	2.5–3
Assisted reproductive technology	2–8
Previous genital infection	2–4
Chlamydia	2
Salpingitis	1.5–6.2
Smoking	1.7–4
Prior abortion	0.6–3
Multiple sexual partners	1.6–3.5
Prior cesarean delivery	1–2.1

Data from Bakken (2007a, b); Barnhart (2006); Bouyer (2003); Gala (2008); Karaer (2006); Virk (2007), and all their colleagues.

Increasing Ectopic Pregnancy Rates

A number of reasons at least partially explain the increased rate of ectopic pregnancies in the United States and many European countries. Some of these include:

1. Increasing prevalence of sexually transmitted infections, especially those caused by *Chlamydia trachomatis* (Centers for Disease Control and Prevention, 2007)
2. Identification through earlier diagnosis of some ectopic pregnancies otherwise destined to resorb spontaneously
3. Popularity of contraception that predisposes pregnancy failures to be ectopic
4. Tubal sterilization techniques that with contraceptive failure increase the likelihood of ectopic pregnancy
5. Assisted reproductive technology
6. Tubal surgery, including salpingotomy for tubal pregnancy and tuboplasty for infertility.

Mortality

According to the World Health Organization (2007), ectopic pregnancy is responsible for almost 5 percent of maternal deaths in developed countries. But deaths from ectopic pregnancy in the United States have become uncommon since the 1970s. As shown in Figure 10-2, the case-fatality rate from ectopic pregnancy

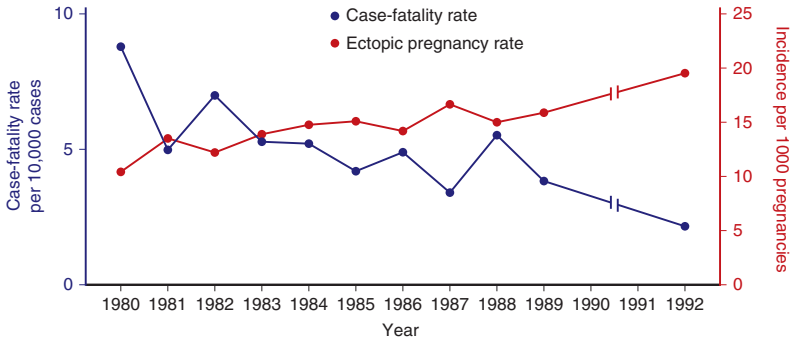

FIGURE 10-2 Case-fatality rate and incidence of ectopic pregnancy for the United States, 1980–1992. (From the Centers for Disease Control and Prevention, 1995.)

declined markedly from 1980 to 1992. This decrease is likely due to improved diagnosis and management. Still, according to Grimes (2006), from 1991 through 1999, estimated mortality rates for ectopic pregnancies were 32 per 100,000 deliveries compared with maternal death rates of 7 per 100,000 for liveborns. There remains a marked disparity between black and white women for both incidence and case-fatality rates. For example, Anderson and colleagues (2004) reported that the ectopic pregnancy-related mortality ratio in black women in Michigan was 18 times higher than for white women.

TUBAL PREGNANCY

The fertilized ovum may lodge in any portion of the oviduct, giving rise to ampullary, isthmic, and interstitial tubal pregnancies (see Fig. 10-1). In rare instances, the fertilized ovum may implant in the fimbriated extremity. The ampulla is the most frequent site, followed by the isthmus. Interstitial pregnancy accounts for only about 2 percent. From these primary types, secondary forms of tubo-abdominal, tubo-ovarian, and broad-ligament pregnancies occasionally develop.

Because the tube lacks a submucosal layer, the fertilized ovum promptly burrows through the epithelium, and the zygote comes to lie near or within the muscularis. The rapidly proliferating trophoblast may invade the subjacent muscularis, however, half of ampullary ectopic pregnancies stay within the tubal lumen with preservation of the muscularis layer in 85 percent (Senterman and associates, 1988). The embryo or fetus in an ectopic pregnancy is often absent or stunted.

Tubal Rupture

The invading, expanding products of conception may rupture the oviduct at any of several sites (Fig. 10-3). Before precise methods to measure human chorionic gonadotropin (hCG) were available, many cases of tubal pregnancy ended in rupture during the first trimester. As a rule, whenever there is tubal rupture in the first few weeks, the pregnancy is situated in the isthmic portion of the tube. When the fertilized ovum is implanted well within the interstitial portion, rupture usually occurs later (Fig. 10-4). Rupture is usually spontaneous, but it may follow coitus or bimanual examination. There are usually symptoms, and signs of hypovolemia are common.

Tubal Abortion

The frequency of tubal abortion depends in part on the implantation site. Abortion is common in ampullary pregnancies, whereas rupture is the usual outcome with isthmic pregnancies. With hemorrhage, there is further disruption of the connection between the placenta and membranes and the tubal wall. If placental separation is complete, all of the products of conception may be extruded through the fimbriated end into the peritoneal cavity. At this point, hemorrhage may cease and symptoms eventually disappear. Some bleeding usually persists as long as products remain in the oviduct. Blood slowly trickles from the tubal fimbria into the peritoneal cavity and typically pools in the rectouterine cul-de-sac. If the fimbriated extremity is occluded, the fallopian tube may gradually become distended by blood, forming a hematosalpinx.

Abdominal Pregnancy

With either tubal abortion or intraperitoneal rupture, the entire conceptus may be extruded from the tube, or if the rent is small, profuse hemorrhage may occur without extrusion. If an early conceptus is expelled essentially undamaged into the peritoneal cavity, its placental attachment may persist, or it may reimplant almost anywhere and grow as an abdominal pregnancy (Worley and colleagues, 2008). This is unusual, and most small conceptuses are resorbed. Occasionally, they may remain in the cul-de-sac for years as an encapsulated mass, or even become calcified to form a *lithopedion* (Berman and Katsiyiannis, 2001).

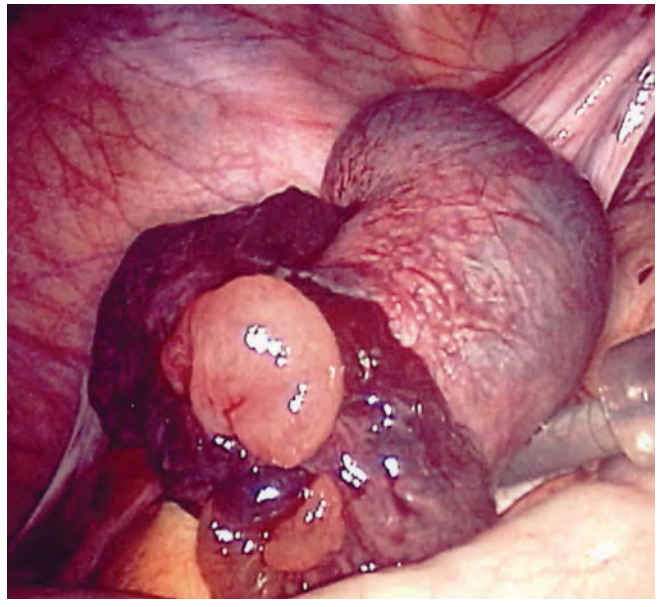

FIGURE 10-3 Ruptured ampullary early tubal pregnancy. (Used with permission from Dr. Togas Tulandi.)

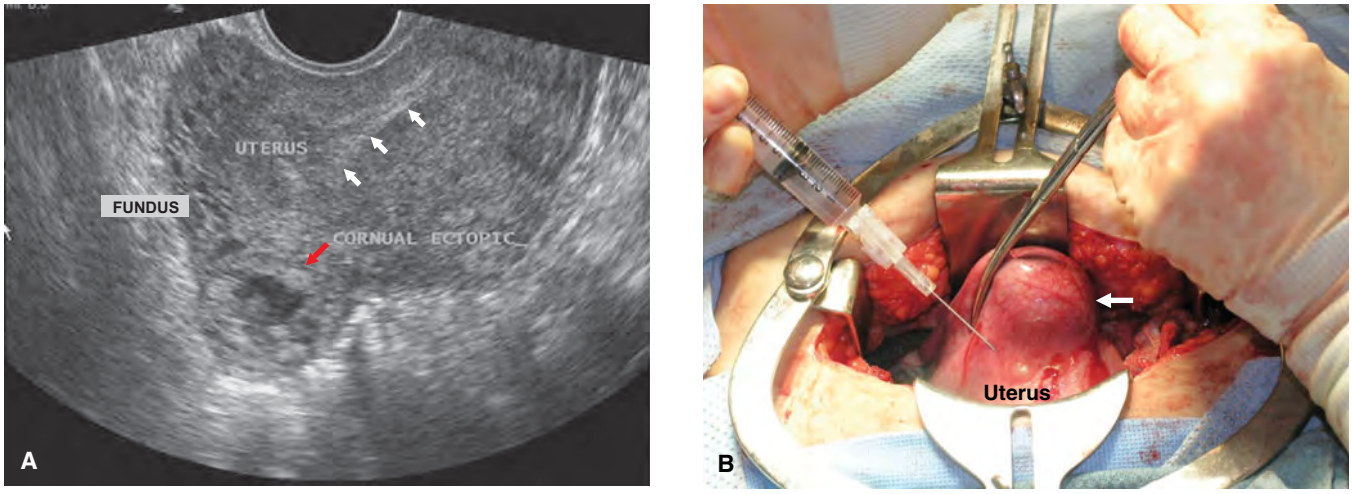

FIGURE 10-4 Cornual ectopic pregnancy. **A.** Transvaginal sonogram, parasagittal view shows an empty uterine cavity (*white arrows*) and a mass lateral to the uterine fundus (*red arrow*). (Courtesy of Dr. Elysia Moschos.) **B.** Intraoperative photograph during cornual resection of an ectopic pregnancy. A Pean clamp is placed across the round ligament, uteroovarian ligament, and fallopian tube distal to the cornual pregnancy (*white arrow*). The surgeon is injecting a dilute vasopressin solution at the cornual base prior to incision. (Used with permission from Dr. Marlene Corton.)

Broad Ligament Pregnancy

In zygotes implanted toward the mesosalpinx, rupture may occur at the portion of the tube not immediately covered by peritoneum. The gestational contents may be extruded into a space formed between the folds of the broad ligament and then become an intraligamentous or broad ligament pregnancy.

Interstitial and Cornual Pregnancy

Although used interchangeably, these are slightly different implantations. Cornual implantation describes those in the upper and lateral uterine cavity, whereas interstitial denotes those implanted within the proximal intramural portion of the tube (Malinowski and Bates, 2006). Together, they account for 2 to 3 percent of all tubal gestations (Fig. 10-1). In the past, rupture would not occur usually until 14 to 16 weeks, often with severe hemorrhage. Currently, interstitial and cornual pregnancy are usually diagnosed before rupture (Fig. 10-4). Both may be treated by cornual resection via laparotomy. Alternatively, several authors have described treatment with uterus-sparing laparoscopic surgery or methotrexate (Eun, 2009; Soriano, 2008; Tulandi, 2004, and all their associates).

Multifetal Ectopic Pregnancy

Heterotopic Ectopic Pregnancy

The word *heterotopic* pregnancy is used in place of the older term *combined* pregnancy. It defines a uterine pregnancy coexisting with a second pregnancy in an extrauterine location. Because, strictly speaking, heterotopic is synonymous with ectopic, the use of "heterotopic ectopic pregnancy" is tautological. Although most heterotopic pregnancies are tubal and uterine, they are also seen with ovarian, cervical, and other pregnancies.

The natural incidence of a tubal pregnancy accompanied by a coexisting uterine gestation is approximately 1 per 30,000 pregnancies. Because of ART, however, its incidence has increased to 1 in 7000 overall, and following ovulation induction, it may be as high as 0.5 to 1 percent (Mukul and Teal, 2007). A heterotopic pregnancy is more likely and should be considered with any of the following:

- Conception achieved by assisted reproductive techniques
- Persistent or rising hCG levels after dilatation and curettage for an induced or spontaneous abortion
- A uterine fundus larger than menstrual dates
- More than one corpus luteum
- Absent vaginal bleeding in the presence of signs and symptoms of an ectopic pregnancy
- Sonographic evidence of uterine and extrauterine pregnancy.

Multifetal Tubal Pregnancy

Twin tubal pregnancy with both embryos in the same tube as well as with one in each tube has been reported (Rolle and colleagues, 2004). Berkes and associates (2008) describe a rare case of three embryos implanting ectopically in one tube following IVF.

Clinical Manifestations

Women with a tubal pregnancy have diverse clinical manifestations that largely depend on whether there is rupture. Earlier patient presentation and more precise diagnostic technology have enabled identification before rupture in most cases. Typically, the woman does not suspect tubal pregnancy and assumes that she has a normal early pregnancy, or that she is having a miscarriage. **Symptoms and signs of ectopic pregnancy are often subtle or even absent.**

Without early diagnosis, the natural history of "classical" cases is characterized by variably delayed menstruation followed by slight vaginal bleeding or spotting. With rupture, there is

usually severe lower abdominal and pelvic pain that is frequently described as sharp, stabbing, or tearing. Vasomotor disturbances develop, ranging from vertigo to syncope. There is tenderness during abdominal palpation, and bimanual pelvic examination, especially cervical motion, causes exquisite pain. The posterior vaginal fornix may bulge because of blood in the rectouterine cul-de-sac, or a tender, boggy mass may be felt to one side of the uterus. Symptoms of diaphragmatic irritation, characterized by pain in the neck or shoulder, especially on inspiration, develop in perhaps half of women with sizable intraperitoneal hemorrhage.

Symptoms and Signs

Most women present for care early in the course of a developing ectopic pregnancy. In some, the diagnosis is made even before the onset of symptoms. Common findings include the following:

1. *Pain.* Pelvic and abdominal pain are reported by 95 percent of women with tubal pregnancy. With more advanced gestation, Dorfman and associates (1984) reported that gastrointestinal symptoms (80 percent) and dizziness or light-headedness (58 percent) were common. With rupture, pain may be anywhere in the abdomen.
2. *Abnormal bleeding.* Amenorrhea with some degree of vaginal spotting or bleeding is reported by 60 to 80 percent of women with tubal pregnancy. Approximately one fourth mistake the bleeding for true menstruation. Although profuse vaginal bleeding is suggestive of an incomplete abortion, such bleeding occasionally is seen with tubal gestations.
3. *Abdominal and pelvic tenderness.* With early unruptured ectopic pregnancies, tenderness is uncommon. With rupture, however, exquisite tenderness during abdominal and vaginal examination, especially with cervical motion, is demonstrable in more than three fourths of women.
4. *Uterine changes.* Although minimal early, later the uterus may be pushed to one side by an ectopic mass. The uterus may also be enlarged due to hormonal stimulation. The degree to which the endometrium is converted to decidua is variable. The finding of uterine decidua without trophoblast *suggests* ectopic pregnancy, but absence of decidual tissue does not exclude it.
5. *Vital signs.* Although generally normal before rupture, responses to moderate hemorrhage include no change in vital signs, a slight rise in blood pressure, or a vasovagal response with bradycardia and hypotension. Birkhahn and colleagues (2003) noted that in 25 women with ruptured ectopic pregnancy, the majority on presentation had a heart rate of less than 100 beats per minute and a systolic blood pressure greater than 100 mm Hg. Blood pressure will fall and pulse will rise only if bleeding continues and hypovolemia becomes significant.

Diagnosis of Ectopic Pregnancy

Laboratory Tests

Human Chorionic Gonadotropin (β-hCG). Rapid and accurate determination of pregnancy is essential in evaluating women with complaints suggestive of ectopic pregnancy. Current serum and urine pregnancy tests that use enzyme-linked immunosorbent assays (ELISAs) for β-hCG are sensitive to levels of 10 to 20 mIU/mL and are positive in greater than 99 percent of ectopic pregnancies (Kalinski and Guss, 2002). However, rare cases of ectopic pregnancy with a negative serum β-hCG assay result have been reported (Grynberg and colleagues, 2009; Lee and Lamaro, 2009).

Serum Progesterone. A single progesterone measurement can be used to establish with high reliability that there is a normally developing pregnancy. A value exceeding 25 ng/mL excludes ectopic pregnancy with 92.5-percent sensitivity (Lipscomb and co-workers, 1999a; Pisarska and colleagues, 1998). Conversely, values below 5 ng/mL are found in only 0.3 percent of normal pregnancies (Mol and colleagues, 1998). Thus, values <5 ng/mL suggest either an intrauterine pregnancy with a dead fetus or an ectopic pregnancy. Because in most ectopic pregnancies, progesterone levels range between 10 and 25 ng/mL, the clinical utility is limited (American College of Obstetricians and Gynecologists, 2008).

Novel Serum Markers. A number of preliminary studies have been done to evaluate novel markers to detect ectopic pregnancy. These include vascular endothelial growth factor (VEGF), cancer antigen 125 (CA125), creatine kinase, fetal fibronectin, and mass spectrometry-based proteomics (Daniel, 1999; Ness, 1998; Predanic, 2000; Shankar, 2005, and all their co-workers). None of these are in current clinical use.

Hemogram. After hemorrhage, depleted blood volume is restored toward normal by hemodilution over the course of a day or longer. Even after substantive hemorrhage, hemoglobin or hematocrit readings may at first show only a slight reduction. Hence, after an acute hemorrhage, a decrease in hemoglobin or hematocrit level over several hours is a more valuable index of blood loss than is the initial level. In about half of women with a ruptured ectopic pregnancy, varying degrees of leukocytosis up to 30,000/μL may be documented.

Sonography

This imaging tool is indispensable to confirm the clinical diagnosis of suspected ectopic gestation. In many cases, its location and size are also ascertained by sonography.

Transvaginal Sonography (TVS). High-resolution transvaginal sonography has revolutionized the care of women with suspected ectopic pregnancy. It is an integral part of most algorithms directed at ectopic pregnancy identification and is discussed in that context on p. 243.

Transabdominal Sonography. Identification of tubal pregnancy products is difficult using transabdominal sonography. If a gestational sac is clearly identified within the uterine cavity, ectopic pregnancy is still a consideration if ART was used. Conversely, with sonographic absence of a uterine pregnancy, a positive assay for β-hCG, fluid in the cul-de-sac, and an abnormal pelvic mass, ectopic pregnancy is almost certain (Romero and associates, 1988). A uterine pregnancy usually is

not recognized using abdominal sonography until 5 to 6 menstrual weeks or 28 days after timed ovulation (Batzer and co-workers, 1983).

Culdocentesis

This simple technique was used commonly in the past to identify hemoperitoneum. The cervix is pulled toward the symphysis with a tenaculum, and a long 16- or 18-gauge needle is inserted through the posterior vaginal fornix into the cul-de-sac. If present, fluid can be aspirated, however, failure to do so is interpreted only as unsatisfactory entry into the cul-de-sac and does not exclude an ectopic pregnancy, either ruptured or unruptured. Fluid containing fragments of old clots, or bloody fluid that does not clot, is compatible with the diagnosis of hemoperitoneum resulting from an ectopic pregnancy. If the blood subsequently clots, it may have been obtained from an adjacent blood vessel rather than from a bleeding ectopic pregnancy.

Multimodality Diagnosis

Ectopic pregnancies are identified with the combined use of clinical findings along with serum analyte testing and transvaginal sonography. A number of algorithms have been proposed, but most include five key components:

1. Transvaginal sonography
2. Serum β-hCG level—both the initial level and the pattern of subsequent rise or decline
3. Serum progesterone level
4. Uterine curettage
5. Laparoscopy and occasionally, laparotomy.

One algorithm for suspected ectopic pregnancy evaluation is shown in Figure 10-5. **The choice of diagnostic algorithm applies only to hemodynamically stable women—those with presumed rupture should undergo prompt surgical therapy.** For a suspected unruptured ectopic pregnancy, all diagnostic strategies involve trade-offs. Strategies that maximize detection of ectopic pregnancy may result in the interruption of one normal pregnancy for every 100 women evaluated. Conversely, those that reduce the potential for interruption of a normal pregnancy will delay diagnosis of more ectopic pregnancies. And some do not recommend diagnostic curettage as shown in the algorithm because it results in unnecessary medical or surgical therapy for ectopic pregnancy (Barnhart and colleagues, 2002).

Use of Transvaginal Sonography (TVS). In a woman in whom ectopic pregnancy is suspected, TVS is performed, and findings that indicate intrauterine or ectopic pregnancy are sought.

Endometrial Cavity. A trilaminar endometrial pattern is unique for diagnosis of ectopic pregnancy—its specificity is 94 percent, but with a sensitivity of only 38 percent (Hammoud and associates, 2005). Anechoic fluid collections, however, which would normally suggest an early intrauterine gestational sac, may also be seen with ectopic pregnancy. These include pseudogestational sac and decidual cyst:

1. All pregnancies induce an endometrial decidual reaction, and sloughing of the decidua can create an intracavitary fluid collection called a *pseudogestational sac*, or *pseudosac*. This one-layer sac characteristically lies in the midline within the endometrial cavity and can be seen contiguous with the endometrial stripe. In contrast, gestational sacs are usually eccentrically located (Dashefsky and colleagues, 1988). When a pseudosac is noted, the risk of ectopic pregnancy is increased (Nyberg and associates, 1987; Hill and co-workers, 1990).
2. A *decidual cyst* is identified as an anechoic area lying within the endometrium but remote from the canal and often at the endometrial-myometrial border. Ackerman and colleagues (1993) suggested this finding represents early decidual breakdown and precedes decidual cast formation. For these reasons, the American College of Obstetricians and Gynecologists (2004) advises caution in diagnosing an intrauterine pregnancy in the absence of a definite yolk sac or embryo. The yolk sac is typically seen within a gestational sac at 5.5 weeks' gestational age (Fig. 10-6).

Adnexa. When fallopian tubes and ovaries are visualized and an extrauterine yolk sac or embryo is identified, a tubal pregnancy is clearly confirmed (Fig. 10-6). But, such findings are present in only 15 to 30 percent of cases (Paul and co-workers, 2000).

In some cases, a *halo* or tubal ring surrounded by a thin hypoechoic area caused by subserosal edema can be seen. According to Burry and associates (1993), this has a positive-predictive value of 92 percent and a sensitivity of 95 percent. In their meta-analysis of 10 studies, Brown and Doubilet (1994) reported that the finding of any adnexal mass, other than a simple ovarian cyst, was the most accurate sonographic finding. It had a sensitivity of 84 percent, specificity of 99 percent, positive-predictive value of 96 percent, and negative-predictive value of 95 percent.

Differentiation of an ectopic pregnancy from a corpus luteum cyst can be challenging. With transvaginal color Doppler imaging, placental blood flow within the periphery of the complex adnexal mass—the *ring of fire*—can be seen (Fig. 10-7). This also may be seen with a corpus luteum of pregnancy. Swire and co-workers (2004) observed that the wall of the corpus luteum is less echogenic compared with both the tubal halo and the endometrium. They found that a spongiform, lace-like, or reticular pattern seen within the corpus luteum cyst is classical for hemorrhage.

Rectouterine Cul-De-Sac. Free peritoneal fluid suggests intra-abdominal bleeding. As little as 50 mL can be seen in the cul-de-sac using the transvaginal transducer, and transabdominal imaging helps to assess the extent of hemoperitoneum. Detection of peritoneal fluid in conjunction with an adnexal mass is highly predictive of ectopic pregnancy (Nyberg and associates, 1991).

At the current level of technology, the absence of suggestive sonographic findings does not exclude an ectopic pregnancy. That said, sonography has decreased the need for diagnostic laparoscopy and/or curettage to establish the diagnosis of ectopic pregnancy.

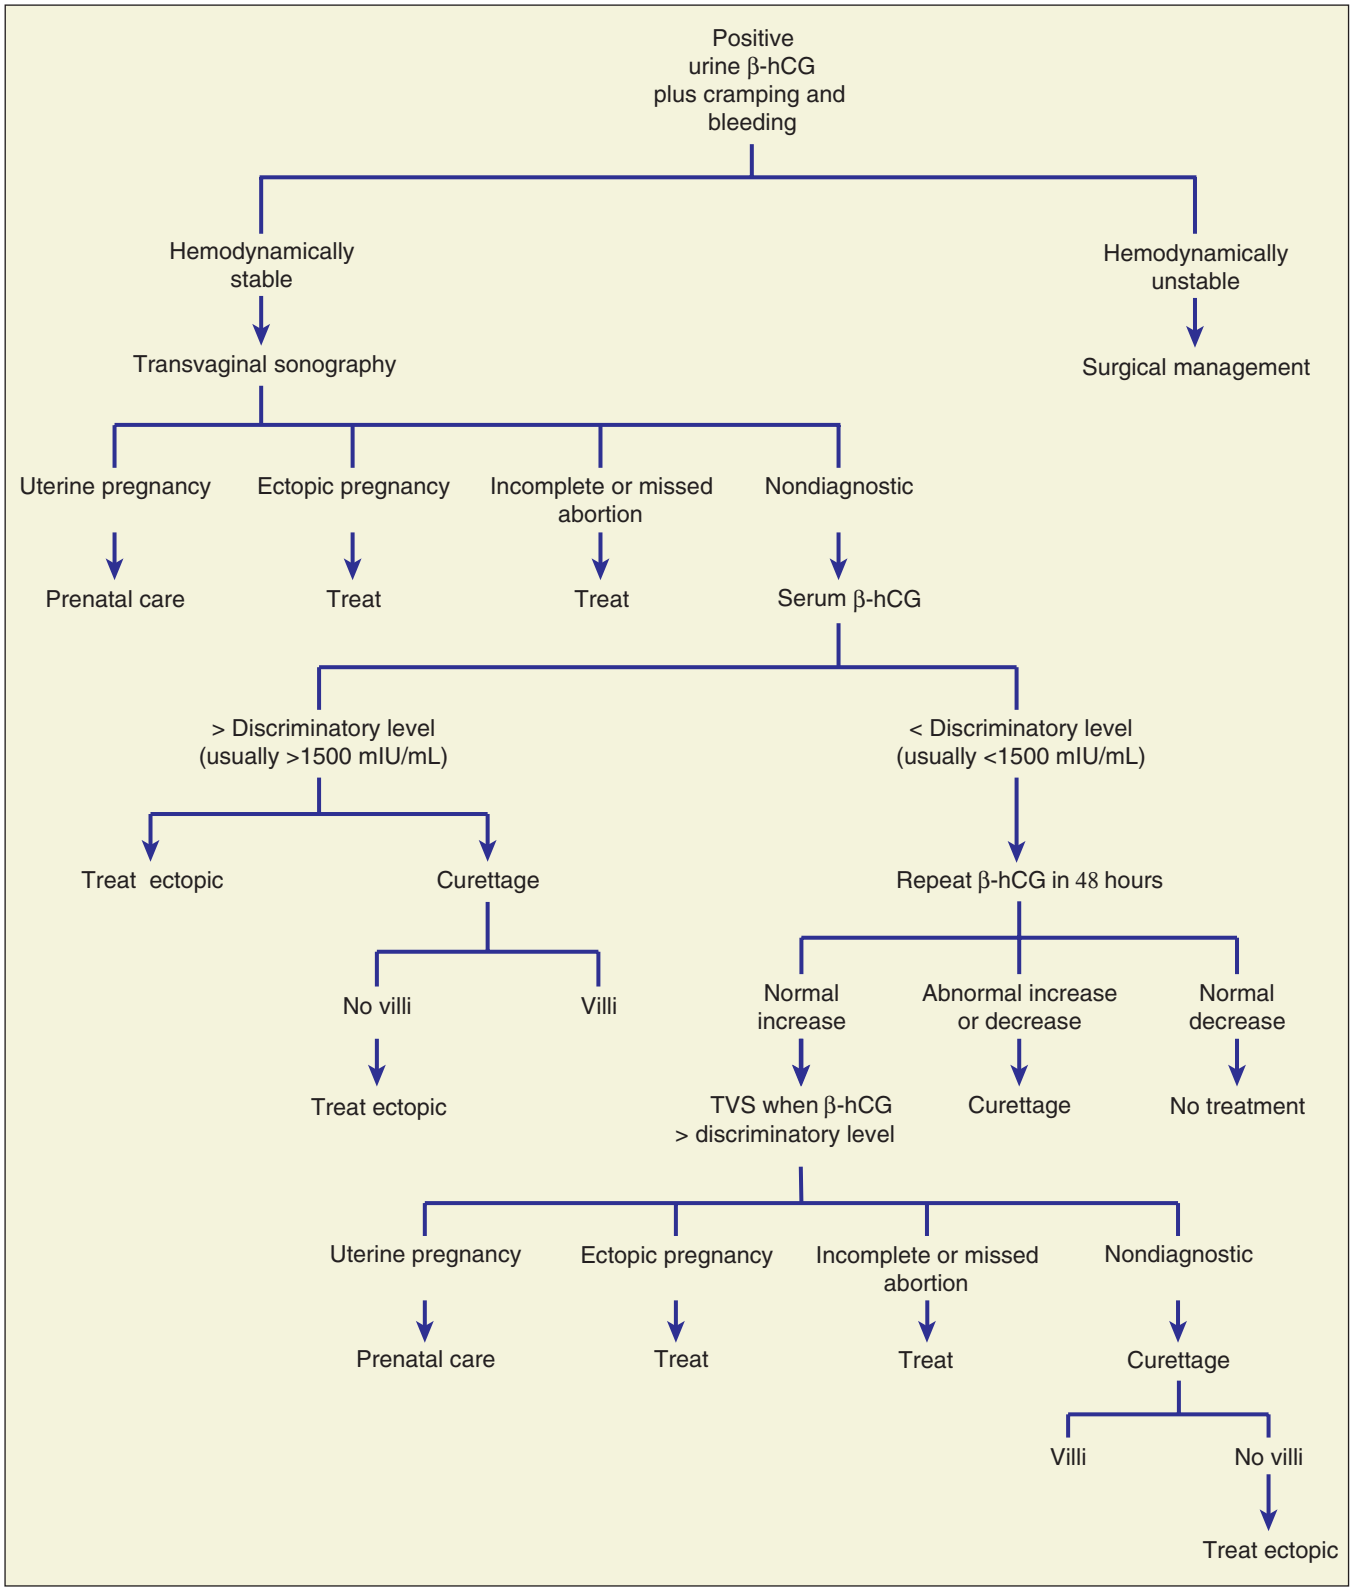

FIGURE 10-5 One suggested algorithm for evaluation of a woman with a suspected ectopic pregnancy. hCG = human chorionic gonadotropin; TVS = transvaginal sonography. (Modified from Gala, 2008.)

Nondiagnostic Transvaginal Sonography. In many cases, sonography is nondiagnostic and subsequent management is based on serial serum β-hCG values and repeated sonographic examinations. A number of investigators have described *discriminatory* β-hCG levels above which failure to visualize a uterine pregnancy indicates with high reliability that the pregnancy either is not alive or is ectopic. Barnhart and colleagues (1994) reported that an empty uterus with a serum β-hCG concentration of ≥1500 mIU/mL was 100-percent accurate in excluding a live uterine pregnancy. Thus, if the initial β-hCG level exceeds

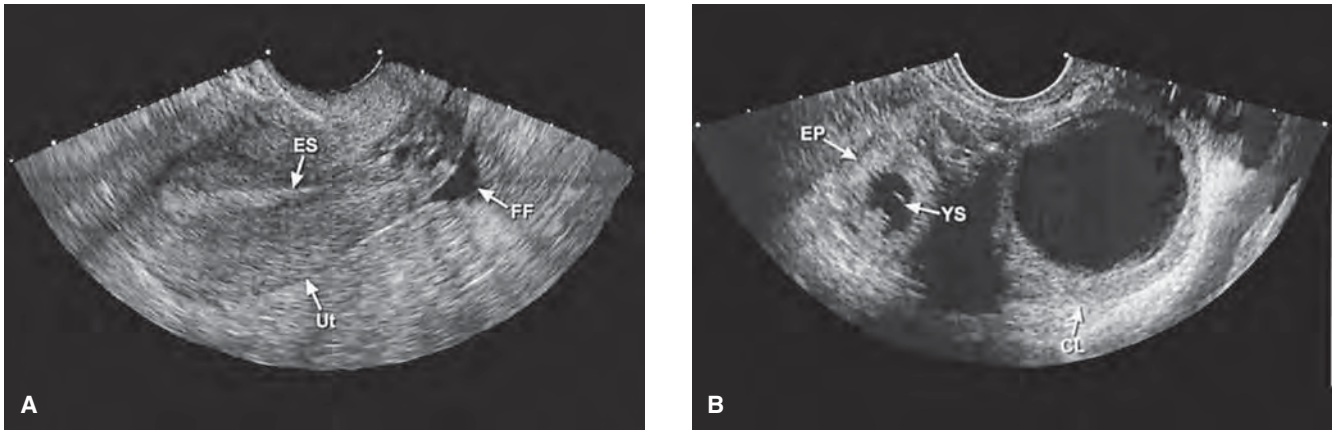

FIGURE 10-6 Vaginal sonogram of an ectopic pregnancy. **A.** The uterus (*Ut*) is seen with a normal endometrial stripe (*ES*). A small amount of free fluid (*FF*) is visible in the posterior cul-de-sac. **B.** The tubal ectopic pregnancy (*EP*) with its yolk sac (*YS*) is seen along with a corpus luteum (*CL*) cyst. (Used with permission from Dr. Michelle L. Robbin.)

the discriminatory level—1500 mIU/mL in this case, and no live intrauterine pregnancy is seen with TVS, then the diagnosis is narrowed to an intrauterine pregnancy with a dead fetus versus an ectopic pregnancy. Early multifetal gestation, of course, remains a possibility. Curettage will distinguish an ectopic from a nonliving uterine pregnancy. Conversely, if an intrauterine embryo, fetus, or placenta is identified by TVS, the diagnosis is apparent. When none of these is identified, tubal pregnancy is a probability.

If the initial β-hCG level is below the discriminatory value, early uterine pregnancy is a possibility, and serial assays of β-hCG, in conjunction with serial TVS evaluations, are usually done. Kadar and Romero (1987) reported that mean doubling time for serum β-hCG levels with early normal pregnancy was approximately 48 hours. The lowest normal value for this increase was 66 percent. Barnhart and co-workers (2004) reported a 53-percent 48-hour *minimum* rise with a 24-hour *minimum* rise of 24 percent (**Table 10-2**). Importantly, Silva and colleagues (2006) caution that a third of women with an ectopic pregnancy will have a 53-percent rise at 48 hours. They further reported that there is no single pattern to characterize ectopic pregnancy and that approximately half have decreasing β-hCG levels, whereas the other half have increasing levels.

Failure to maintain this minimum rate of increased β-hCG production, along with an empty uterus, is suggestive of an ectopic pregnancy or completed abortion. Thus, appropriately selected women with a suspected ectopic pregnancy, but whose initial β-hCG level is below the discriminatory level, are seen at 2- to 3-day intervals for further evaluation. If the β-hCG level rises insufficiently, plateaus, or exceeds the discriminatory level without evidence of a uterine pregnancy by TVS, then a live intrauterine pregnancy can be excluded. Next, distinction between a nonliving intrauterine and an ectopic pregnancy is made by uterine curettage. Barnhart and associates (2003) reported that endometrial biopsy was less sensitive than curettage.

A single serum progesterone measurement may clarify the diagnosis in a few cases (American College of Obstetricians and Gynecologists, 2008; Stovall and associates, 1989, 1992). Most values, however, fall between customary normal values of 5 to 20 or 25 ng/mL. Buckley and colleagues (2000) reported progesterone levels to be conclusive in only a fourth of women. One caveat is that pregnancy achieved with ART may be associated with higher than usual progesterone levels (Perkins and associates, 2000). All drawbacks considered, serum levels of at least 25 ng/mL after spontaneous conception provide reassurance

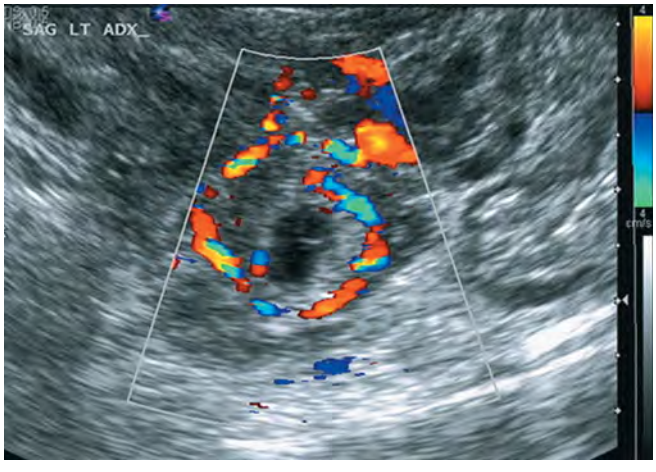

FIGURE 10-7 Color Doppler transvaginal sonogram of an ectopic pregnancy. The "ring of fire" reflects placental blood flow around the periphery of the pregnancy. This finding may also be seen with a corpus luteum cyst. (Used with permission from Dr. Elysia Moschos.)

TABLE 10-2. Lower Normal Limits for Percentage Increase of Serum β-hCG During Early Uterine Pregnancy

Sampling Interval (days)	Increase from Initial Value (percent)
1	24–29
2	53–66
3	114
4	175
5	255

Data from Barnhart (2004) and Kadar (1981) and their co-workers.

that an ectopic pregnancy is *unlikely*. Mol and colleagues (1998) performed a meta-analysis of 22 studies and reported that a serum progesterone level < 5 ng/mL predicted a dying pregnancy with almost 100-percent specificity but only 60-percent sensitivity. Values of > 20 ng/mL were 95-percent specific for a healthy normal pregnancy, but with only 40-percent sensitivity.

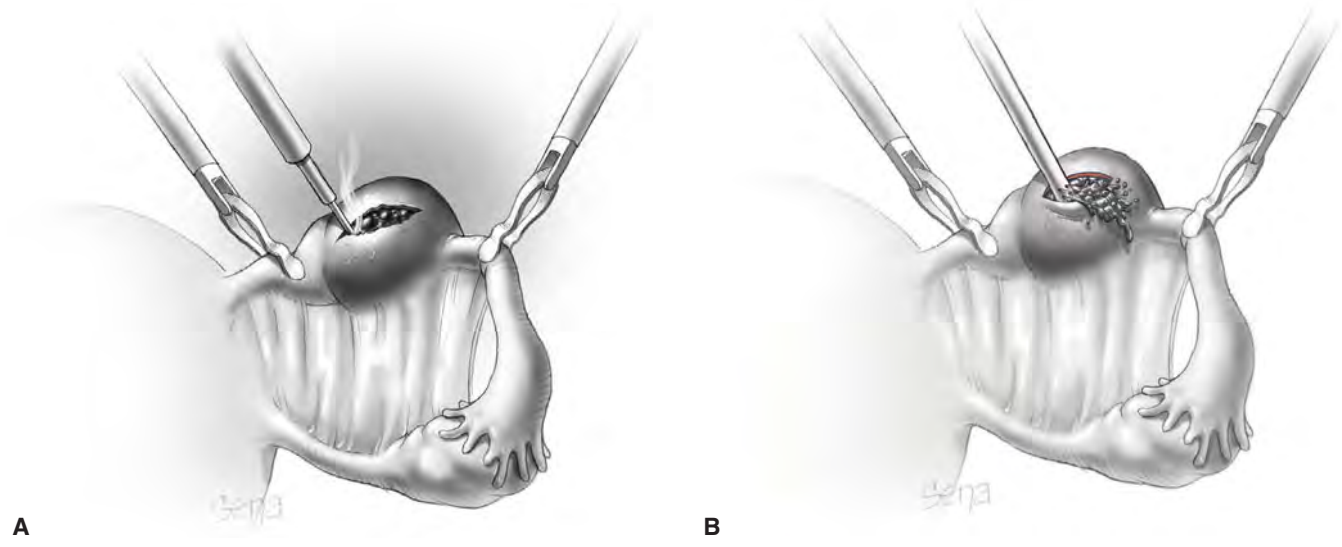
Laparoscopic Diagnosis

Direct visualization of the fallopian tubes and pelvis by laparoscopy offers a reliable diagnosis in most cases of suspected ectopic pregnancy. There is also a ready transition to definitive operative therapy, which is discussed subsequently.

Management

In many cases, early diagnosis allows definitive surgical or medical management of unruptured ectopic pregnancy—sometimes even before the onset of symptoms. In either case, treatment before rupture is associated with less morbidity and mortality and a better prognosis for fertility. D-negative women with an ectopic pregnancy who are not sensitized to D-antigen should be given anti-D immunoglobulin (see Chap. 29, p. 624).

Surgical Management



Laparoscopy is the preferred surgical treatment for ectopic pregnancy unless the woman is hemodynamically unstable. There have been only a few prospective studies in which laparotomy was compared with laparoscopic surgery. Hajenius and associates (2007) performed a Cochrane Database review, and their findings are summarized:

1. There were no significant differences in overall tubal patency following salpingostomy determined at second-look laparoscopy.
2. Each method was followed by a similar number of subsequent uterine pregnancies.
3. There were fewer subsequent ectopic pregnancies in women treated laparoscopically, although this was not statistically significant.
4. Laparoscopy resulted in shorter operative times, less blood loss, less analgesic requirements, and shorter hospital stays.
5. Laparoscopic surgery was slightly but significantly less successful in resolving tubal pregnancy.
6. The costs for laparoscopy were significantly less, although some argue that costs are similar when cases converted to laparotomy are considered.

As experience has accrued, cases previously managed by laparotomy—for example, ruptured tubal pregnancies or interstitial pregnancies—can safely be managed by laparoscopy (Sagiv and colleagues, 2001).

Tubal surgery is considered *conservative* when there is tubal salvage. Examples include salpingostomy, salpingotomy, and fimbrial expression of the ectopic pregnancy. *Radical surgery* is defined by salpingectomy. Conservative surgery may increase the rate of subsequent uterine pregnancy but is associated with higher rates of persistently functioning trophoblast (Bangsgaard and colleagues, 2003).

Salpingostomy. This procedure is used to remove a small pregnancy that is usually less than 2 cm in length and located in the distal third of the fallopian tube (**Fig. 10-8**). A 10- to 15-mm linear incision is made with unipolar needle cautery on the antimesenteric border over the pregnancy. The products usually will extrude from the incision and can be carefully removed or flushed out using high-pressure irrigation that more thoroughly removes the trophoblastic tissue (Al-Sunaidi and Tulandi, 2007). Small bleeding sites are controlled with needlepoint electrocoagulation or laser, and the incision is left unsutured to heal

A **B**

FIGURE 10-8 Linear salpingostomy for ectopic pregnancy. **A.** Linear incision for removal of a small tubal pregnancy is created on the antimesenteric border of the tube. **B.** Products of conception may be flushed from the tube using an irrigation probe. Alternatively, products may be removed with grasping forceps. Following evacuation of the tube, bleeding sites are treated with electrosurgical coagulation or laser, and the incision is not sutured. If the incision is closed, the procedure is termed a *salpingotomy*. (From Hoffman, 2008, with permission.)

by secondary intention. Natale and associates (2003) reported that serum β-hCG levels > 6000 mIU/mL are associated with a higher risk of implantation into the muscularis and thus with more tubal damage.

Salpingotomy. Seldom performed today, salpingotomy is essentially the same procedure as salpingostomy except that the incision is closed with delayed-absorbable suture. According to Tulandi and Saleh (1999), there is no difference in prognosis with or without suturing.

Salpingectomy. Tubal resection may be used for both ruptured and unruptured ectopic pregnancies. When removing the oviduct, it is advisable to excise a wedge of the outer third (or less) of the interstitial portion of the tube. This so-called *cornual resection* is done in an effort to minimize the rare recurrence of pregnancy in the tubal stump. Even with cornual resection, however, a subsequent interstitial pregnancy is not always prevented (Kalchman and Meltzer, 1966).

Persistent Trophoblast. Incomplete removal of trophoblast may result in persistent ectopic pregnancy. Because of this, Graczykowski and Mishell (1997) administered a "prophylactic" 1 mg/m^2 dose of methotrexate postoperatively. Persistent trophoblast complicates 5 to 20 percent of salpingostomies and can be identified by persistent or rising hCG levels. Usually β-hCG levels fall quickly and are at about 10 percent of preoperative values by day 12 (Hajenius and colleagues, 1995; Vermesh and associates, 1988). Also, if the postoperative day 1 serum β-hCG value is less than 50 percent of the preoperative value, then persistent trophoblast rarely is a problem (Spandorfer and co-workers, 1997).

According to Seifer (1997), factors that increase the risk of persistent ectopic pregnancy include:

1. Small pregnancies, that is, less than 2 cm
2. Early therapy, that is, before 42 menstrual days
3. Serum β-hCG levels exceeding 3000 mIU/mL
4. Implantation medial to the salpingostomy site.

In the face of persistent or increasing β-hCG, additional surgical or medical therapy is necessary.

Medical Management with Methotrexate

This folic acid antagonist is highly effective against rapidly proliferating trophoblast, and it has been used for more than 40 years to treat gestational trophoblastic disease (see Chap. 11, p. 263). It is also used for early pregnancy termination (see Chap. 9, p. 232). Tanaka and associates (1982) first used methotrexate to treat an interstitial pregnancy, and since then, it has been used successfully for all varieties of ectopic pregnancy. In the largest single-center series, Lipscomb and colleagues (1999a) reported a 91-percent success rate in 350 women given methotrexate therapy. Moreover, 80 percent of these women required only one dose.

Active intra-abdominal hemorrhage is a contraindication to chemotherapy. According to the Practice Committee of the American Society for Reproductive Medicine (2006), other absolute contraindications include intrauterine pregnancy; breast feeding; immunodeficiency, alcoholism; chronic hepatic, renal, or pulmonary disease; blood dyscrasias; and peptic ulcer disease.

Patient Selection. The best candidate for medical therapy is the woman who is asymptomatic, motivated, and compliant. With medical therapy, some classical predictors of success include:

1. *Initial serum β-hCG level.* This is the single best prognostic indicator of successful treatment with single-dose methotrexate. The prognostic value of the other two predictors is likely directly related to their relationship with β-hCG concentrations. Menon and co-workers (2007) performed a systematic review of studies totaling more than 500 women treated with single-dose methotrexate for ectopic pregnancy. They reported failure rates of 1.5 percent if the initial serum hCG concentration was <1000 mIU/mL; 5.6 percent with 1000-2000 mIU/mL; 3.8 percent with 2000-5000 mIU/mL; and 14.3 percent when levels were between 5000 and 10,000 mIU/mL.
2. *Ectopic pregnancy size.* Although these data are less precise, many early trials used "large size" as an exclusion criterion. Lipscomb and colleagues (1998) reported a 93-percent success rate with single-dose methotrexate when the ectopic mass was <3.5 cm, compared with success rates between 87 and 90 percent when the mass was >3.5 cm.
3. *Fetal cardiac activity.* Although this is a relative contraindication to medical therapy, the admonition is based on limited evidence. Most studies report increased failure rates if there is cardiac activity, Lipscomb and colleagues (1998) reported an 87-percent success rates in such cases.

Dose, Administration, and Toxicity. The three general schemes for methotrexate administration are shown in Table 10-3. These three are essentially those recommended by the American College of Obstetricians and Gynecologists (2008). In most studies, the intramuscular methotrexate dose was 50 mg/m^2. Although single-dose treatment is easier to administer and monitor than variable-dose therapy, it may have a higher failure rate (Hajenius and co-workers, 2007). And although methotrexate can be given orally, Lipscomb and co-workers (2002) reported it to be less effective than that given intramuscularly. Direct injection of methotrexate into the ectopic mass is seldom used with tubal ectopic pregnancy.

These regimens are associated with minimal laboratory changes and symptoms, although occasional toxicity may be severe. Kooi and Kock (1992) reviewed 16 studies and reported that adverse effects were resolved by 3 to 4 days after methotrexate was discontinued. The most common were liver involvement—12 percent, stomatitis—6 percent, and gastroenteritis—1 percent. One woman had bone marrow depression. Case reports also describe life-threatening neutropenia and fever, transient drug-induced pneumonitis, and alopecia, as well as death in a woman with renal failure (Buster and Pisarska, 1999; Kelly and colleagues, 2006). Importantly, nonsteroidal anti-inflammatory drugs may enhance methotrexate toxicity, whereas vitamins containing folic acid may lower its efficacy. Using anti-müllerian hormone assays, Oriol and co-workers (2008) concluded that ovarian reserve was not compromised by single-dose methotrexate therapy.

TABLE 10-3. Methotrexate Therapy for Primary Treatment of Ectopic Pregnancy

Regimen	Surveillance
Single dose[a] Methotrexate, 50 mg/m^2 IM	Measure β-hCG levels days 4 and 7: • If difference ≥ 15 percent, repeat weekly until undetectable • If difference < 15 percent between day 4 and 7 levels, repeat methotrexate dose and begin new day 1 • If fetal cardiac activity present day 7, repeat methotrexate dose, begin new day 1 • Surgical treatment if β-hCG levels not decreasing or fetal cardiac activity persists after three doses methotrexate
Two dose Methotrexate, 50 mg/m^2 IM, days 0, 4	Follow-up as for single-dose regimen
Variable dose (up to four doses): Methotrexate, 1 mg/kg IM, days 1, 3, 5, 7 Leucovorin, 0.1 mg/kg IM, days 2, 4, 6, 8	Measure β-hCG levels day 1, 3, 5, and 7. Continue alternate-day injections until β-hCG levels decrease ≥ 15 percent in 48 hours, or four doses of methotrexate given. Then, weekly β-hCG until undetectable

[a]Preferred by surgeons.
IM = intramuscular.
Regimens from Buster and Pisarska (1999), Kirk (2007), Lipscomb (2007), Pisarska (1998, 1999), and all their colleagues.

Monitoring Efficacy of Therapy. Serum β-hCG levels are used to monitor response to both medical and surgical therapy. Patterns of serum level decline described by Saraj and colleagues (1998) are shown in Figure 10-9. After linear salpingostomy, serum β-hCG levels *declined rapidly* over days and then more gradually, with a mean resolution time of about 20 days. In contrast, after single-dose methotrexate, mean serum β-hCG levels *increased* for the first 4 days, and then gradually declined with a mean resolution time of 27 days. Lipscomb and colleagues (1998) used single-dose methotrexate to successfully treat 287 women and reported that the average time to resolution—defined as serum hCG level < 15 mIU/mL, was 34 days. Importantly, the longest time was 109 days.

As shown in Table 10-3, monitoring single-dose therapy calls for serum β-hCG determinations at 4 and 7 days. About 15 to 20 percent of women require a second dose of methotrexate. Kirk and colleagues (2007) recently confirmed the efficacy of the "15 percent, day 4 and 7 rule." With variable-dose methotrexate, levels are measured at 48-hour intervals until they fall more than 15 percent. After successful treatment, weekly serum β-hCG determinations are measured until undetectable. Outpatient surveillance is preferred, but if there is any question of safety or compliance, the woman is hospitalized. Failure is judged when the β-hCG level plateaus or rises or tubal rupture occurs. Importantly, tubal rupture can occur in the face of declining β-hCG levels.

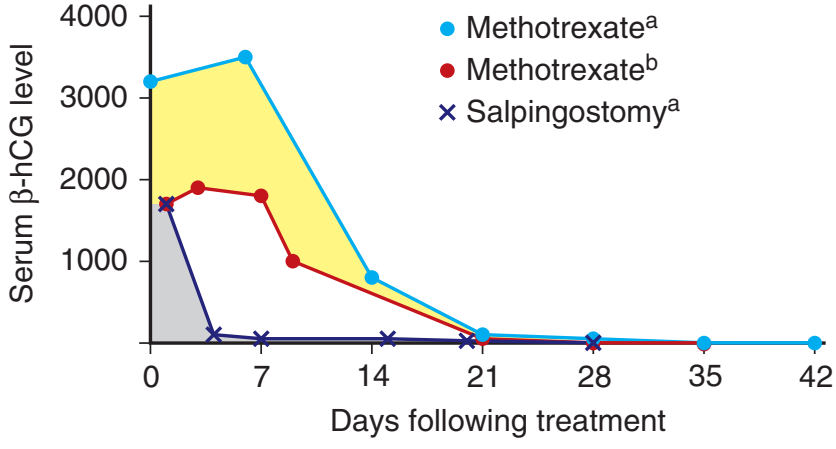


FIGURE 10-9 Schematic of comparative patterns of serum β-hCG level decline after single-dose methotrexate treatment or laparoscopic salpingostomy for unruptured ectopic pregnancy. Values are approximate. Yellow area is range *between* mean values reported by [a]Saraj and colleagues (1998) and those reported by [b]Dilbaz and associates (2006). Gray area represents area under the curve for mean values following salpingostomy reported by [a]Saraj and colleagues (1998).

Separation Pain. An important observation is that 65 to 75 percent of women initially given methotrexate will have increasing pain beginning several days after therapy. This *separation pain* generally is mild and relieved by analgesics. In a series of 258 methotrexate-treated women by Lipscomb and colleagues (1999b), 20 percent had pain severe enough to require evaluation in the clinic or emergency room. Ultimately, 10 of these 53 underwent surgical exploration. Said another way, 20 percent of women given single-dose methotrexate will have significant pain, and 20 percent of these will require laparoscopy.

Persistent Ectopic Pregnancy. The failure rate is similar for either medical or surgical management (Table 10-4). In three randomized trials, 5 to 14 percent of women treated initially with methotrexate ultimately required surgery, whereas 4 to 20 percent of those undergoing laparoscopic resection eventually received methotrexate for persistent trophoblast (Fernandez, 1998; Hajenius, 1997, 2007; Saraj, 1998, and all their associates).

TABLE 10-4. Representative Reproductive Performance in 3198 Women Following Primary Treatment for Ectopic Pregnancy

			Subsequent Pregnancy (percent)	
Management	Successful Treatment[a] (percent)	Tubal Patency[b] (percent)	Uterine	Ectopic
Salpingostomy	93	76	58	12
Methotrexate				
Single-dose	87	81	61	8
Variable-dose	93	75	52	8
Expectant	68	76	57	13

[a]Defined as resolution of ectopic pregnancy.
[b]Not all women were evaluated for patency.
Data from Buster and Krotz (2007).

Rupture of Persistent Ectopic Pregnancy. This is the worst form of primary therapy failure with a 5 to 10-percent occurrence in women treated medically. Lipscomb and associates (1998) described a 14-day mean time to rupture, but one woman had tubal rupture 32 days after single-dose methotrexate.

Expectant Management

In select cases, it is reasonable to observe very early tubal pregnancies that are associated with stable or falling serum β-hCG levels. As many as a third of such women will present with declining β-hCG levels (Shalev and colleagues, 1995). Stovall and Ling (1992) restrict expectant management to women with these criteria:

1. Tubal ectopic pregnancies only
2. Decreasing serial β-hCG levels
3. Diameter of the ectopic mass not >3.5 cm
4. No evidence of intra-abdominal bleeding or rupture by transvaginal sonography.

Trio and colleagues (1995) reported spontaneous resolution of ectopic pregnancy in 49 of 67, or 73 percent of selected women treated expectantly. Resolution without treatment was more likely if the initial serum β-hCG level was <1000 mIU/mL. In another 60 women managed expectantly, Shalev and associates (1995) reported spontaneous resolution in almost half.

With expectant management, subsequent rates of tubal patency and intrauterine pregnancy are comparable with surgery and medical management (see Table 10-4). **The potentially grave consequences of tubal rupture, coupled with the established safety of medical and surgical therapy, require that expectant therapy be undertaken only in appropriately selected and counseled women.** According to the American College of Obstetricians and Gynecologists (2008), 88 percent of ectopic pregnancies will resolve if the β-hCG is <200 mIU/mL.

ABDOMINAL PREGNANCY

Strictly defined, abdominal pregnancy is an implantation in the peritoneal cavity exclusive of tubal, ovarian, or intraligamentary implantations. Although a zygote can traverse the tube and implant primarily in the peritoneal cavity, most abdominal pregnancies are thought to follow early tubal rupture or abortion. In cases of advanced extrauterine pregnancy, it is not unusual that the placenta is still at least partially attached to the uterus or adnexa (Fig. 10-10). Worley and colleagues (2008) recently

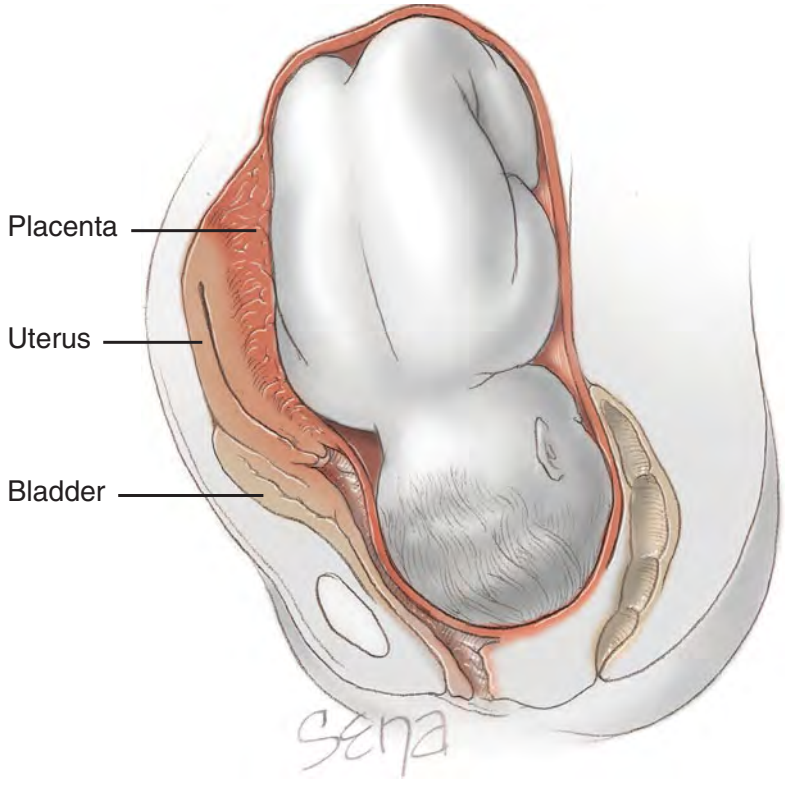

FIGURE 10-10 Abdominal pregnancy at term. The placenta is implanted on the posterior surface of the uterus and broad ligament. The enlarged, flattened uterus is located just beneath the anterior abdominal wall. The cervix and vagina are dislodged anteriorly and superiorly by the large fetal head in the cul-de-sac.

described our experiences with 10 women with such pregnancies that were 18 to 43 weeks' gestational age—five of these were 26 weeks or greater. Although only three of 10 met strict criteria for abdominal pregnancy by the location of placental implantation, in all 10, the fetus was located intra-abdominally. The placenta was implanted in a massively dilated tube in three pregnancies at 18, 26, and 30 weeks; and two others were implanted in a rudimentary horn at 20 and 22 weeks. Naim and associates (2008) reported an advanced abdominal pregnancy from an earlier uterine rupture. These likely are to become more common because of cesarean scar pregnancy, discussed on page 253.

Because of these vicissitudes, the reported incidence of abdominal pregnancy will vary depending on definitions used. More than 20 years ago, the Centers for Disease Control and Prevention estimated its incidence to be 1 in 10,000 live births (Atrash and co-workers, 1987). In the report cited above from Parkland Hospital, advanced abdominal pregnancy had an incidence of about 1 in 25,000 births. Using the stricter criteria, however, the incidence was about 1 in 85,000.

Diagnosis

A high index of suspicion is warranted with advanced extrauterine gestations because they cause symptoms that are often vague and nonspecific. Presenting complaints may include abdominal pain, nausea and vomiting, bleeding or decreasing to absent fetal movements. Many women, however, are asymptomatic. Findings that might suggest the diagnosis include elevated levels of maternal serum alpha-fetoprotein (Costa and associates, 1991; Worley and co-workers, 2008). Although abnormal fetal positions can be palpated, the ease of palpating fetal parts is not a reliable sign. The cervix may be displaced, depending in part on the fetal position (Zeck and colleagues, 2007).

Sonography

Findings with an abdominal pregnancy using sonography most often do not provide an unequivocal diagnosis. Oligohydramnios is common but nonspecific. In some suspected cases, however, sonographic findings may be diagnostic. For example, the fetal head may be seen to lie immediately adjacent to the maternal bladder with no interposed uterine tissue (Kurtz and associates, 1982). Even with ideal conditions, however, a sonographic diagnosis of abdominal pregnancy is missed in half of cases (Costa and associates, 1991; Worley and colleagues, 2008).

Magnetic Resonance (MR) Imaging

This can be used to confirm a diagnosis of abdominal pregnancy following a suspicious sonographic examination (Fig. 10-11). Although described as accurate and specific by Harris and associates (1988) and Wagner and Burchardt (1995), our experiences are that it is not totally reliable. At our institutions, abdominal pregnancy has been incorrectly diagnosed as a placenta previa, and conversely, an intrauterine pregnancy with degenerating fibroids has been misdiagnosed as an abdominal pregnancy. Whenever an abdominal pregnancy is identified, MR imaging should be done to provide maximal information concerning placental implantation (Bertrand and colleagues, 2009).

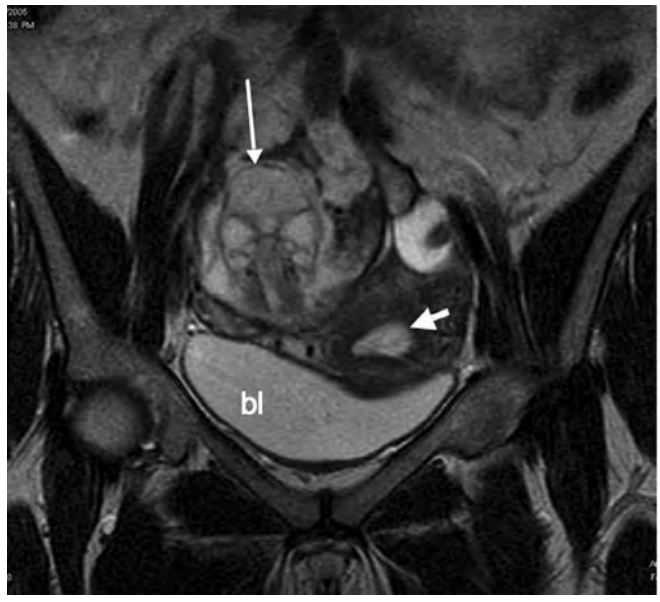

FIGURE 10-11 T2-weighted single-shot fast-spin echo (SSFSE) magnetic resonance coronal pelvic image of an 18-week abdominal pregnancy. The fetal head (*long arrow*) is not contained within the uterine cavity (*short arrow*). The maternal bladder (*bl*) is inferior to these structures. The high-signal-intensity area superior to the uterus is an ovarian cyst. (Reprinted from *American Journal of Obstetrics and Gynecology*, Vol. 198, No. 3, KC Worley, MD Hnat, and FG Cunningham, Advanced extrauterine pregnancy: Diagnostic and therapeutic challenges, pp. 297.e1–297.e7, Copyright 2008, with permission from Elsevier.)

Computed Tomography

Costa and associates (1991) maintain that computed tomography is superior to MR imaging, but its use is limited because of concerns for fetal radiation. In cases of certain abdominal pregnancy, and in the absence of MR imaging, knowledge of the placental implantation site would outweigh any fetal risks in our estimation.

Management

An abdominal pregnancy is life-threatening, and clinical management depends on the gestational age at diagnosis. Some recommend waiting until fetal viability with in-hospital observation if pregnancy is diagnosed after 24 weeks (Cartwright and associates, 1986; Hage and colleagues, 1988). Such management carries a risk for sudden and life-threatening hemorrhage, and we are of the opinion that termination generally is indicated when the diagnosis is made. Certainly, before 24 weeks, conservative treatment rarely is justified.

Once placental implantation has been assessed, several options are available. Preoperative angiographic embolization has been used successfully in some women with advanced abdominal pregnancy. Alternatively, catheters placed in the uterine arteries may be inflated to decrease intraoperative blood loss. In either case, vascularization of ectopic placental implantation may be difficult to occlude. Other preoperative considerations include insertion of ureteral catheters, bowel preparation, assurance of sufficient blood products, and availability of a multidisciplinary surgical team. Should such resources not be available, elective transfer of a

woman with a known advanced extrauterine pregnancy to a tertiary care facility is recommended.

The principal surgical objectives with an abdominal pregnancy include delivery of the fetus and careful assessment of placental implantation without provoking hemorrhage. Anatomical derangements often complicate fetal delivery and increase the risk of intraoperative injury. After delivery, placental implantation is assessed carefully because the surrounding areas will be quite vascular even if there is no placental invasion.

Management of the Placenta

Placental removal may precipitate torrential hemorrhage because the normal hemostatic mechanism of myometrial contractions to constrict hypertrophied blood vessels is lacking. This can develop spontaneously or more likely, when the surgeon is attempting to locate the exact site of placental attachment. Therefore, it is best to avoid unnecessary exploration of surrounding organs. If it is obvious that the placenta can be safely removed or if there is already hemorrhage from its implantation site, then removal begins immediately. When possible, blood vessels supplying the placenta should be ligated first.

Leaving the Placenta in Situ. Some advocate leaving the placenta in place as the lesser of two evils. It decreases the chance of immediate life-threatening hemorrhage, but at the expense of long-term sequelae. Unfortunately, when left in the abdominal cavity, the placenta commonly becomes infected with subsequent formation of abscesses, adhesions, intestinal obstruction, and wound dehiscence (Bergstrom and colleagues, 1998; Martin and associates, 1988). Partial ureteral obstruction with reversible hydronephrosis has also been described (Weiss and Stone, 1994). In many of these cases, surgical removal becomes inevitable.

If the placenta is left, its involution may be monitored using sonography and serum β-hCG levels (France and Jackson, 1980; Martin and McCaul, 1990). Color Doppler sonography can be used to assess changes in blood flow. In some cases, and usually depending on its size, placental function rapidly declines, and the placenta is resorbed. In one case described by Belfar and associates (1986), placental resorption took more than 5 years. In the 10 women from Parkland Hospital described by Worley and colleagues (2008), the placenta was left implanted in two. Both developed disastrous complications with hemorrhage and infection.

Methotrexate use is controversial. It has been recommended to hasten involution and has been reported to cause accelerated placental destruction with accumulation of necrotic tissue and infection with abscess formation (Rahman and associates, 1982). It is difficult to envision a supporting role for the use of an antimetabolite for a senescent organ.

Maternal and Fetal Outcomes

The maternal mortality rate is increased substantively with advanced abdominal pregnancy. With appropriate preoperative planning, however, the mortality rate has been reduced from approximately 20 percent to less than 5 percent (Stevens, 1993). Fetal salvage in an abdominal pregnancy is gestational-age dependent. In the cases from Parkland Hospital, all infants born after 26 weeks survived, albeit with numerous neonatal complications (Worley and associates, 2008). In an earlier review, Stevens (1993) found that survival of infants born after 30 weeks was 63 percent. He also reported fetal malformations and deformations in 20 percent. The most common deformations were facial or cranial asymmetry, or both, and various joint abnormalities. The most common malformations were limb deficiency and central nervous system anomalies.

OVARIAN PREGNANCY

Ectopic pregnancy implanted in the ovary is rare. Traditional risk factors for ovarian ectopic pregnancy are similar to those for tubal pregnancy, but use of an IUD seems to be disproportionately associated (Gray and Ruffolo, 1978; Pisarska and Carson, 1999). Although the ovary can accommodate more readily than the fallopian tube to the expanding pregnancy, rupture at an early stage is the usual consequence. This would seem more likely with a twin ovarian pregnancy (Garg and colleagues, 2009). Nonetheless, there are recorded cases in which ovarian pregnancies went to term, and a few infants survived (Williams and associates, 1982).

Diagnosis

Findings are likely to mimic those of a tubal pregnancy or a bleeding corpus luteum. Serious bleeding is seen in approximately one third of cases. At surgery, early ovarian pregnancies are likely to be considered corpus luteum cysts or a bleeding corpus luteum. Use of transvaginal sonography has resulted in a more frequent diagnosis of unruptured ovarian pregnancies (Marcus and Brinsden, 1993; Sidek and colleagues, 1994). Such early diagnosis may allow for a medical approach.

Management

The classical management for ovarian pregnancies has been surgical. Early bleeding for small lesions has been managed by ovarian wedge resection or cystectomy (Schwartz and colleagues, 1993). With larger lesions, ovariectomy is most often performed, and laparoscopy has been used to resect or to perform laser ablation (Goldenberg and associates, 1994; Herndon and colleagues, 2008). Finally, methotrexate has been used successfully to treat unruptured ovarian pregnancies (Chelmow and associates, 1994; Raziel and Golan, 1993; Shamma and Schwartz, 1992).

CERVICAL PREGNANCY

Implantation of the zygote in the cervix is uncommon, but the incidence is increasing as a result of ART (Ginsburg and coworkers, 1994; Peleg and associates, 1994). According to Jeng and colleagues (2007), 60 percent of women with a cervical pregnancy had previously undergone dilation and curettage. In a typical case, the endocervix is eroded by trophoblast, and the pregnancy proceeds to develop in the fibrous cervical wall. The higher the trophoblast is implanted in the cervical canal, the greater is its capacity to grow and hemorrhage. A heterotopic

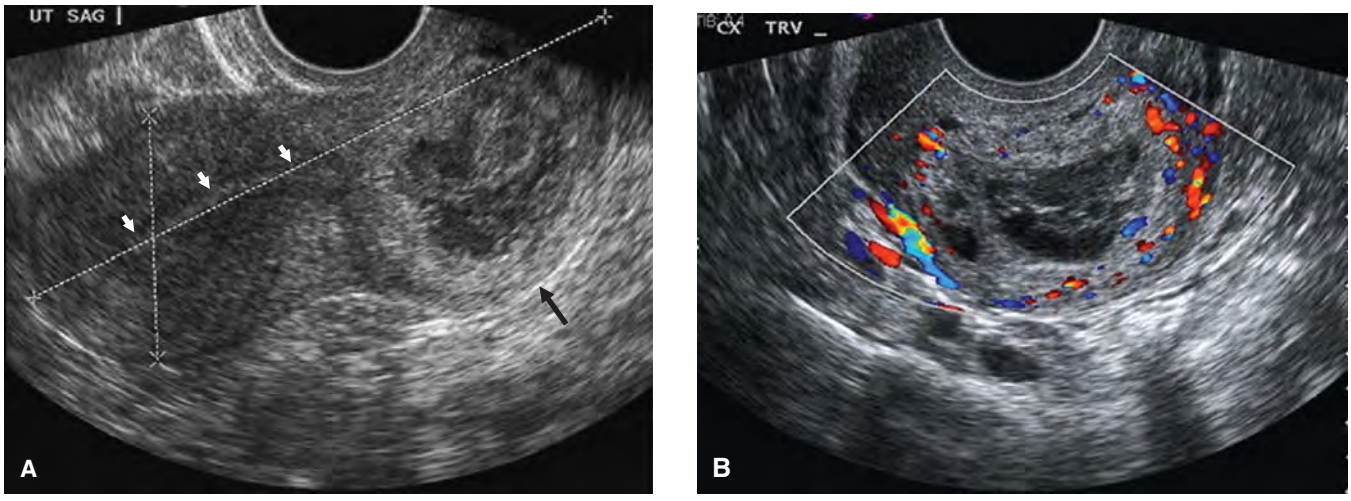

FIGURE 10-12 A. Transvaginal sonography, sagittal view of a cervical pregnancy. Sonographic findings with cervical pregnancy may include: (1) an hourglass uterine shape and ballooned cervical canal; (2) gestational tissue at the level of the cervix (*black arrow*); (3) absent intrauterine gestational tissue (*white arrows*); and (4) a portion of the endocervical canal seen interposed between the gestation and the endometrial canal. **B.** In a transverse view of the cervical pregnancy, Doppler color flow shows abundant vascularization. (Used with permission from Dr. Elysia Moschos.)

cervical pregnancy and a twin cervical pregnancy were recently reported by Shah (2009) and Trojano (2009) and their associates.

Painless vaginal bleeding is reported by 90 percent of women with a cervical pregnancy—a third of these have massive hemorrhage (Ushakov and colleagues, 1997). Only a fourth have abdominal pain with bleeding. As pregnancy progresses, a distended, thin-walled cervix with a partially dilated external os may be evident. Above the cervical mass, a slightly enlarged uterine fundus may be palpated. According to Jeng and colleagues (2007), a 14-week cervical pregnancy is the most advanced case reported. They described experiences with 38 referred cases at a mean of 8.8 weeks and whose serum β-hCG levels ranged from 2800 to 103,000 mIU/mL. Identification of cervical pregnancy is based on speculum examination, palpation, and transvaginal sonography. Findings include an empty uterus and a gestation filling the cervical canal as shown in **Figure 10-12**. Magnetic resonance imaging and three-dimensional sonography have been used to confirm the diagnosis (Bader-Armstrong and associates, 1989; Sherer and colleagues, 2008).

Management

In the past, hysterectomy was often necessary because of profuse hemorrhage that accompanied attempts at cervical pregnancy removal. With hysterectomy, the risk of urinary tract injury is increased because of the enlarged, barrel-shaped cervix. To avoid the morbidity of surgery and sterilization, other approaches have been developed.

Cerclage

Hemorrhage associated with cervical pregnancy can be managed successfully by placing a heavy silk ligature around the cervix (Bachus, 1990; Bernstein, 1981; Fruscalzo, 2008, and all their associates). This is similar to that with a McDonald cerclage discussed in Chapter 9 (p. 219). The suture effectively ligates the bilateral descending cervical branches of the uterine artery at a level above the pregnancy to control bleeding. Mashiach and colleagues (2002) described the successful management and resolution of four cervical pregnancies using a Shirodkar cerclage. In one of these cases, a concurrent intrauterine pregnancy progressed to term, and a healthy infant was delivered vaginally.

Curettage and Tamponade

Nolan (1989) and Thomas (1991) and their associates recommend placement of hemostatic cervical sutures at 3 and 9 o'clock to ligate descending cervical branches of the uterine artery. Suction curettage is then performed, followed immediately by insertion of a Foley catheter into the cervical canal. The 30-mL catheter bulb is inflated, and the vagina is packed tightly with gauze to further tamponade bleeding. A suction catheter tip may be left above the vaginal packing to ensure adequate drainage and to monitor blood loss.

Arterial Embolization

Successful selective preoperative uterine artery embolization has been described by Nakao and colleagues (2008) as well as others. This technique, detailed in Chapter 35 (p. 797), also has been used successfully to control bleeding following medical therapy (Cosin and associates, 1997). Kung and colleagues (2004) employed a combination of laparoscopically assisted uterine artery ligation followed by hysteroscopic endocervical resection to successfully treat six cervical pregnancies.

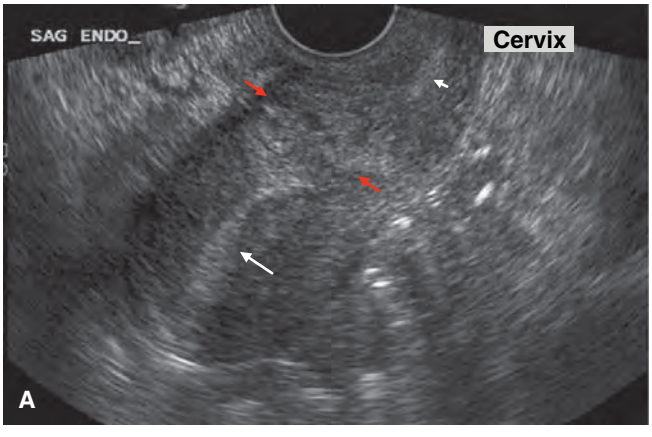
Medical Management

Methotrexate and other medical treatments have been used successfully for cervical pregnancies. In many centers, including ours, methotrexate has become the first-line therapy in the stable woman. The general guidelines for methotrexate use for

ectopic pregnancy are as described earlier (see Table 10-3). The drug has also been injected directly into the gestational sac with or without potassium chloride to induce fetal death (Kaplan, 1990; Marcovici, 1994; Timor-Tritsch, 1994, and all their colleagues).

Pregnancies of more than 6 weeks' duration generally require induction of fetal death with potassium chloride or prolonged methotrexate therapy. Kung and Chang (1999) reviewed 62 cases and reported that women in whom the fetus was alive had a higher failure rate with single-dose methotrexate. Verma and Goharkhay (2009) treated 24 cervical pregnancies with a single-dose intramuscular methotrexate protocol with doses between 50 and 75 mg/m^2. For women in whom fetal cardiac activity was detectable, sonographically guided fetal intracardiac injection of 2 mL (2 mEq/mL) potassium chloride (KCl) solution was added. If β-hCG levels did not decline more than 15 percent after 1 week, a second dose of methotrexate was given to some patients. Here again the experiences of Jeng and colleagues (2007) with 38 referred cases is instructive. Many of these were relatively far advanced—half were >9 weeks and 60 percent had fetal heart action. These women were treated with 50-mg methotrexate injected into the gestational sac with a 22-gauge *needle through the transducer*. If there was cardiac activity, then KCl was injected into the heart or thoracic cavity. Three women developed significant hemorrhage with membrane rupture. An intracervical Foley catheter was placed for tamponade for 3 days, and a second 50-mg methotrexate dose was given intramuscularly. Treatment was successful in all 38 women with a mean resolution of 38 days—range 21 to 68 days. Song and associates (2009) described management of 50 cases with similar results for regression in 30 given methotrexate. They observed that sonographic resolution lagged far behind serum β-hCG regression.

CESAREAN SCAR PREGNANCY (CSP)



Implantation of an otherwise normal pregnancy into a prior cesarean delivery uterine scar was reported more than 30 years ago by Larsen and Solomon (1978). These vary in size and in many ways are similar to a placenta increta with all of its proclivity to cause torrential hemorrhage (see Chap. 35, p. 778).

Incidence

From their reviews, Rotas (2006) and Ash (2007) and their colleagues cite an increasing incidence of cesarean scar pregnancies (CSP) of about 1:2000 pregnancies. This is likely to increase as does the cesarean delivery rate (see Chaps. 25 and 26). Indeed, these may comprise up to 5 percent of ectopic pregnancies in women with at least one prior cesarean delivery. It is not known if the incidence increases with multiple procedures or if it is affected by either one- or two-layer uterine incision closure. At least one case of recurrent scar pregnancy has been described (Holland and Bienstock, 2008).

Clinical Presentation

This varies depending on the gestational age, which ranges from 5 to 6 weeks up to midpregnancy. Pain and bleeding are most common, but up to 40 percent of women are asymptomatic, and the diagnosis is made during routine sonographic examination (Rotas and associates, 2006). In some cases, early rupture leads to an abdominal pregnancy (Teng and co-workers, 2007).

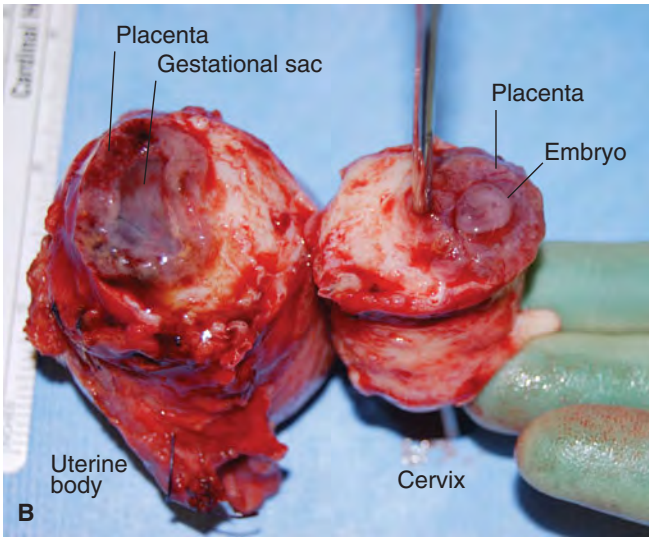


FIGURE 10-13 A. Transvaginal sonogram sagittal view shows a uterus with a cesarean scar pregnancy (CSP). The diagnosis is suggested by criteria that include an empty uterine cavity appearing as a bright hyperechoic endometrial stripe (*long, white arrow*); an empty cervical canal (*short, white arrow*); and an intracavitary mass seen in the anterior wall of the uterine isthmus (*red arrows*). (Courtesy of Dr. Elysia Moschos.) **B.** This hysterectomy specimen with a cesarean scar pregnancy is transversely sectioned at the level of the uterine isthmus and through the gestational sac. The uterine body lies to the left, and the cervix is on the right. A metal probe is placed through the endocervical canal to show the eccentric development of this gestation. Only a thin layer of myometrium overlies this pregnancy, which pushes anteriorly through the uterine wall. (Courtesy of Drs. Sunil Balgobin, Manisha Sharma, and Rebecca Stone.)

Diagnosis and Management

Presentation is too variable to have a concise recommendation for diagnosis. Suffice it to say, a high clinical index of suspicion is warranted in a woman with a prior cesarean delivery. Moschos and associates (2008) have described our experiences from Parkland Hospital with first-trimester sonographic diagnosis, and an example is shown in **Figure 10-13**. Management is gestational-age dependent and includes methotrexate treatment, curettage, hysteroscopic resection, uterine-preserving resection by laparotomy or laparoscopy, a combination of these, or hysterectomy (Ash, 2007; Demirel, 2009; Fylstra, 2003; Halperin, 2009; Rotas, 2006; Wang, 2006, and all their colleagues).

OTHER SITES OF ECTOPIC PREGNANCY

A number of intra-abdominal placental implantations have been cited in case reports. Most are variations on abdominal pregnancy as discussed on page 249. *Splenic pregnancy* has been reported by Mankodi and associates (1977) and Cormio and associates (2003). In their review, Shippey and colleagues (2007) found 14 cases of *hepatic pregnancy*. A few cases of *retroperitoneal pregnancy* have been reported (Goldberg and associates, 2007; Iwama and colleagues 2008). Khalil and associates (2006) found 16 cases of *omental pregnancy* reported since 1903. Although laparotomy is preferred by many for these ectopic abdominal pregnancies, Yi and colleagues (2008) described the laparoscopic excision of an omental pregnancy. Varma and co-workers (2003) described a live-born 35-week infant whose placenta implanted exclusively on the omentum. Fishman and co-workers (1998) described implantation of a 6-week *diaphragmatic pregnancy* in a woman with abdominal and shoulder pain, dyspnea, and a hemothorax.

CHAPTER 11

Gestational Trophoblastic Disease

HYDATIDIFORM MOLE—MOLAR PREGNANCY 257
GESTATIONAL TROPHOBLASTIC NEOPLASIA 261

The term *gestational trophoblastic disease* refers to a spectrum of pregnancy-related placental tumors. Gestational trophoblastic disease is divided into molar and nonmolar tumors. Nonmolar tumors are grouped as *gestational trophoblastic neoplasia.* The American College of Obstetricians and Gynecologists (2004) terms these as *malignant gestational trophoblastic disease.* Although these tumors are histologically distinct and have varying propensities to invade and metastasize, it became evident during the 1970s that histological confirmation was not necessary to provide effective treatment. Instead, a system was adopted based principally on clinical findings and serial serum measurements of human chorionic gonadotropin (β-hCG). A number of schemas have been used over the past 30 years to classify these tumors on the basis of malignant potential, and to direct clinical staging and optimal treatment. The International Federation of Gynecology and Obstetrics (FIGO) trophoblastic disease classification scheme is frequently used (Table 11-1). When these management algorithms are followed, most gestational tumors—both benign and malignant—are eminently curable (Berkowitz and Goldstein, 2009).

HYDATIDIFORM MOLE—MOLAR PREGNANCY

Molar pregnancy is characterized histologically by abnormalities of the chorionic villi that consist of trophoblastic proliferation and edema of villous stroma. Although moles usually occupy the uterine cavity, occasionally they develop as ectopic pregnancies (Abdul and co-workers, 2008; Chauhan and colleagues, 2004). The degree of tissue changes and absence or presence of a fetus or embryonic elements is used to describe them as *complete* or *partial* (Table 11-2).

Complete Hydatidiform Mole

Features of a complete hydatidiform mole are shown in Table 11-2. Grossly, the chorionic villi appear as a mass of clear vesicles (Fig. 11-1). These vary in size from barely visible to a few centimeters and often hang in clusters from thin pedicles. Histologically, they typically show hydropic degeneration and villous edema; absence of villous blood vessels; varying degrees of proliferation of the trophoblastic epithelium; and absence of embryonic elements such as a fetus and amnion.

Ploidy

The chromosomal composition of complete moles is usually diploid and of paternal origin. About 85 percent are 46,XX with both sets of chromosomes paternal in origin (Wolf and Lage, 1995). Termed *androgenesis,* the ovum is fertilized by a haploid sperm, which duplicates its own chromosomes after meiosis. The chromosomes of the ovum are either absent or inactivated. In other complete moles, the chromosomal pattern may be 46,XY due to dispermic fertilization (Bagshawe and Lawler, 1982).

Lawler and colleagues (1991) described 200 molar pregnancies. Of the 151 complete moles, 128 or 85 percent were diploid, 3 were triploid, and 1 was haploid. Of the 49 partial moles, 86 percent were triploid. Niemann and co-workers (2006) approached this another way. They classified 162 moles as diploid and 105 as triploid without regard for other criteria for complete or partial moles. In this study, all persistent or malignant sequelae were in women with diploid moles.

Malignant Potential

Complete molar pregnancy has a higher incidence of malignant sequela compared with partial moles. In most studies, 15 to 20 percent of complete moles had evidence of persistent

TABLE 11-1. Classification of Gestational Trophoblastic Disease

Hydatidiform mole
Complete
Partial
Gestational trophoblastic neoplasia[a]
Invasive mole
Choriocarcinoma
Placental site trophoblastic tumor
Epithelioid trophoblastic tumor

[a]Also called malignant gestational trophoblastic disease. Modified from the International Federation of Gynecology and Obstetrics (FIGO Oncology Committee, 2002).

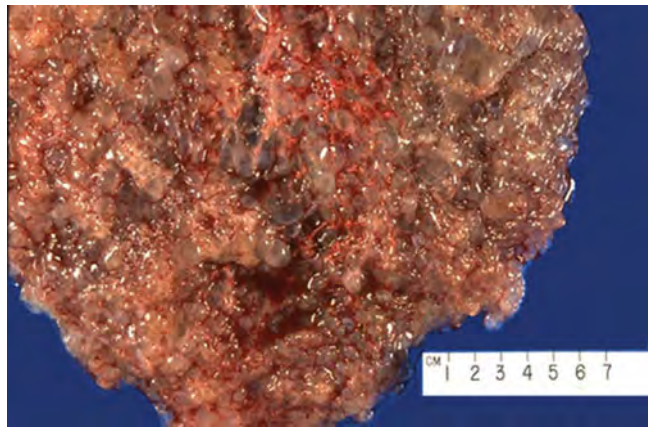

FIGURE 11-1 A complete or classical hydatidiform mole. (Courtesy of Dr. Michael G. O'Connor.)

trophoblastic disease (Kerkmeijer and colleagues, 2006; Soper, 2006). Interestingly, earlier molar evacuation does not lower this risk (Schorge and co-workers, 2000).

Partial Hydatidiform Mole

Features of a partial or incomplete molar pregnancy include some element of fetal tissue and hydatidiform changes that are focal and less advanced. There is slowly progressive swelling within the stroma of characteristically avascular chorionic villi, whereas vascular villi that have a functioning fetal-placental circulation are spared (Shapter and McLellan, 2001).

As shown in Table 11-2, the karyotype typically is triploid—69, XXX, 69,XXY, or much less commonly, 69,XYY. These are each composed of one maternal and two paternal haploid sets of chromosomes (Berkowitz and colleagues, 1986, 1991; Wolf and Lage, 1995). Only 3 of 270 molar pregnancies studied by Niemann and associates (2006) were tetraploid. The nonviable fetus associated with a triploid partial mole typically has multiple malformations (Philipp and co-workers, 2004). In the review by Jauniaux (1999), 82 percent of fetuses had symmetrical growth restriction.

The risk of persistent trophoblastic disease after a partial mole is substantially lower than that following a complete molar pregnancy (Table 11-2). Moreover, persistent disease seldom is choriocarcinoma. Seckl and associates (2000) documented only 3 of 3000 of partial moles to be complicated by choriocarcinoma. Growdon and co-workers (2006) found that higher postevacuation β-hCG levels correlated with increased risk for persistent disease. Specifically, levels ≥ 200 mIU/mL in the third through eighth week postevacuation were associated with at least a 35-percent risk of persistent disease.

Twin Molar Pregnancy

A twin gestation composed of a complete diploid molar pregnancy and a normal pregnancy is not rare (Fig. 11-2). Niemann and associates (2006) reported that 5 percent of diploid moles were part of a twin pregnancy with a fetus. Survival of the normal coexisting fetus is variable and depends on whether the diagnosis is made, and if so, whether problems from the molar component such as preeclampsia or hemorrhage develop. In their review, Vejerslev (1991) found that of 113 such pregnancies, 45 percent progressed to 28 weeks, and of these, 70 percent of neonates survived.

Compared with a partial mole, women with these types of twin pregnancies have a substantive risk of developing subsequent

TABLE 11-2. Features of Partial and Complete Hydatidiform Moles

Feature	Partial Mole	Complete Mole
Karyotype	Usually 69,XXX or 69,XXY	46,XX or 46,XY
Pathology		
Embryo fetus	Often present	Absent
Amnion, fetal red blood cells	Often present	Absent
Villous edema	Variable, focal	Diffuse
Trophoblastic proliferation	Variable, focal, slight to moderate	Variable, slight to severe
Clinical presentation		
Diagnosis	Missed abortion	Molar gestation
Uterine size	Small for dates	50% large for dates
Theca-lutein cysts	Rare	25–30%
Medical complications	Rare	Frequent
Persistent trophoblastic disease	1–5%	15–20%

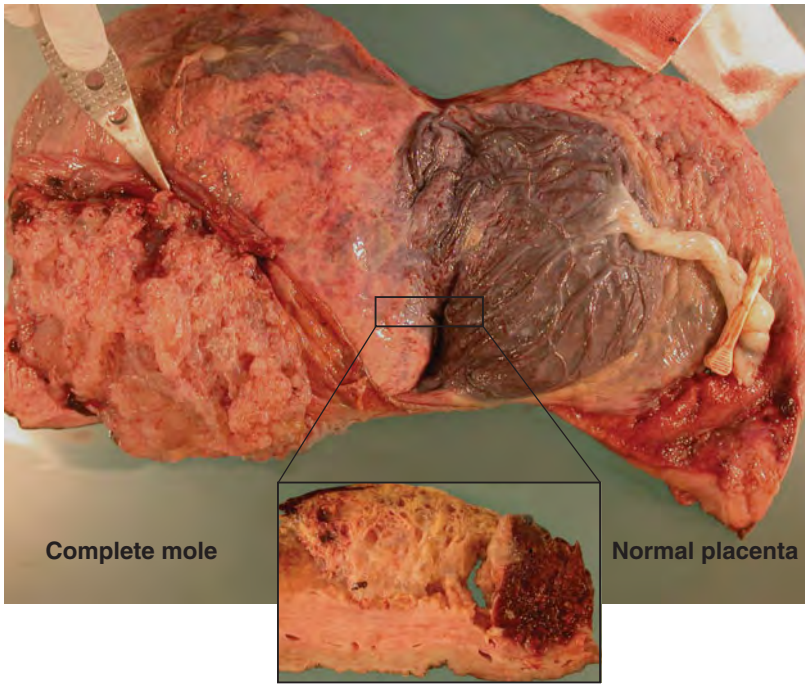

FIGURE 11-2 Photograph of placentas from a twin pregnancy with one normal twin and with a complete mole. The complete mole (*left*) shows the characteristic vesicular structure. The placenta on the *right* appears grossly normal. A transverse section through the border between these two is shown (*inset*). (Courtesy of Drs. April Bleich, Pamela Kothari, and Brian Levenson.)

gestational trophoblastic neoplasia. But this risk does not appear greater than following a singleton complete mole (Niemann and associates, 2007b). In their review of 77 pregnancies, Sebire and colleagues (2002b) reported that 21 percent of pregnancies not terminated subsequently required chemotherapy for persistent disease. This rate is not significantly different from the rate of 16 percent among women who terminate their pregnancies. In the series by Niemann and colleagues (2006), 25 percent of such twin pregnancies subsequently needed chemotherapy.

Histological Diagnosis of Hydatidiform Moles

Histological changes of complete and partial moles are listed in Table 11-2. Attempts to relate the histological structure of individual complete moles to their subsequent malignant potential have generally been disappointing (Fukunaga, 2005; Novak and Seah, 1954; Paradinas, 1997, and all their colleagues).

Cytometry

Moles evacuated early may have not yet developed the histological findings characteristic of their type. Thus, either *flow cytometry* or *automated image cytometry* can be used to determine cellular ploidy (Crisp and associates, 2003; Niemann and colleagues, 2006). Immunostaining techniques are also useful to highlight cells that are of pure paternal derivation from those of both maternal and paternal derivation (Genest and co-workers, 2002; Merchant and associates, 2005).

Theca-Lutein Cysts

In 25 to 60 percent of women with a complete mole, the ovaries contain multiple theca-lutein cysts. These may vary from microscopic to 10 cm or more in diameter. Their surfaces are smooth, often yellowish, and lined with lutein cells. They are thought to result from overstimulation of lutein elements by large amounts of hCG secreted by proliferating trophoblastic cells. Montz and colleagues (1988) reported that persistent gestational trophoblastic disease was more likely in women with theca-lutein cysts, especially if bilateral. This is logical because cysts are more likely with higher serum hCG levels, which may portend a worse prognosis (Niemann and co-workers, 2006). Such cysts are also seen with fetal hydrops, placental hypertrophy, and multifetal pregnancy (see Chap. 5, p. 110). Larger cysts may undergo torsion, infarction, and hemorrhage. Because they regress, oophorectomy is not performed unless the ovary is extensively infarcted.

Epidemiology and Risk Factors

The incidence of hydatidiform mole has been relatively constant in the United States and Europe at 1 to 2 per 1000 pregnancies (Drake and colleagues, 2006; Loukovarra and associates, 2005). It is more prevalent in Hispanics and American Indians (Smith and co-workers, 2006). Until recently, it was held to be much more frequent in some Asian countries however, these data were from hospital studies and thus misleading (Schorge and associates, 2000). In a Korean study, Kim and colleagues (2004) used current terminology and classification and reported a population-based incidence of 2 per 1000 deliveries.

Age

Maternal age at either extreme of the reproductive spectrum is a risk factor for molar pregnancy. Specifically, adolescents and women aged 36 to 40 years have a twofold risk and those over 40 years have an almost tenfold risk (Altman and associates, 2008; Sebire and colleagues, 2002a).

Prior Molar Pregnancy

There is a substantively increased risk for recurrent trophoblastic disease. In a review of 12 series totaling almost 5000 molar pregnancies, the frequency of recurrent moles was 1.3 percent (Loret de Mola and Goldfarb, 1995). The risk is 1.5 percent for a complete mole and 2.7 percent for a partial mole (Garrett and colleagues, 2008). With two prior molar pregnancies, Berkowitz and associates (1998) reported that 23 percent of women had a third mole! Repetitive hydatidiform moles in women with different partners suggest that an oocyte defect leads to molar development.

Other Risk Factors

Oral contraceptive use and its duration as well as previous miscarriage increase the chances for a molar pregnancy as much as

twofold (Palmer and co-workers, 1999). Other studies implicate smoking, various vitamin deficiencies, and increased paternal age.

Clinical Course

The "typical" clinical presentation of women with a molar pregnancy has changed considerably over the past several decades because of earlier diagnosis. Most women present for pregnancy care early and undergo sonography, thus molar pregnancies are detected before they grow to larger sizes with more complications (Kerkmeijer and co-workers, 2009). In many ways, this changing presentation picture is analogous to that of ectopic pregnancy. In general, symptoms tend to be more pronounced with complete moles compared with partial moles (Drake and colleagues, 2006; Niemann and associates, 2007a).

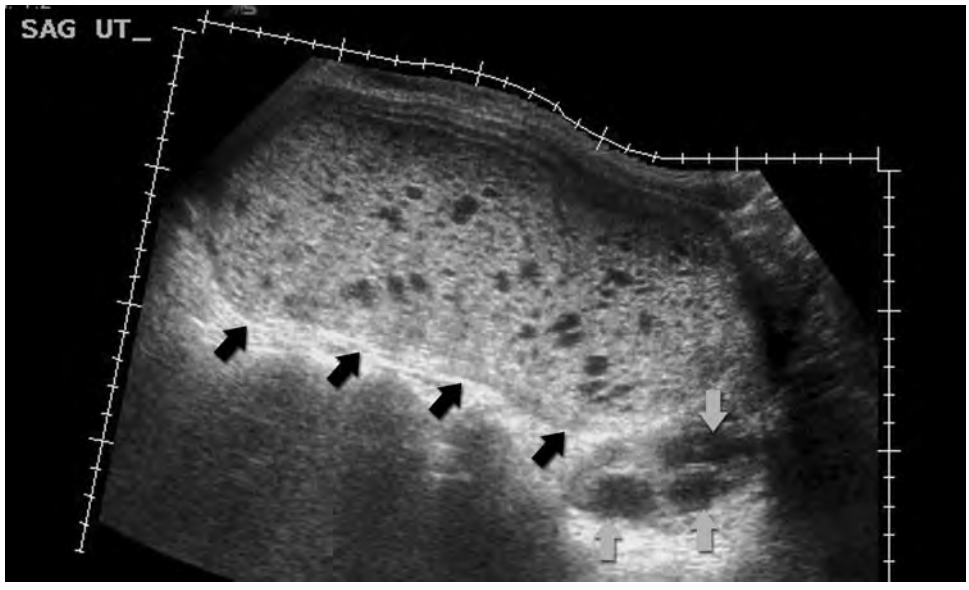

FIGURE 11-3 Sagittal sonogram image of a 20-week-sized uterus with a complete hydatidiform mole (*black arrows*) and associated ovarian theca-lutein cysts (*white arrows*).

Clinical Presentation

There is usually 1 to 2 months of *amenorrhea*. There may be significant *nausea and vomiting*. Eventually, *uterine bleeding* is almost universal and may vary from spotting to profuse hemorrhage. It may begin just before spontaneous molar abortion or more often, follow an intermittent course for weeks to months. In more advanced moles, there may be considerable concealed uterine hemorrhage with moderate iron-deficiency anemia.

In about half of cases, *uterine growth* is more rapid than expected. The uterus has a soft consistency. Large theca-lutein cysts may be difficult to distinguish from the enlarged uterus on bimanual examination. And although the uterus is enlarged, typically no fetal heart motion is detected.

As the consequence of the thyrotropin-like effect of hCG, plasma free thyroxine levels are often elevated and TSH levels are decreased. Despite this, clinically apparent *thyrotoxicosis* is unusual, but thyroid storm has been reported (Chiniwala and colleagues, 2008). In our experiences, the serum free-T_4 levels rapidly normalize after uterine evacuation. Occasionally, *early-onset preeclampsia* develops with a large mole. Because gestational hypertension is rarely seen before 24 weeks, preeclampsia that develops before this time should raise concerns for molar pregnancy. Interestingly, none of the 24 women with a complete mole described by Coukos and colleagues (1999) experienced hyperemesis, clinical thyrotoxicosis, or preeclampsia.

Trophoblastic Deportation or Embolization

Variable amounts of trophoblast escape into the pelvic venous system at the time of molar evacuation (Hankins and colleagues, 1987). In some women, this tissue subsequently invades the pulmonary parenchyma to cause persistent trophoblastic disease or overt metastases. Acutely, the volume of tissue may be sufficient to produce clinically apparent acute pulmonary embolism or edema. Although deportation of massive amounts of trophoblastic tissue is probably uncommon, fatalities have been described (Delmis and co-workers, 2000).

Diagnosis

Some women will present early with spontaneous passage of molar tissue. In most cases, however, there are varying durations of amenorrhea, usually followed by irregular bleeding. These almost always prompt pregnancy testing and sonography. If left untreated, spontaneous expulsion usually occurs around 16 weeks. The characteristic sonographic appearance of a complete mole includes a complex, echogenic uterine mass with numerous cystic spaces and no fetus or amnionic sac (Fig. 11-3). Sonographic features of a partial mole include a thickened, hydropic placenta with fetal tissue (Zhou and co-workers, 2005). Importantly, in early pregnancy, sonography will demonstrate the characteristic appearance in as few as a third of women with a partial mole (John and associates, 2005). Occasionally, molar pregnancy may be confused for a uterine leiomyoma or multifetal pregnancy.

Management

Current mortality rates from molar pregnancies have been practically reduced to zero by prompt diagnosis and appropriate therapy. There are two important basic tenets for management of all molar pregnancies. The first is evacuation of the mole, and the second is regular follow-up to detect persistent trophoblastic disease. Most clinicians obtain a preoperative chest radiograph, but unless there is evidence of extrauterine disease, computed tomography (CT) or magnetic resonance (MR) imaging to evaluate the liver or brain is not done routinely. Laboratory work includes a hemogram to assess anemia, blood type and antibody screen, serum hepatic transaminase levels to assess liver involvement, and a baseline serum β-hCG level (Soper, 2006). That said, Knowles and colleagues (2007) analyzed the

effectiveness of preevacuation testing for suspected molar pregnancy. They concluded that hemogram and blood type with antibody screen alone were appropriate for most patients without suspicious signs or symptoms.

The unusual circumstance of twinning with a complete mole plus a fetus and placenta is problematic, especially if there are no apparent fetal anomalies found with sonography or karyotypic aberrations. Neither maternal risks nor the likelihood of a healthy offspring have been precisely established if pregnancy is continued (Vejerslev, 1991).

Prophylactic Chemotherapy

The long-term prognosis for women with a hydatidiform mole is not improved with prophylactic chemotherapy (Goldstein and Berkowitz, 1995). Because toxicity—including death—may be significant, it is not recommended routinely (American College of Obstetricians and Gynecologists, 2004).

Suction Curettage

Molar evacuation by suction curettage is usually the preferred treatment regardless of uterine size. For large moles, adequate anesthesia and blood-banking support is imperative. With a closed cervix, preoperative dilatation with an osmotic dilator may be helpful (see Chap. 9, p. 229). The cervix is then further dilated to allow insertion of a 10- to 12-mm suction curette. After most of the molar tissue has been removed, oxytocin is given. After the myometrium has contracted, *thorough but gentle curettage* with a large sharp curette usually is performed. We have found that intraoperative sonography helps to ensure that the uterine cavity has been emptied.

Other Methods of Termination

In the United States, only rarely are labor induction or hysterotomy used for molar evacuation. Both will likely increase blood loss and may increase the incidence of persistent trophoblastic disease (American College of Obstetricians and Gynecologists, 2004).

Hysterectomy

If no further pregnancies are desired, hysterectomy may be preferred to suction curettage. It is a logical procedure in women aged 40 and older, because at least a third of these women go on to develop persistent gestational trophoblastic neoplasia. Although hysterectomy does not eliminate this possibility, it markedly reduces its likelihood (Soper, 2006). Finally, hysterectomy is an important adjunct to treatment of chemoresistant tumors (Doumplis and colleagues, 2007; Lurain and associates, 2008).

Postevacuation Surveillance

Consistent follow-up is imperative for women in whom a molar pregnancy has been evacuated. The long-term goal is to ensure complete resolution of trophoblastic disease, with chemotherapy if necessary. The following steps are recommended:

1. Prevent pregnancy for a minimum of 6 months using hormonal contraception.
2. After a baseline serum β-hCG level is obtained within 48 hours *after* evacuation, levels are monitored every 1 to 2 weeks while still elevated. This is important to detect persistent trophoblastic disease. Even small amounts of trophoblastic tissue can be detected by the assay. These levels should progressively fall to an undetectable level as shown in Figure 11-4.
3. Chemotherapy is not indicated as long as these serum levels continue to regress. A rise or persistent plateau demands evaluation for persistent gestational trophoblastic disease and usually treatment. An increase signifies trophoblastic proliferation that is most likely malignant unless the woman is again pregnant.
4. Once the β-hCG level falls to a normal level, serum β-hCG levels are determined monthly for another 6 months. If undetectable, surveillance can then be discontinued and pregnancy allowed.

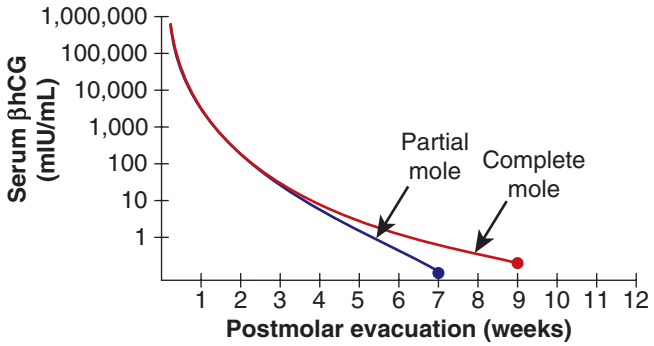

FIGURE 11-4 Schematic illustration of composite medians of β-subunit chorionic gonadotropin regression curves in women with a partial or complete hydatidiform mole. (Composite constructed using median data reported by Golfier (2007), Schlaerth (1981), Wolfberg (2004, 2005, 2006), and all their colleagues.)

Such intensive monitoring has a high noncompliance rate. Fortunately, recent observations indicate that verifying undetectable β-hCG levels for 6 months is likely unnecessary. A number of investigators have reported that no woman with a partial or complete mole whose serum β-hCG levels became undetectable subsequently developed persistent disease (Chan, 2006; Lavie, 2005; Wolfberg, 2004, 2006, and all their colleagues). As shown in Figure 11-4, the median times for this are 7 and 9 weeks, respectively. Although not a routine part of surveillance, postevacuation sonographic uterine examination may reveal myometrial nodules or hypervascularity, which may be associated predictors of subsequent gestational trophoblastic neoplasia (GTN) (Garavaglia and co-workers, 2009).

GESTATIONAL TROPHOBLASTIC NEOPLASIA

This group of placental tumors is characterized by their aggressive invasion into the myometrium and propensity to metastasize. Collectively, they are also termed *malignant gestational trophoblastic disease* by the American College of Obstetricians and Gynecologists (2004). Histologically these tumors include invasive mole, choriocarcinoma, placental site trophoblastic tumor, and epithelioid trophoblastic tumor. Because in most cases they are diagnosed by only persistently elevated serum β-hCG levels, there is no tissue available for pathological study. Criteria for diagnosis of postmolar gestational trophoblastic neoplasia are shown in Table 11-3.

TABLE 11-3. Criteria for Diagnosis of Gestational Trophoblastic Neoplasia or Postmolar Gestational Trophoblastic Disease

1. Plateau of serum β-hCG level (±10 percent) for four measurements during a period of 3 weeks or longer—days 1, 7, 14, 21.
2. Rise of serum β-hCG > 10 percent during three weekly consecutive measurements or longer, during a period of 2 weeks or more—days 1, 7, 14.
3. The serum β-hCG level remains detectable for 6 months or more.
4. Histological criteria for choriocarcinoma.

Criteria of the International Federation of Gynecology and Obstetrics (FIGO Oncology Committee, 2002).

Gestational trophoblastic neoplasia almost always develops with or follows some form of recognized pregnancy. Most follow a hydatidiform mole, but neoplasia may follow an abortion, normal pregnancy, or even an ectopic pregnancy (Cortés-Charry and co-workers, 2006; Nugent and associates, 2006).

Histopathological Classification

As discussed, the diagnosis of neoplasia is usually made by persistently elevated serum β-hCG levels without confirmation by pathological study. Importantly, management is not directed by histological findings.

Invasive Mole

This common manifestation of neoplasia is characterized by excessive trophoblastic overgrowth with extensive tissue invasion by trophoblastic cells and whole villi. There is penetration deep into the myometrium, sometimes with involvement of the peritoneum, adjacent parametrium, or vaginal vault. Such tumors almost always arise from partial or complete moles (Sebire and associates, 2005). They are locally invasive, but generally lack the pronounced tendency to widespread metastasis typical of choriocarcinoma.

Gestational Choriocarcinoma

This extremely malignant tumor may be considered a carcinoma of the chorionic epithelium. It has an incidence of about 1 in 30,000 pregnancies—two thirds develop after a normal delivery and a third follow molar gestations. It should be considered when persistent bleeding follows any pregnancy event (Soper, 2006).

The characteristic gross picture of these tumors is that of a rapidly growing mass invading both myometrium and blood vessels, causing hemorrhage and necrosis (Fig. 11-5). The tumor is dark red or purple and ragged or friable. If it involves the endometrium, then bleeding, sloughing, and infection of the surface usually occur early. Masses of tissue buried in the myometrium may extend outward, appearing on the uterus as dark, irregular nodules that eventually penetrate the peritoneum.

Although cytotrophoblastic and syncytial elements are involved, one or the other may predominate. Microscopically,

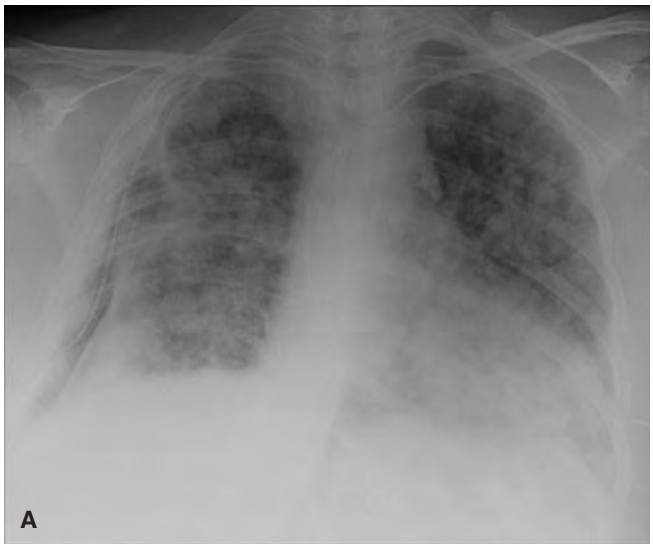

FIGURE 11-5 Choriocarcinoma is evident in the fundus of the hysterectomy specimen. (Courtesy of Dr. Ona Faye-Petersen.)

columns and sheets of these trophoblastic cells penetrate the muscle and blood vessels. They sometimes create a plexiform arrangement and at other times are completely disorganized, interspersed with clotted blood. And, in contrast to hydatidiform or invasive mole, there is not a villous pattern. Factors involved in malignant chorionic transformation are unknown, but its normal predisposition of invasive growth and erosion of blood vessels is greatly augmented.

Metastases often develop early and are generally blood-borne because of the affinity of trophoblastic cells for blood vessels. The most common sites are the lungs in more than 75 percent of cases, and the vagina in about 50 percent. Overall, Berry and colleagues (2008) reported vaginal metastases in 4.5 percent of 806 women with gestational trophoblastic neoplasia. The vulva, kidneys, liver, ovaries, brain, and bowel also may contain metastases (Fig. 11-6). Ovarian theca-lutein cysts are identified in over a third of cases.

Placental Site Trophoblastic Tumor

The rare variant of trophoblastic neoplasia arises from the placental implantation site following normal term pregnancy, spontaneous or induced abortion, or an ectopic or molar pregnancy (Feltmate and colleagues, 2001; Moore-Maxwell and Robboy, 2004). Histologically, there are intermediate trophoblastic cells, many of which are prolactin producing (Miller and associates, 1989). For this reason, serum β-hCG levels are relatively low compared with tumor mass. A high proportion of free β-hCG—over 30 percent—is accurate for diagnosis of this tumor (Cole and colleagues, 2008). Bleeding is the main presenting symptom. Locally invasive tumors are resistant to

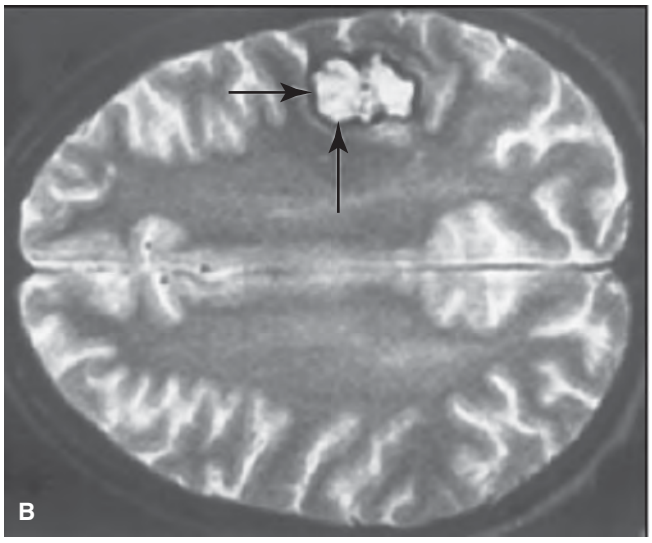

FIGURE 11-6 Metastatic choriocarcinoma. **A.** Chest radiograph demonstrates widespread metastatic lesions. (Courtesy of Dr. Michael G. O'Connor.) **B.** Cranial MRI scan shows a large metastasis on the left (*black arrows*). (Courtesy of Dr. Ilana Ariel.) **C.** Autopsy specimen shows multiple hemorrhagic hepatic metastasis. (Courtesy of Dr. Michael G. O'Connor.)

chemotherapy and hysterectomy is the best treatment (Baergen and associates, 2006). Cases managed without hysterectomy have been reported (Numnum and co-workers, 2006).

Epithelioid Trophoblastic Tumor

This rare trophoblastic tumor is distinct from gestational choriocarcinoma and placental site trophoblastic tumor (Macdonald and colleagues, 2008). In their recent review, Palmer and associates (2008) found only 52 reported cases. The preceding pregnancy event may be remote or, in some cases, cannot be confirmed. Epithelioid trophoblastic tumor develops from neoplastic transformation of chorionic-type intermediate trophoblast. Microscopically, it resembles placental site trophoblastic tumor, but the cells are smaller and display less nuclear pleomorphism (Allison and co-workers, 2006). Grossly, the tumor grows in a nodular fashion rather than the infiltrative pattern of placental site tumor. Hysterectomy is the primary method of treatment, but approximately a fourth of these women present with metastatic disease. There are too few reported cases to evaluate the efficacy of chemotherapy.

Clinical Course

The most common finding with gestational trophoblastic neoplasms is irregular bleeding associated with uterine subinvolution. The bleeding may be continuous or intermittent, with sudden and sometimes massive hemorrhage. Myometrial perforation from trophoblastic growth may cause intraperitoneal hemorrhage (Hancock and Tidy, 2002). Some women present with metastatic lesions to the vagina or vulva. In others, the uterine tumor has disappeared, leaving only distant metastases. If untreated, choriocarcinoma is invariably fatal.

Diagnosis

Consideration for the possibility of gestational trophoblastic neoplasia is the most important factor in diagnosis. Unusually persistent bleeding after pregnancy of any type should prompt measurement of serum β-hCG levels and consideration for diagnostic curettage. Persistent or rising serum β-hCG levels in the absence of pregnancy are indicative of trophoblastic neoplasia.

After thorough pelvic assessment, then hemogram, renal and liver function studies, and chest radiograph are obtained (Darby and associates, 2009). Solitary or multiple pulmonary nodules are suggestive of metastasis and should prompt further imaging of the brain, abdomen, and pelvis (Garner and colleagues, 2004). The threshold for additional imaging beyond chest radiograph should be low. Moodley and Moodley (2004) described three women with normal chest radiograph readings but who had lung metastases identified with CT-scanning. Positron emission

computed tomography (PET/CT) scanning may also be useful (Niemann and co-workers, 2006).

Staging and Prognostic Scoring

Clinical staging is similar to that for ovarian cancer except that stage III allows pulmonary involvement. Risk assessment is done using the modified World Health Organization (WHO) Prognostic Scoring System (FIGO Oncology Committee, 2002). Scores of 0 to 4 are given for each category that includes age; type of antecedent pregnancy and interval from it; serum β-hCG concentration; size of tumor, its site, and the number of metastases; and previous chemotherapy. When summed, low-risk neoplasia generally includes cumulative scores of 0 to 6. Kohorn (2007) has proposed a dynamic scoring system that includes tumor response.

Treatment

In general, oncology referral is preferable. Single-agent chemotherapy is given for nonmetastatic or low-risk metastatic neoplasia (Horowitz and co-workers, 2009). Abrão and colleagues (2008) reviewed 108 low-risk cases and found methotrexate or actinomycin D alone equally effective compared with a combination of the two. Methotrexate is less toxic than actinomycin D, but both are usually curative (Chan and colleagues, 2006; Schorge and colleagues, 2008). There is no need for hospitalization to begin initial therapy (Carter and colleagues, 2008). Virtually all women with nonmetastatic tumors or low-risk gestational trophoblastic neoplasia are cured with these if treated early. In 150 women with low-risk GTN, Growden and co-workers (2009) found that metastatic disease, single-day methotrexate infusion, and complete mole histology were risk factors for additional chemotherapy beyond the first course.

Repeat curettage may cause perforation and is avoided unless there is bleeding or a substantial amount of retained molar tissue. On the other hand "debulking" by curettage hastens response (van Trommel and co-workers, 2005). For women who have completed childbearing, hysterectomy is an option. Carlini and colleagues (2006) reported a woman who responded to chemotherapy after selective uterine artery embolization for heavy vaginal bleeding.

Chemotherapy subsequent to the initial dose is guided by serial serum β-hCG levels. Of note, failure may be falsely assumed when *phantom hCG* caused by heterophilic antibodies interferes with the hCG assay (American College of Obstetricians and Gynecologists, 2004).

Women are classified as high risk when the modified WHO prognostic score is 7 or greater. In these women, combination chemotherapy—with its increased toxicity—has produced cure rates between 67 and 85 percent (Lurain and co-workers, 2006a; Soper, 2006). One is the *EMA-CO regimen—E*toposide, *M*ethotrexate, *A*ctinomycin D, *C*yclophosphamide, and *O*ncovin (vincristine). Surgery and radiotherapy are also frequently employed (Lurain and co-workers, 2006b).

Subsequent Pregnancy

Surveillance is, at a minimum, 6 months for molar pregnancy, 1 year for gestational trophoblastic neoplasia, and up to 2 years if there are metastases. Fertility is not impaired, and pregnancy outcomes are usually normal following successful treatment (Schorge and associates, 2000). The primary concern is the 2-percent risk for developing trophoblastic disease in a subsequent pregnancy (Garrett and colleagues, 2008).

CHAPTER 12

Genetics

CHROMOSOMAL ABNORMALITIES 266
MODES OF INHERITANCE 275
GENETIC TESTS 282

Genetics is the branch of science that deals with genes, heredity, and the variation of inherited characteristics. *Medical genetics* is the study of the etiology, pathogenesis, and natural history of human diseases that are at least partially genetic in origin. Diagnosis, management, and prevention of such diseases are also part of this field.

Genetic disease is common. Between 2 and 3 percent of newborns have a recognized structural defect, another 3 percent have a defect diagnosed by age 5, and by age 18, another 8 to 10 percent are discovered to have one or more functional or developmental abnormalities. Added to these is the susceptibility to many common diseases that have a genetic basis as well as most cancers, which develop as the result of cumulative mutations. All in all, an astounding two thirds of the population will experience a disease with a genetic component in their lifetimes. Tests available for the prenatal diagnosis of selected genetic diseases and the rationale accompanying their use are described throughout Chapter 13.

The *Human Genome Project,* supported principally by the National Human Genome Research Institute, accomplished complete sequencing of the human genome in 2003. Efforts have since focused on *genomics*, the study of functions and interactions of all genes, to better understand the biology of disease (Burke, 2003; McKusick and Ruddle, 2003). The *Online Mendelian Inheritance in Man—OMIM* was developed in 1985 by the National Library of Medicine in collaboration with Johns Hopkins University. In 1995, it was developed for the World Wide Web by the National Center for Biotechnology Information. It is an up-to-date compendium of human genes and phenotypes. As of April 2009, the OMIM listed more than 12,700 unique genes with known sequence. Of these, greater than 12,000 are autosomal dominant or recessive, more than 600 are X- or Y-linked, and 37 are mitochondrial. OMIM has also catalogued more than 2800 mendelian conditions that either have a known molecular basis or have an identified responsible gene that has been sequenced. And finally, the catalogue has more than 1500 conditions for which the molecular basis remains unknown. In the future, it is likely that consideration of individual genetic background and specific traits and susceptibilities will enhance routine medical care. From the foregoing, it is obvious that knowledge of genetic principles is essential for all clinicians.

CHROMOSOMAL ABNORMALITIES

The 22 pairs of autosomes and one pair of sex chromosomes can be affected by a wide range of numerical and structural abnormalities that profoundly affect gene expression.

Standard Nomenclature

Karyotypes are reported using nomenclature agreed upon by the genetics community and codified as the International System for Human Cytogenetic Nomenclature (ISCN, 2009). Karyotypic abnormalities fall into two broad categories—those of chromosome *number*, such as *trisomy*, and those of chromosome *structure*, such as a *translocation* or *deletion*. Each chromosome has a short arm—the "p" or *petit* arm and a long arm—the "q" arm—named for the next letter in the alphabet. The two arms are separated by the centromere. When reporting a karyotype, the total number of chromosomes is listed first, corresponding to the number of centromeres present. This is followed by the sex chromosomes—XX or XY, and then by a description of any structural variation or abnormality. Specific abnormalities are indicated

TABLE 12-1. Examples of Karyotype Designations Using the International System for Human Cytogenetic Nomenclature (2009)

Karyotype	Description
46,XY	Normal male chromosome constitution
47,XX,+21	Female with trisomy 21
47,XY,+21/46,XY	Male who is a mosaic of trisomy 21 cells and cells with normal constitution
46,XY,del(4)(p14)	Male with terminal deletion of the short arm of chromosome 4 at band p14
46,XX,dup(5)(p14p15.3)	Female with duplication of the short arm of chromosome 5 from band p14 to band p15.3
45,XY,der(13;14)(q10;q10)	Male with a "balanced" Robertsonian translocation of the long arms of chromosomes 13 and 14; the karyotype now has one normal 13, one normal 14, and the translocation chromosome, thereby reducing the chromosome number by 1 (to 45)
46,XY,t(11;22)(q23;q11.2)	Male with a balanced reciprocal translocation between chromosomes 11 and 22; breakpoints are at 11q23 and 22q11.2
46,XX,inv(3)(p21q13)	Inversion of chromosome 3 that extends from p21 to q13—because it includes the centromere, this is a pericentric inversion
46,X,r(X)(p22.1q27)	Female with one normal X chromosome and one ring X chromosome; the breakpoints indicate that the regions distal to p22.1 and q27 are deleted from the ring
46,X,i(X)(q10)	Female with one normal X chromosome and an isochromosome of the long arm of the X chromosome

Adapted from Jorde and colleagues (2006), courtesy of Dr. Fred Elder.

by standard abbreviations, such as *dup (duplication), del (deletion),* and *t (translocation)*. The region or bands of the p or q arms affected are then specifically designated. Some examples of standard nomenclature for writing a karyotype are shown in Table 12-1.

Chromosomal abnormalities figure prominently in assessments of the impact of genetic disease, accounting for 50 percent of embryonic deaths, 5 to 7 percent of fetal losses, 6 to 11 percent of stillbirths and neonatal deaths, and 0.9 percent of live births (Hook, 1992; Jacobs and colleagues, 1992; Tolmie, 1995).

Abnormalities of Chromosome Number

The most easily recognized chromosomal abnormalities are numerical. *Aneuploidy* is inheritance of an extra chromosome—*trisomy,* or loss of a chromosome—*monosomy*. These differ from *polyploidy*, which is characterized by an abnormal number of an entire haploid chromosomal set—for example, triploidy, which is discussed below. The estimated incidence of aneuploidy and other chromosomal abnormalities is shown in Table 12-2.

Autosomal Trisomies

In most cases, trisomy results from meiotic *nondisjunction*, in which chromosomes: (1) fail to pair up, (2) pair up properly but separate prematurely, or (3) fail to separate. The risk of autosomal trisomy increases with maternal age as shown in Figure 12-1. Oocytes are held suspended in midprophase of meiosis I from birth until ovulation—in some cases for 50 years. Aging is thought to break down chiasmata that keep paired chromosomes aligned. When meiosis is completed at the time of ovulation, nondisjunction causes one gamete to have two copies of the affected chromosome. And if fertilized, trisomy will result. The other gamete receives no copies and is monosomic if fertilized.

Male and female gametes are affected at different frequencies—3 to 4 percent of sperm and 10 to 20 percent of oocytes are aneuploid because of meiotic errors. Although each chromosome pair is equally likely to have a segregation error, only trisomies 21, 18, and 13 can result in a term pregnancy. And many fetuses with these common trisomies will be lost before term. Snijders and colleagues (1999) reported that with trisomy 21, the fetal death rate was 30 percent between 12 and 40 weeks and about 20 percent between 16 and 40 weeks. Other trisomies have severe abnormalities, resulting in even higher rates of pregnancy loss (Fig. 12-2). For example, trisomy 1 has never been reported. Trisomy 16 accounts for 16 percent of all first-trimester losses but is never seen later.

Trisomy 21. In 1866, J. L. H. Down described a group of mentally retarded children with distinctive physical features. Nearly

TABLE 12-2. Frequency and Distribution of Chromosomal Abnormalities

	Frequency (Percent)		
Abnormality	**Abortion**	**Stillborn**	**Liveborn**
Trisomy, all types	25	4	0.3
Sex chromosomal monosomy	8.7	0.1	0.05
Triploidy	6.4	0.2	—
Tetraploidy	2.4	—	—
Structural	2	0.8	0.5
Total	~50	~5	~0.9

100 years later, Lejeune and colleagues (1959) discovered that *Down syndrome* is caused by trisomy 21. The karyotype for trisomy 21, shown in **Figure 12-3**, occurs overall in 1 in 800 to 1000 newborns. Because it is the most common nonlethal trisomy, it is the focus of most genetic screening and testing protocols (see Chap. 13, p. 292). About 95 percent of Down syndrome cases result from maternal nondisjunction of chromosome 21 to 75 percent during meiosis I and 25 percent during meiosis II. The remaining 5 percent of Down syndrome cases result from mosaicism or a translocation, which is discussed below.

Some typical Down syndrome characteristics in newborns are shown in **Figure 12-4**. These infants have epicanthal folds with up-slanting palpebral fissures, a flat nasal bridge, a small head with flattened occiput, and marked hypotonia with tongue protrusion. There is frequently loose skin at the nape of the neck, as well as short fingers, a single palmar crease, hypoplasia of the middle phalanx of the fifth finger, and a prominent space or "sandal-toe-gap" between the first and second toes. Associated major abnormalities that may be visualized by sonographic examination include cardiac anomalies, particularly endocardial cushion defects, and gastrointestinal anomalies such as duodenal atresia (see Fig. 16-19, p. 359).

Children with Down syndrome have an increased incidence of leukemia and thyroid disease. Their intelligence quotient (IQ) ranges from 25 to 50, with a few individuals testing higher. Most affected children have social skills averaging 3 to 4 years ahead of their mental age.

Recurrence Risk. With a pregnancy complicated by trisomy 21 from nondisjunction, the woman has an approximate 1-percent risk for any trisomy in a subsequent pregnancy. This pertains until it is exceeded by her age-related risk, after which, her age-related risk predominates. Because of this risk, invasive prenatal diagnosis is offered as discussed in Chapter 13 (p. 299). Parental chromosomal studies are not necessary unless the trisomy was due to an unbalanced translocation. Females with Down syndrome are fertile, and approximately a third of their offspring will have Down syndrome (Scharrer and colleagues, 1975). Down syndrome males have markedly decreased spermatogenesis and are almost always sterile. That said, a few cases

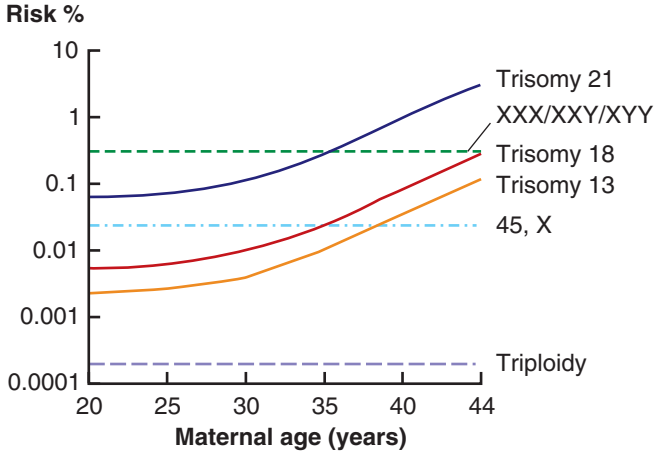

FIGURE 12-1 Maternal age-related risk for selected aneuploidies. (Redrawn from Nicolaides, 2004, with permission.)

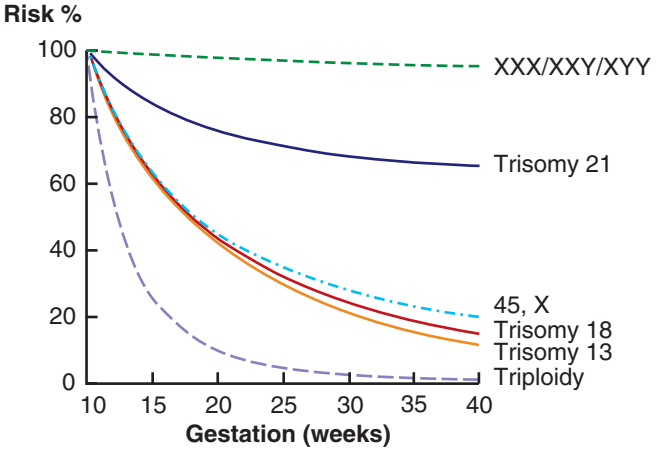

FIGURE 12-2 Gestational-age-related risk for selected chromosomal abnormalities, relative to the risk at 10 weeks' gestation. (Redrawn from Nicolaides, 2004, with permission.)

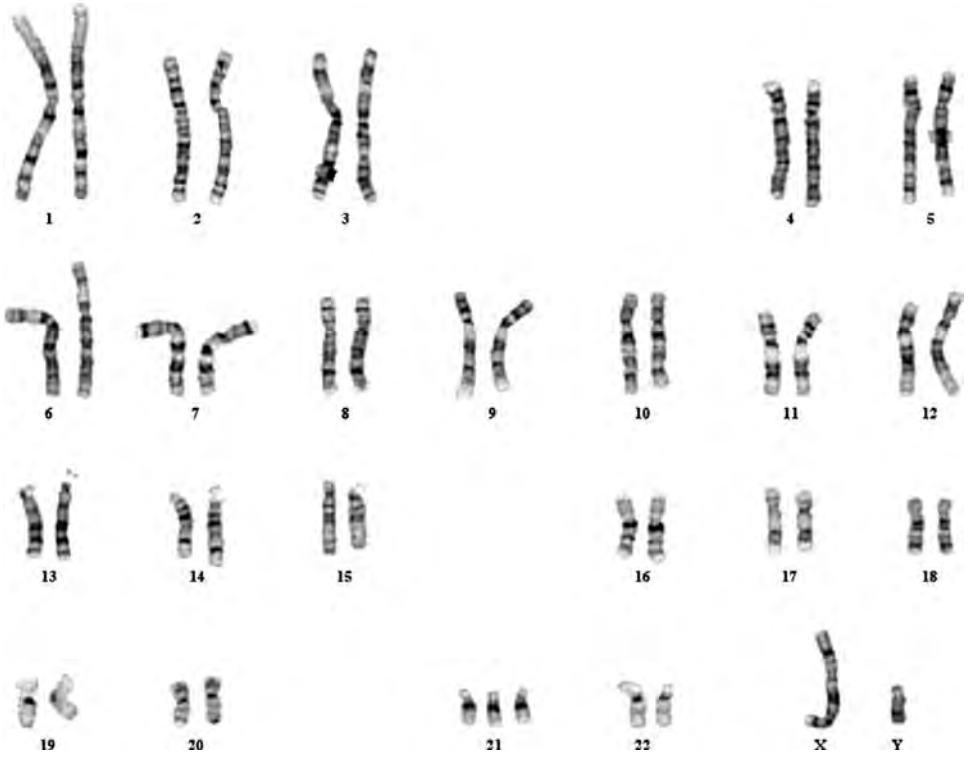

FIGURE 12-3 Abnormal male karyotype with trisomy 21, consistent with Down syndrome (47,XY, + 21). (Used with permission from Dr. Frederick Elder.)

of reproduction have been reported (Pradhan and co-workers, 2006; Zuhlke and co-workers, 1994).

Trisomy 18. Also known as *Edwards syndrome,* trisomy 18 has an overall frequency of 1 in 8000 newborns and is three to four times more common in females. As with other aneuploidies, its incidence is much higher in the first trimester, and 85 percent of fetuses die between 10 weeks and term (Fig. 12-2). Trisomy 18 fetuses usually are growth restricted, with a mean birthweight of 2340 g reported by Snijders and colleagues (1995).

Striking facial features include prominent occiput, rotated and malformed ears, short palpebral fissures, and a small mouth. The hands are often clenched, with the second and fifth fingers overlapping the third and fourth (Jones, 1997). Virtually every organ system can be affected by trisomy 18. Almost 95 percent have cardiac defects—most commonly ventricular or atrial septal defects or patent ductus arteriosus. Other anomalies include horseshoe kidney, radial bone aplasia, hemivertebrae, hernias, diastasis, and imperforate anus. These infants are usually frail and have frequent apneic spells. In a report from the National Center

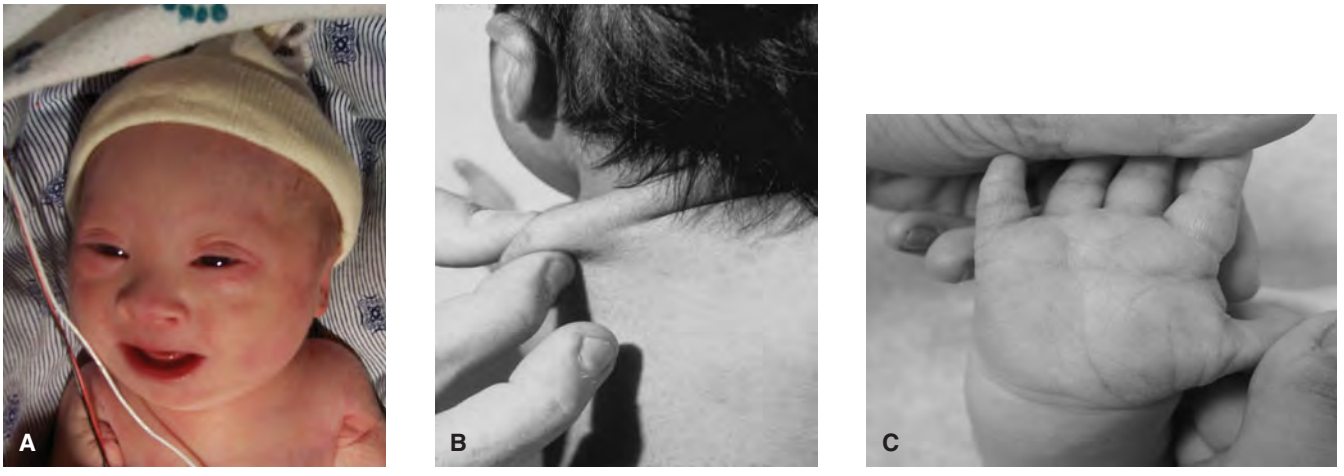

FIGURE 12-4 Trisomy 21—Down Syndrome. **A.** Characteristic facial appearance. **B.** Redundant nuchal tissue. **C.** Single transverse palmar crease. (Photographs courtesy of Dr. Charles P. Read and Dr. Lewis Weber.)

on Birth Defects and Developmental Disabilities, Rasmussen and associates (2003) described a median survival of 14 days. Up to 10 percent survived to 1 year, and rare reports describe profoundly retarded survivors older than 10 years.

If the pregnancy is continued, mode of delivery should be discussed in advance because these fetuses commonly have fetal heart rate abnormalities during labor. Indeed, in years past, more than half of undiagnosed cases were delivered by cesarean for "fetal distress" (Schneider and colleagues, 1981).

Trisomy 13. Known as *Patau syndrome,* trisomy 13 has an incidence of approximately 1 in 20,000 births. Common abnormalities include cardiac defects in 80 to 90 percent and holoprosencephaly in 70 percent. The latter may be accompanied by microcephaly, hypotelorism, and pronounced abnormalities of the orbits, nose, and palate. Affected fetuses also may have abnormal ears, an omphalocele, polycystic kidneys, radial bone aplasia, areas of skin aplasia, and polydactyly. In a review of 70 live-born infants with trisomy 13, Rasmussen and colleagues (2003) found a median survival of 7 days, and up to 10 percent survived to 1 year. Counseling regarding prenatal diagnosis and delivery is approached as described with trisomy 18.

Trisomy 13 is the only aneuploidy that has been associated with an increased risk for preeclampsia. Accompanied by hyperplacentosis, preeclampsia develops in up to half of pregnancies with trisomy 13 carried beyond the second trimester (Tuohy and James, 1992). Interestingly, chromosome 13 contains a gene for an angiogenic protein associated with preeclampsia—*soluble fms-like tyrosine kinase-1—sFlt-1* (see also Chap. 34, p. 714). Bdolah and colleagues (2006) found that mothers carrying trisomy 13 fetuses had increased levels of sFlt-1 early in pregnancy, which may be explained by the extra copy of chromosome 13. These investigators hypothesized that this may be the etiology of preeclampsia in such cases.

Other Trisomies. It is rare to see live-born neonates with other autosomal trisomies, although mosaicism involving a few other autosomal chromosomes has been reported.

Monosomy

Nondisjunction creates an equal number of nullisomic and disomic gametes. There is, however, no recognized association between maternal age and monosomy. This likely is because *autosomal monosomy* is almost universally incompatible with life, and thus monosomic conceptuses die before implantation (Garber and co-workers, 1996). As a rule, missing chromosomal material is more devastating than having extra chromosomal material. The one exception is *monosomy X—Turner syndrome,* which is discussed below.

Polyploidy

This is an abnormal number of complete haploid chromosomal sets. Polyploidy accounts for about 20 percent of abortions and is rarely seen in later pregnancies. Two thirds of *triploidy* cases result from fertilization of one egg by two sperm. The other third are caused by failure of one of the meiotic divisions, leading to a diploid chromosomal complement in either the egg or more frequently, the sperm. The origin of the extra set of chromosomes determines the phenotype. If the extra chromosomes are paternal—*diandric*, the result is usually a partial hydatidiform mole with abnormal fetal structures (see Chap. 11, p. 258). If the extra set of chromosomes is maternal—*digynic*, a fetus and placenta develop, but the fetus is severely growth restricted. Triploid fetuses of either kind are frequently dysmorphic.

If a woman has a triploid fetus that survived past the first trimester, the recurrence risk is 1 to 1.5 percent (Gardner and Sutherland, 1996). Thus, prenatal diagnosis is offered in subsequent pregnancies (see Chap. 13, p. 296).

Tetraploidy always results in 92,XXXX or 92,XXYY, suggesting a postzygotic failure to complete an early cleavage division (Nussbaum and colleagues, 2007). The conceptus invariably succumbs, and the recurrence risk for tetraploidy is minimal.

Sex Chromosome Abnormalities

45,X

Also called *Turner syndrome,* this is the only monosomy compatible with life. It is the most common aneuploidy in abortuses and accounts for 20 percent of first-trimester losses. Its prevalence is about 1 in 5000 liveborns (Sybert and McCauley, 2004).

There are three distinct phenotypes seen with 45,X. At least 98 percent of conceptuses are so abnormal that they abort early. The second phenotype is often identified by abnormal sonographic findings, which include cystic hygromas (see Fig. 16-12, p. 356). These frequently are accompanied by hydrops progressing to fetal demise. The third, and least common, phenotype is found in those born alive. Their features include short stature, broad chest with widely spaced nipples, congenital lymphedema with puffy fingers and toes, low hairline with webbed posterior neck, and minor bone and cartilage abnormalities. Between 30 and 50 percent have a major cardiac malformation, usually aortic coarctation or bicuspid aortic valve. Intelligence is generally in the normal range, although individuals frequently have visual-spatial organization deficits and difficulty with nonverbal problem solving and with interpretation of subtle social cues (Jones, 2006). Over 90 percent also have ovarian dysgenesis and require lifelong hormone replacement beginning just before adolescence.

The reason for the wide range in phenotypes is that approximately half of live-born infants with Turner syndrome have mosaicism. In such cases, there are two or more populations of cells—for example, 45,X/46,XX or 45,X/46,XY (Saenger, 1996; Sybert and McCauley, 2004). Sometimes mosaicism is detected in peripheral blood cells, and other times it is expressed only in tissues that are not routinely tested (Fernandez, 1996; Kim, 1999; Nazarenko, 1999, and all their colleagues). For reasons that are not clear, the missing X chromosome is paternally derived in 80 percent of cases (Cockwell and colleagues, 1991; Hassold and associates, 1991).

47,XXX

Approximately 1 in every 1000 female infants has an additional X chromosome—47,XXX. The extra X is maternally derived in more than 90 percent of cases (Milunsky and Milunsky, 2004). Fetuses with XXX do not have an increased incidence of anomalies, and infants do not have any unusual phenotypic features. There is variability in clinical presentation.

Tall stature is common, pubertal development is normal, and fertility is typically normal, although premature ovarian failure has been reported (Holland, 2001). Mental retardation is not a feature of XXX, but these children are at increased risk for a delay in language development and motor skills (Linden and Bender, 2002).

Females with four or five X chromosomes—48,XXXX or 49,XXXXX—are likely to have physical abnormalities apparent at birth. They exhibit varying degrees of mental retardation, and for both males and females, the IQ drops with each additional X chromosome.

47,XXY

Known as *Klinefelter syndrome*, 47,XXY is the most common sex chromosome abnormality. It occurs in approximately 1 per 600 male infants and results from addition of an extra X chromosome to a normal male karyotype. In approximately 50 percent of cases, the extra X chromosome is maternally derived, and in approximately 50 percent, it is paternal (Milunsky and Milunsky, 2004). There is a slight association with both advanced maternal or paternal age (Jacobs and Hassold, 1995; Lowe and colleagues, 2001).

As with XXX, fetuses with XXY do not have an increased incidence of anomalies, and infants do not have any unusual phenotypic features. Boys are typically tall, but although prepubertal development is normal, they do not virilize and thus require testosterone replacement. They have small testes, are infertile as a result of gonadal dysgenesis, and may develop gynecomastia. Mental retardation is not a feature of XXY. In general, IQ scores are within the normal range, although delays in speech, reading, and motor skills are not uncommon.

47,XYY

This aneuploidy occurs in about 1 in 1000 male infants. The extra Y chromosome is of course paternally derived, and there is no association with paternal age (Milunsky and Milunsky, 2004). The incidence of anomalies is not increased, and there are no unusual phenotypic features. Affected individuals tend to be tall, they have normal puberty, and fertility is unimpaired. Early reports indicating that XYY was associated with criminal or violent behavior suffered from ascertainment bias. Children are at increased risk for speech and neuromotor development problems but not for mental retardation. Linden and Bender (2002) followed a series of children prenatally diagnosed with XYY and found their mean IQ scores to be above average.

Males with more than two Y chromosomes—48,XYYY—or with both additional X and Y chromosomes—48,XXYY or 49,XXXYY—have obvious physical abnormalities and significant mental retardation.

Abnormalities of Chromosome Structure

Structural chromosome abnormalities include deletions, duplications, and microdeletions/microduplications; Robertsonian and reciprocal translocations; isochromosomes; paracentric and pericentric inversions; ring chromosomes; and mosaicism. Each is described using the terminology shown in Table 12-1. In general, identification of a fetus with a structural chromosomal abnormality raises two questions:

1. What phenotypic abnormalities or later developmental abnormalities are associated with this finding?
2. Is parental karyotyping indicated—specifically, are the parents at increased risk to carry this abnormality? If so, what is their risk to have future affected offspring?

Deletions and Duplications

A deletion simply means that a portion of a chromosome is missing. A duplication means that a portion of a chromosome has been included twice. These errors are described by the location of the two break points within the chromosome. Some deletions involve segments of DNA large enough to be seen with standard cytogenetic karyotyping. Common deletions are often referred to by eponyms—one example is *del 5p,* which also is called *cri du chat syndrome.*

Most deletions and duplications occur during meiosis and result from malalignment or mismatching during pairing of homologous chromosomes. If the two chromosomes are not aligned properly, the malaligned segment may be deleted as shown in Figure 12-5. If the mismatch remains and the two chromosomes recombine, the result may be a deletion in one and a duplication in the other. If a deletion or duplication is identified in a fetus or child, the parents should be tested to

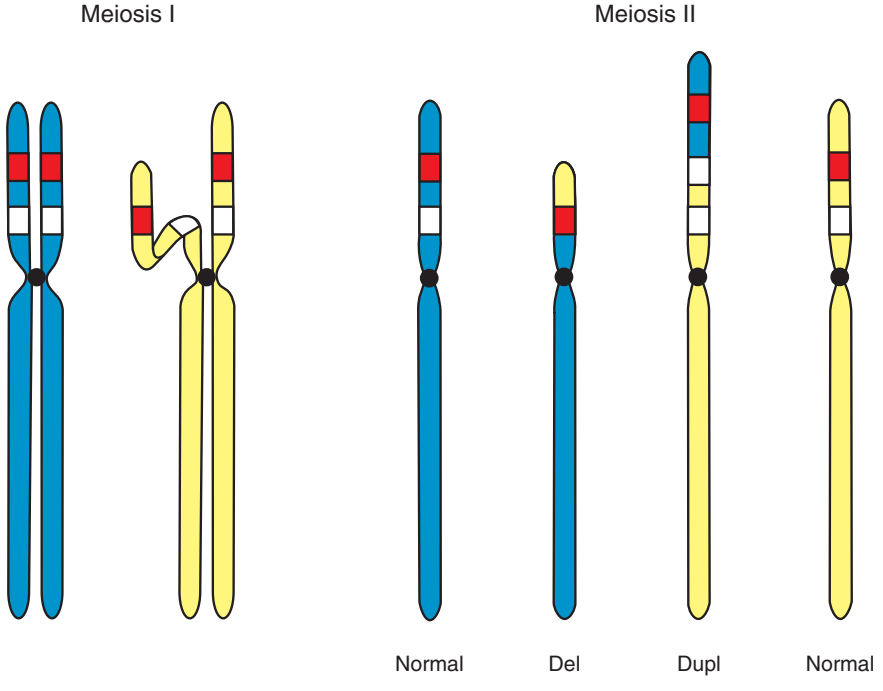

FIGURE 12-5 A mismatch during pairing of homologous chromosomes may lead to a deletion in one chromosome and a duplication in the other. (del = deletion; dup = duplication.)

TABLE 12-3. Some Microdeletion Syndromes Detectable by Fluorescence in-Situ Hybridization

Syndrome	Features	Location
Alagille	Dysmorphic facies, cholestatic jaundice, pulmonic stenosis, butterfly vertebrae, absent deep tendon reflexes, poor school performance	20p11.23–20p12.2
Angelman	Dysmorphic facies—"happy puppet" appearance, mental retardation, ataxia, hypotonia, seizures	15q11.2–q13 (maternal genes)
Cri du chat	Growth restriction, hypotonia, severe mental retardation, abnormal laryngeal development with "cat-like" cry	5p15.2–15.3
Kallmann 1	Hypogonadotropic hypogonadism and anosmia	Xp22.3
Miller-Dieker	Severe neuronal migration abnormalities with lissencephaly, microcephaly, failure to thrive, dysmorphic facies	17p13.3
Prader-Willi	Obesity, hypotonia, mental retardation, short stature, hypogonadotropic hypogonadism, small hands and feet	15q11.2–q13 (paternal genes)
Saethre-Chotzen	Acrocephaly, asymmetry of the skull and face, partial syndactyly of fingers and toes	7p21.1
Smith-Magenis	Dysmorphic facies, speech delay, hearing loss, sleep disturbances, self-destructive behaviors	17p11.2
Velocardiofacial/ DiGeorge	May include conotruncal cardiac defects, cleft palate, velopharyngeal incompetence, thymic and parathyroid abnormalities, learning disability, characteristic facial appearance	22q11.2
Williams-Beuren	Aortic stenosis, peripheral pulmonary arterial stenoses, elfin facies, mental retardation, short stature, infantile hypercalcemia	7q11.23
Wolf-Hirschhorn	Dysmorphic facies, severe mental retardation, polydactyly, cutis aplasia, seizures	4p16.3

Adapted from Online Mendelian Inheritance in Man (2009).

determine if either carries a balanced translocation, as this would significantly increase the recurrence risk.

Microdeletion Syndromes. Some deletions are not large enough to be recognized by traditional karyotyping and thus, molecular cytogenetic techniques are required. *Fluorescence in-situ hybridization* (*FISH*) may be used to detect microdeletions associated with *contiguous gene syndromes*—deletion of a stretch of DNA that contains multiple genes. These deletions cause clinically recognizable syndromes that may include serious but unrelated phenotypic abnormalities. Deletions can occur in any region, however, several are found more frequently than expected by chance alone. This is thought to result from a greater propensity for certain regions to break. Some microdeletion syndromes detectable by FISH are listed in Table 12-3, and FISH technique is discussed on page 283.

DiGeorge and Shprintzen Phenotypes. Both of these phenotypes result from the same 22q11.2 microdeletion (Driscoll and colleagues, 1993). In a population-based study, Botto and colleagues (2003) reported its prevalence to be about 1 in 6000 among whites, blacks, and Asians, and 1 in 3800 among Hispanics. More than 80 percent of patients had heart defects, and a third had major extracardiac anomalies. The deletion accounted for about 1 in 70 cases of major heart defects within the general birth population (Botto and colleagues, 2003).

Shprintzen phenotype is also called *velocardiofacial syndrome.* Affected individuals may have cleft palate, velopharyngeal incompetence, prominent nose, a long face with recessed mandible, cardiac defects, learning difficulties, and short stature. By contrast, the DiGeorge phenotype is characterized by thymic hypo- or aplasia, parathyroid hypo- or aplasia, and conotruncal cardiac malformations. Typical facies includes short palpebral fissures, micrognathia with a short philtrum, and ear anomalies. Mental development is usually normal. The 22q11.2 microdeletion also accounts for a large proportion of conotruncal heart defects in individuals who do not have extracardiac features of either DiGeorge or Shprintzen syndromes (Botto and associates, 2003).

How two so obviously disparate phenotypes can be caused by the same microdeletion has intrigued geneticists since their discovery. One hypothesis is that DiGeorge and Shprintzen phenotypes represent two extremes of a spectrum of abnormalities caused by identical deletions. Another possibility is that each syndrome is caused by a different contiguous gene deletion at the 22q11.2 location. If so, then current cytogenetic methods cannot distinguish differences between the two.

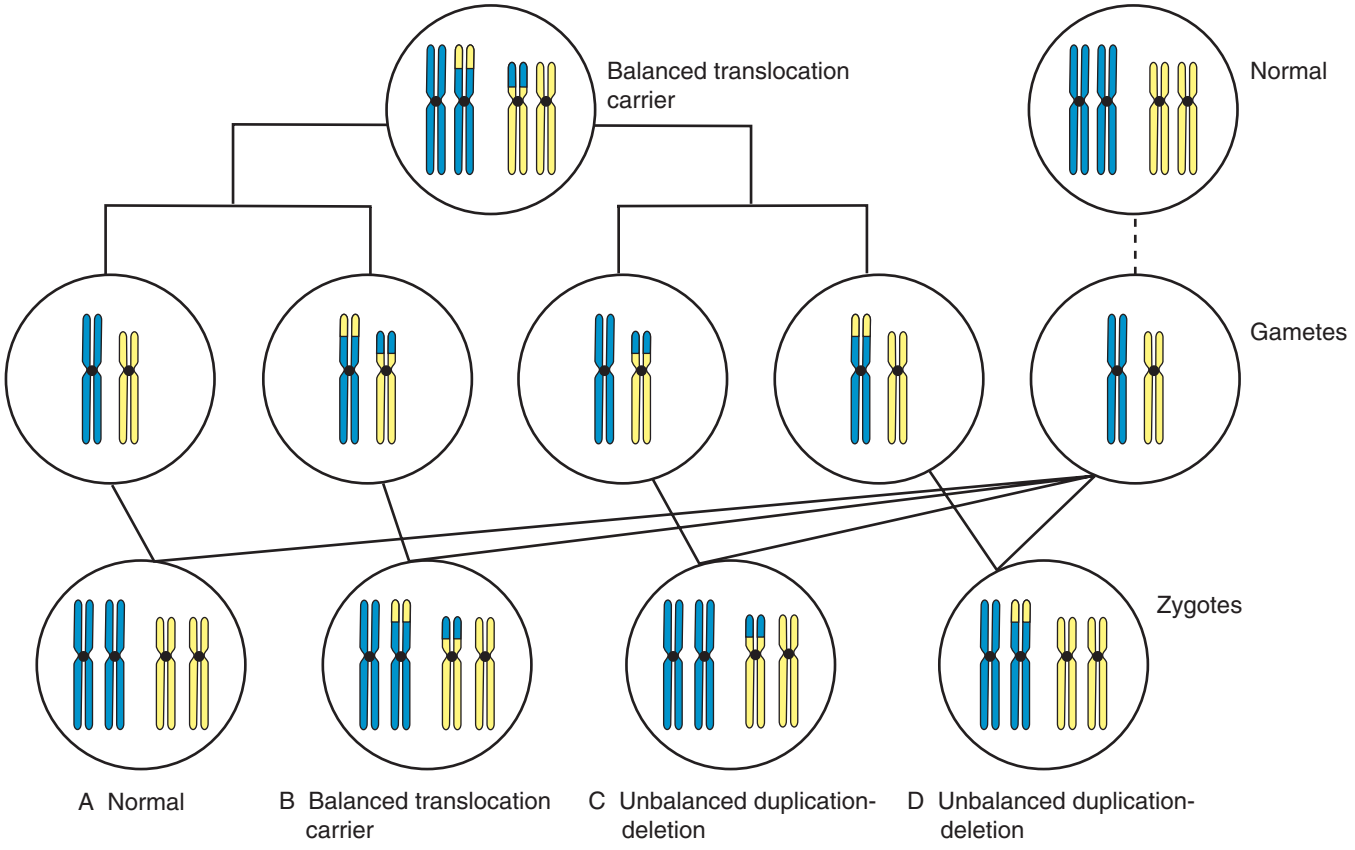

FIGURE 12-6 A carrier of a balanced translocation may produce offspring who are also carriers of the balanced rearrangement **(B)**, offspring with unbalanced translocations **(C, D)**, or offspring with normal chromosomal complements **(A)**.

Microduplication Syndromes. Recently, attention has been focused on genomic syndromes that are characterized by duplication of the very DNA regions that are deleted in recognized microdeletion syndromes. For example, Hassed and colleagues (2004) described four family members with features of the velocardiofacial syndrome, each of whom was found to have an *interstitial microduplication* of 22q11.2—the region *deleted* in this syndrome. Microduplications of the deleted regions in both the *Smith-Magenis syndrome* and the *Williams-Beuren syndrome* also produce clinical syndromes very similar to their respective microdeletion counterparts (Potocki and colleagues, 2000; Somerville and associates, 2005).

Chromosomal Translocations

These are DNA rearrangements in which a segment of DNA breaks away from one chromosome and attaches to another chromosome. The rearranged chromosomes are called *derivative (der) chromosomes*. There are two types of translocations—*reciprocal* and *Robertsonian*.

Reciprocal Translocations. Also termed a double-segment translocation, reciprocal translocation is a rearrangement of chromosomal material in which there are breaks in two different chromosomes, and the fragments are exchanged before the breaks are repaired. If no chromosomal material is gained or lost in this process, it is a *balanced translocation*. Although the transposition of chromosomal segments can cause abnormalities due to repositioning of specific genes, in most cases gene function is not affected and the balanced carrier is phenotypically normal. And offspring who inherit either the two normal chromosomes or the two translocated chromosomes usually have a normal phenotype. Fryns and associates (1992) reported a 6.4-percent incidence of a major anomaly with a balanced translocation—including the 3-percent background risk.

Carriers of a balanced translocation can produce *unbalanced* gametes that result in abnormal offspring. As shown in **Figure 12-6**, if one of the translocated chromosomes and one of the normal co-chromosomes are included in the oocyte or sperm, the result following fertilization will be monosomy for part of one chromosome and trisomy for part of another. The observed risk of many specific translocations can be estimated by a genetic counselor. In general, translocation carriers identified after the birth of an abnormal child have a 5- to 30-percent risk of having live-born offspring with unbalanced chromosomes. Carriers identified for other reasons, for example, during an infertility evaluation, have only a 5-percent risk, probably because their gametes are so abnormal that conceptions are nonviable.

Robertsonian Translocations. These result when the long arms of two individual acrocentric chromosomes—for example, chromosomes 13 and 14—fuse at the centromere to form one derivative chromosome. Translocations may involve any of the acrocentric chromosomes—chromosomes 13, 14, 15, 21, and 22. That said, almost all Robertsonian translocations involve chromosome 14 (Levitan, 1988). Fusion at the centromeres results in the loss of one centromere and the *satellite regions* which comprise

the short arms of each chromosome. These regions contain only genes coding for ribosomal RNA, which also are present in multiple copies on other acrocentric chromosomes. As long as the fused q arms are intact, the translocation carrier is usually phenotypically normal. Because the number of centromeres determines the chromosome count, the typical carrier of a Robertsonian translocation will have only 45 chromosomes.

Robertsonian carriers have reproductive difficulties. If the fused chromosomes are homologous—from the same chromosome pair—the carrier makes only unbalanced gametes. Each egg or sperm contains either both copies of the translocated chromosome, which would result in trisomy if fertilized, or no copy, which would result in monosomy. If the fused chromosomes are nonhomologous, four of the six possible gametes would be abnormal. Some are nonviable, and the actual observed incidence of abnormal offspring is only 15 percent if the translocation is carried by the mother, and 2 percent if carried by the father.

Robertsonian translocations are common. Their incidence overall is about 1 in 1000 newborns—equal to all other translocations combined. These translocations, however, are not a major cause of miscarriage. They are found in less than 5 percent of couples with recurrent pregnancy loss (Smith and Gaha, 1990). Still, identification of a Robertsonian translocation has tremendous impact on reproductive plans and may have implications for other family members. When a fetus or child is found to have a translocation trisomy, chromosomal studies of both parents should be performed. If neither parent is a carrier and the translocation occurred spontaneously, the recurrence risk is extremely low.

Isochromosomes

These abnormal chromosomes are composed of either two q arms or two p arms of one chromosome fused together. Isochromosomes are thought to arise when the centromere breaks transversely instead of longitudinally during meiosis II or mitosis. They also may result from a meiotic error in a chromosome with a Robertsonian translocation. An isochromosome made of the q arms of an acrocentric chromosome behaves like a homologous Robertsonian translocation because no important genetic material is lost. Conversely, such a carrier could produce only abnormal unbalanced gametes. When an isochromosome involves nonacrocentric chromosomes that have p arms containing functional genetic material, the fusion and abnormal centromere break results in two isochromosomes—one composed of both p arms and one composed of both q arms. It is likely that one of these isochromosomes would be lost during cell division, resulting in the deletion of all the genes located on the lost arm. Thus, a carrier is usually phenotypically abnormal, and produces abnormal gametes. An example is isochromosome X, which causes the full Turner syndrome phenotype.

Chromosomal Inversion

These occur when there are two breaks in the same chromosome, and the intervening genetic material is inverted before the breaks are repaired. Although no genetic material is lost or duplicated, the rearrangement may alter gene function. There are two types—*pericentric* and *paracentric*.

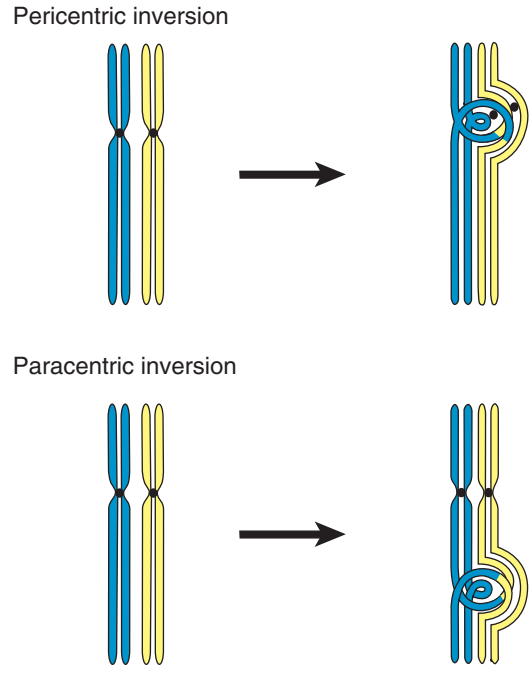

FIGURE 12-7 Mechanism of meiosis in the setting of either **(A)** pericentric inversion (one involving the centromere)or **(B)** paracentric inversion (not involving the centromere). Individuals with pericentric inversions are at increased risk to produce offspring with a duplication/deletion. Those with paracentric inversions are at increased risk for early pregnancy loss.

Pericentric Inversion. This results when the breaks are in each arm of the chromosome so that the inverted chromosome material includes the centromere (Fig. 12-7). Because such inversions cause problems in chromosomal alignment during meiosis, the carrier is at high risk to produce abnormal gametes and thus, abnormal offspring. The risk can be calculated for each specific inversion, but in general, the observed risk is 5 to 10 percent if ascertainment was prompted after the birth of an abnormal child, and 1 to 3 percent if ascertainment was prompted by another reason (Gardner and Sutherland, 1996).

Paracentric Inversion. With a paracentric inversion, the inverted material is from only one arm, and the centromere is not within the inverted segment (Fig. 12-7). The carrier makes either normal balanced gametes or gametes that are so abnormal as to preclude fertilization. Thus, although infertility may be a problem, the risk of abnormal offspring is extremely low.

Ring Chromosome

When there are deletions from both ends of a chromosome, the ends may unite, forming a ring chromosome. If the deletions are substantial, the carrier is phenotypically abnormal. One example is *ring X chromosome,* which may result in the Turner syndrome phenotype.

Telomeres are the physical ends of linear chromosomes. They are specialized nucleoprotein complexes that have important functions in the protection, replication, and stabilization of the chromosomal ends. If only the telomeres are lost, all important genetic material is retained, and the carrier is essentially balanced. The

TABLE 12-4. Mosaicism Encountered in Amniotic Fluid Culture

Type	Prevalence	Description and Significance
Level I	2–3 percent	Single cell with an abnormal karyotype in a single culture—confined to one of several flasks or to one of several colonies on a coverslip. This is usually a cell-culture artifact (pseudomosaicism).
Level II	1 percent	Multiple cells with an abnormal karyotype in a single culture—confined to one of several flasks or to one of several colonies on a coverslip. This is also usually a cell-culture artifact (pseudomosaicism).
Level III	0.1–0.3 percent	Multiple cells in multiple cultures with an abnormal karyotype. Further testing warranted, as a second cell line may be present in the fetus in 60–70 percent of cases (true mosaicism).

ring, however, prevents normal chromosome alignment during meiosis and thus produces abnormal gametes. It also disrupts cell division, which may cause abnormal growth of many tissues and lead to small stature, borderline to moderate mental deficiency, and minor dysmorphisms (Gardner and Sutherland, 1996).

A ring chromosome may form de novo or may be inherited from a carrier parent. In cases of parent-to-child transmission, the mother is the carrier, possibly because a ring chromosome compromises spermatogenesis.

Chromosomal Mosaicism

An individual with mosaicism has two or more cytogenetically distinct cell lines derived from a single zygote. The phenotypic expression of mosaicism depends on many factors, including whether the cytogenetically abnormal cells involve the placenta, the fetus, part of the fetus, or some combination. Mosaicism encountered in cultured amniotic fluid may or may not reflect the actual fetal chromosome complement. Different levels of mosaicism and their clinical significance are presented in Table 12-4. When the abnormal cells involve only a single flask of amniotic fluid, the result is more likely *pseudomosaicism* and explained by cell-culture artifact (Bui and colleagues, 1984; Hsu and Perlis, 1984). When abnormal cells involve multiple cultures, however, true mosaicism is more likely, and further testing of fetal blood or even skin fibroblasts may be warranted. In these cases, a second cell line may be present in 60 to 70 percent of fetuses (Hsu and Perlis, 1984; Worton and Stern, 1984). Consultation with a geneticist may be helpful in evaluating the degree of risk posed by amniotic fluid mosaicism or pseudomosaicism for selected chromosomes, as well as to determine the need for additional testing.

Confined Placental Mosaicism

Studies of chorionic villus sampling have shown that 2 percent of placentas are mosaic, even though the associated fetus is usually normal (Henderson and associates, 1996). Such *confined placental mosaicism* seems to be chromosome specific. Mosaicism involving chromosomes 2, 7, 8, 10, and 12 is usually caused by a mitotic error, whereas that involving chromosomes 9, 16, and 22 is more likely to result from partial correction of a meiotic error (Robinson and colleagues, 1997).

Confined placental mosaicism may have either positive or negative effects. It may play a role in the survival of some cytogenetically abnormal fetuses. For example, trisomy 13 and 18 fetuses who survive to term may do so only because of early "trisomic correction" in some cells that become trophoblasts (Kalousek and co-workers, 1989). Growth restriction may be influenced by *which* chromosome is lost during the trisomic correction. If the fetus retains two normal copies of the chromosome, but both copies are from the same parent, growth may be impaired. This event is referred to as *uniparental disomy* and is discussed later. Conversely, some cytogenetically normal fetuses may have severe growth restriction because the placenta contains a population of aneuploid cells that impair its function (Kalousek and Dill, 1983).

Gonadal mosaicism is confined to the gonads. It likely arises as the result of a mitotic error in cells destined to become the gonad, resulting in a population of abnormal germ cells. Because spermatogonia and oogonia divide throughout fetal life, and spermatogonia continue to divide throughout adulthood, gonadal mosaicism may also be the result of a meiotic error in previously normal dividing germ cells. Gonadal mosaicism may explain de novo autosomal dominant mutations in the offspring of normal parents. This may cause such diseases as achondroplasia or osteogenesis imperfecta as well as X-linked diseases such as Duchenne muscular dystrophy. It also explains the recurrence of such diseases in more than one child in a previously unaffected family. It is because of the potential for gonadal mosaicism that the recurrence risk after the birth of a child with a disease caused by a "new" mutation is approximately 6 percent.

MODES OF INHERITANCE

Monogenic (Mendelian) Inheritance

A monogenic disorder is caused by a mutation or alteration in a single locus or gene in one or both members of a gene pair. Monogenic disorders are also called mendelian to signify that their transmission follows the laws of inheritance proposed by Gregor Mendel. Traditional modes of mendelian inheritance include autosomal dominant, autosomal recessive, X-linked, and Y-linked. Other monogenic patterns of inheritance include mitochondrial inheritance, uniparental disomy, imprinting, and trinucleotide repeat expansion, that is, *anticipation* (Guttmacher and Collins, 2002).

By age 25, about 0.4 percent of the population exhibits an abnormality attributed to a monogenic disorder, and 2 percent will have at least one such disorder during their lifetime.

It is important to emphasize that it is the *phenotype* that is dominant or recessive, not the genes. In some dominant diseases, for example, the normal gene may still be directing the production of normal protein, but the phenotype is determined by protein produced by the abnormal gene. Likewise, the heterozygous carrier of some recessive diseases may produce detectable levels of the abnormal gene product, but he or she does not display features of the disease because the phenotype is directed by the product of the normal co-gene**.** For example, erythrocytes from carriers of sickle-cell anemia contain about 30 percent hemoglobin S, however, because the remaining hemoglobin is A, these cells do not sickle under normal oxygen conditions.

Although transmission patterns of these diseases are consistent with mendelian inheritance, their phenotypes are strongly influenced by modifying genes and environmental factors. Some common single-gene disorders affecting adults are listed in Table 12-5.

TABLE 12-5. Some Common Single-Gene Disorders

Autosomal Dominant
Achondroplasia
Acute intermittent porphyria
Adult polycystic kidney disease
Antithrombin III deficiency
BRCA1 and BRCA2 breast cancer
Ehlers-Danlos syndrome
Familial adenomatous polyposis
Familial hypercholesterolemia
Hereditary hemorrhagic telangiectasia
Hereditary spherocytosis
Huntington disease
Hypertrophic obstructive cardiomyopathy
Long QT syndrome
Marfan syndrome
Myotonic dystrophy
Neurofibromatosis type 1 and 2
Tuberous sclerosis
von Willebrand disease
Autosomal Recessive
α_1-Antitrypsin deficiency
Congenital adrenal hyperplasia
Cystic fibrosis
Gaucher disease
Hemochromatosis
Homocystinuria
Phenylketonuria
Sickle cell anemia
Tay-Sachs disease
Thalassemia syndromes
Wilson disease
X Linked
Androgen insensitivity syndrome
Chronic granulomatous disease
Color blindness
Fabry disease
Fragile X syndrome
Glucose-6-phosphate deficiency
Hemophilia A and B
Hypophosphatemic rickets
Muscular dystrophy—Duchenne and Becker
Ocular albinism type 1 and 2

Autosomal Dominant Inheritance

If only one member of a gene pair determines the phenotype, that gene is considered to be dominant. An individual carrying a gene that causes an autosomal dominant disease has a 50-percent chance of passing on the affected gene with each conception. A gene with a dominant mutation generally specifies the phenotype in preference to the normal gene. That said, not all individuals will necessarily manifest an autosomal dominant condition the same way. Factors that affect the phenotype of an autosomal dominant condition include *penetrance*, *expressivity*, and occasionally, presence of *co-dominant genes*.

Penetrance. This term describes whether or not an autosomal dominant gene is expressed at all. A gene with some kind of recognizable phenotypic expression in all individuals has 100-percent penetrance. If some carriers express the gene but some do not, then penetrance is *incomplete*. This is quantitatively expressed by the ratio of those individuals with any phenotypic characteristics of the gene to the total number of gene carriers. For example, a gene that is expressed in some way in 80 percent of individuals who have that gene is 80-percent penetrant. Incomplete penetrance may explain why some autosomal dominant diseases appear to "skip" generations.

Expressivity. This term refers to the degree to which the phenotypic features are expressed. If all individuals carrying the affected gene do not have identical phenotypes, the gene has *variable expressivity*. Expressivity of a gene can range from complete or severe manifestations to only mild features of the disease. An example of a disease with variable expressivity is neurofibromatosis.

Co-dominant Genes. If alleles in a gene pair are different from each other, but both are expressed in the phenotype, they are considered to be co-dominant. A common example is the human major blood groups—because their genes are co-dominant, both A and B red-cell antigens can be expressed simultaneously in one individual. Another example is the several genes responsible for hemoglobinopathies. The individual with one gene directing production of sickle hemoglobin and the other directing production of hemoglobin C produces both S and C hemoglobins.

Advanced Paternal Age. Increasing paternal age significantly increases the risk of spontaneous new mutations. These may result in offspring with autosomal dominant disorders, such as neurofibromatosis or achondroplasia (Friedman, 1981). Such new mutations may also result in offspring carrying X-linked conditions, and they may be a factor in early pregnancy loss. The incidence of new autosomal dominant mutations among newborns

whose fathers are 40 years old is at least 0.3 percent. There is some evidence that paternal age also may affect the incidence of isolated structural abnormalities (McIntosh and colleagues, 1995).

Advanced paternal age is *not* associated with an increased risk for aneuploidy, probably because aneuploid sperm cannot fertilize an egg.

Autosomal Recessive Inheritance

A trait that is recessive is expressed only when both copies of the gene function identically. Thus, autosomal recessive diseases develop only when both gene copies are abnormal. Phenotypic alterations in gene carriers—that is, *heterozygotes*—usually are undetectable clinically but may be recognized at the biochemical or cellular level. For example, many enzyme deficiency diseases are autosomal recessive. The enzyme level in a carrier will be about half of normal, but because enzymes are made in great excess, this reduction usually does not cause disease. It does, however, represent a phenotypic alteration and can be used for screening purposes. Other recessive conditions do not produce any phenotypic changes in the carrier and can be identified only by molecular methods.

Unless they are screened for a specific disease, such as cystic fibrosis, carriers usually are recognized only after the birth of an affected child or the diagnosis of an affected family member (see Chap. 13, p. 297). A couple whose child has an autosomal recessive disease has a 25-percent recurrence risk with each conception. The likelihood that a normal sibling of an affected child is a carrier of the gene is two out of three. Thus, 1/4 of offspring will be homozygous normal, 2/4 will be heterozygote carriers, and 1/4 will be homozygous abnormal. Another way to look at this is that three of four children will be phenotypically normal, and two of these three will be carriers.

The carrier child will not have affected children, unless his or her partner is also a heterozygous carrier or is homozygous and has the disease. Because genes leading to rare autosomal recessive conditions have a low prevalence in the general population, the chance that a partner will be a gene carrier is low unless the couple is either related or is a member of an at-risk population (American College of Obstetricians and Gynecologists, 2004).

Inborn Errors of Metabolism. Most of these autosomal recessive diseases result from the absence of a crucial enzyme leading to incomplete metabolism of proteins, sugars, or fats. The metabolic intermediates that build up are toxic to a variety of tissues, resulting in mental retardation or other abnormalities.

Phenylketonuria (PKU). This classic example of an autosomal recessive defect results from diminished or absent *phenylalanine hydroxylase* activity. Homozygotes are unable to metabolize phenylalanine to tyrosine. If the diet is unrestricted, incomplete protein metabolism leads to abnormally high phenylalanine levels that cause neurological damage and mental retardation. There also is hypopigmented hair, eyes, and skin because phenylalanine competitively inhibits tyrosine hydrolase, which is essential for melanin production. The disease affects 1 in 10,000 to 15,000 white newborns. There is tremendous geographical and ethnic variation, with incidences ranging from 5 to 190 cases per million.

PKU is notable for two reasons. First, it is one of the few metabolic disorders for which treatment exists. Homozygotes who ingest a phenylalanine-restricted diet can avoid many of the clinical consequences of the disease. Early diagnosis and limitation of dietary phenylalanine beginning in infancy are essential to prevent neurological damage. Accordingly, all states and many countries now mandate newborn screening for PKU, and about 100 cases per million births are identified worldwide. The special diet should be continued indefinitely, as patients who abandon the phenylalanine-restricted diet are reported to have a significantly lower IQ (Koch and co-workers, 2000).

The second reason is that women with PKU are at risk to have otherwise normal heterozygous offspring who sustain damage in utero as a result of being exposed to high phenylalanine concentrations during pregnancy. Phenylalanine readily crosses the placenta, and hyperphenylalaninemia has significant risk for miscarriage and for offspring with mental retardation, microcephaly, low birth weight, and congenital heart defects. For this reason, women with PKU should adhere to the phenylalanine-restricted diet if they are contemplating pregnancy, and then throughout pregnancy (Clarke, 2003). In the Maternal Phenylketonuria Collaborative Study, 572 pregnancies were followed over 18 years. Findings showed that maintenance of serum phenylalanine levels in the 160 to 360 μmol/L—2 to 6 mg/dL—range significantly reduced the risk of fetal abnormalities (Koch and colleagues, 2003; Platt and co-workers, 2000). The study further demonstrated that women who established optimal phenylalanine levels of 120 to 360 μmol/L between 0 and 10 weeks had children with mean IQ in the normal range at age 6 to 7 years (Koch and colleagues, 2003).

Consanguinity. Two individuals are considered consanguineous if they have at least one ancestor in common. First-degree relatives share half of their genes, second-degree relatives share a fourth, and third-degree relatives—cousins—share one eighth. Because of the potential for shared deleterious genes, consanguineous unions are at increased risk to produce children with otherwise rare autosomal recessive diseases. They are also at increased risk to have offspring with multifactorial conditions that are subsequently discussed.

First-cousin marriages, the most frequent consanguineous mating, carry a twofold increased risk over background of abnormal offspring—4 to 6 percent if there is no family history of genetic disease. If one of the partners has a sibling with an autosomal recessive disease, the risk of affected offspring is many times higher than if he or she had chosen an unrelated partner.

Incest is defined as a sexual relationship between first-degree relatives such as parent and child or brother and sister and is universally illegal. Progeny of such unions carry the highest risk of abnormal outcome, and up to 40 percent of offspring are abnormal as a result of both recessive and multifactorial disorders (Friere-Maia, 1984; Nadiri, 1979).

X-Linked and Y-linked Inheritance

Most X-linked diseases are recessive. Some of the best known examples are color blindness, hemophilia A, and Duchenne muscular dystrophy. When a woman carries a gene causing an

X-linked recessive condition, each son has a 50-percent risk of being affected, and each daughter has a 50-percent chance of being a carrier.

Males carrying an X-linked recessive gene are usually affected because they lack a second X chromosome to express the normal dominant gene. When a male has an X-linked disease, none of his sons will be affected because they cannot receive the abnormal X-linked gene from him. Women carrying an X-linked recessive gene are generally unaffected by the disease it causes. In some cases, however, because of skewed *lyonization*—inactivation of one X chromosome in each cell—female carriers may have features of the condition. An example is a woman who has the gene for hemophilia A and who herself has bleeding tendencies (Plug and colleagues, 2006). Similarly, some female carriers of Duchenne muscular dystrophy may develop cardiomyopathy and conduction defects (Politano and colleagues, 1996). Identification of such symptoms may be valuable in caring for the pregnant woman and providing accurate prenatal diagnosis.

X-linked dominant disorders mainly affect females because they tend to be lethal in male offspring. Examples include focal dermal hypoplasia, vitamin D-resistant rickets, and incontinentia pigmenti.

The Y chromosome carries genes important for sex determination and a variety of cellular functions such as spermatogenesis and bone development. Deletion of genes on the long arm results in severe spermatogenic defects, whereas genes at the tip of the short arm are critical for chromosomal pairing during meiosis and for fertility.

Mitochondrial Inheritance

Each human cell contains hundreds of mitochondria, each containing its own genome and associated replication system. In this sense, they behave autonomously. Mitochondria are inherited exclusively from the mother. Human oocytes contain approximately 100,000 mitochondria, but sperm contain only 100 and these are destroyed after fertilization. Each mitochondrion has multiple copies of a 16.5-kb circular DNA molecule that contains 37 unique genes. Mitochondrial DNA encodes peptides required for oxidative phosphorylation, as well as ribosomal and transfer RNAs.

Because mitochondria contain genetic information, their inheritance allows the transmission of genes from mother to offspring without the possibility of recombination. If a mitochondrial mutation occurs, it may segregate into a daughter cell during cell division and thus be propagated. If an oocyte containing largely mutated mitochondrial DNA is fertilized, the offspring may have a mitochondrial disease. Mitochondrial diseases have a characteristic transmission pattern—individuals of both sexes can be affected, but transmission is only through females.

As of April 2009, 26 mitochondrial diseases or conditions with known molecular basis were described in the OMIM website. Examples include myoclonic epilepsy with ragged red fibers (MERRF), Leber optic atrophy, Kearns-Sayre syndrome, Leigh syndrome, and interestingly, susceptibility to both aminoglycoside-induced deafness and chloramphenicol toxicity.

TABLE 12-6. Some Disorders Caused by DNA Triplet Repeat Expansion

DNA Triplet Repeat Expansion—Anticipation

Mendel's first law states that genes are passed unchanged from parent to progeny. Barring the new mutations, this law still applies to many genes or traits. Certain genes, however, are unstable, and their size, and consequently their function, may be altered as they are transmitted from parent to child. This is manifested clinically by *anticipation*, a phenomenon in which disease symptoms seem to be more severe and to appear at an earlier age in each successive generation. Examples include fragile X syndrome and myotonic dystrophy, both of which are caused by expansion of a repeated trinucleotide segment of DNA. Examples of other DNA triplet (trinucleotide) repeat diseases are shown in Table 12-6.

Fragile X Syndrome. This is the most common form of *familial* mental retardation and affects about 1 in 4000 males and 1 in 8000 females (American College of Obstetricians and Gynecologists, 2006). It is an X-linked disorder characterized by mental retardation that is borderline to severe. Males have an average IQ score of 35 to 45, whereas the IQ in females is generally higher (Nelson, 1995). Affected individuals also may have autistic behavior, attention-deficit/hyperactivity disorder—ADHD, as well as speech and language problems. The physical phenotype includes a narrow face with large jaw, long prominent ears, and macroorchidism in postpubertal males.

Fragile X is caused by expansion of a repeated trinucleotide DNA segment—CGG, that is, cytosine-guanine-guanine—at chromosome Xq27. When the CGG number reaches a critical size, the *fragile X mental retardation 1 (FMR1)* gene becomes methylated and thereby inactivated, and thus, *FMR1 protein* is not produced (Migeon, 1993). The number of repeats and the degree of methylation determines whether or not an individual is affected by the syndrome, as well as its severity (Cutillo, 1994). Clinically, four groups have been described:

1. Full mutation—more than 200 repeats
2. Premutation—61 to 200 repeats
3. Intermediate—41 to 60 repeats
4. Unaffected—fewer than 40 repeats

Males who have the full mutation typically have methylation of the FMR1 gene and full expression of the syndrome. In females, expression is variable, due to X-inactivation of the affected X chromosome.

Although individuals with premutations were initially considered to be normal, more recent research has been focused on three

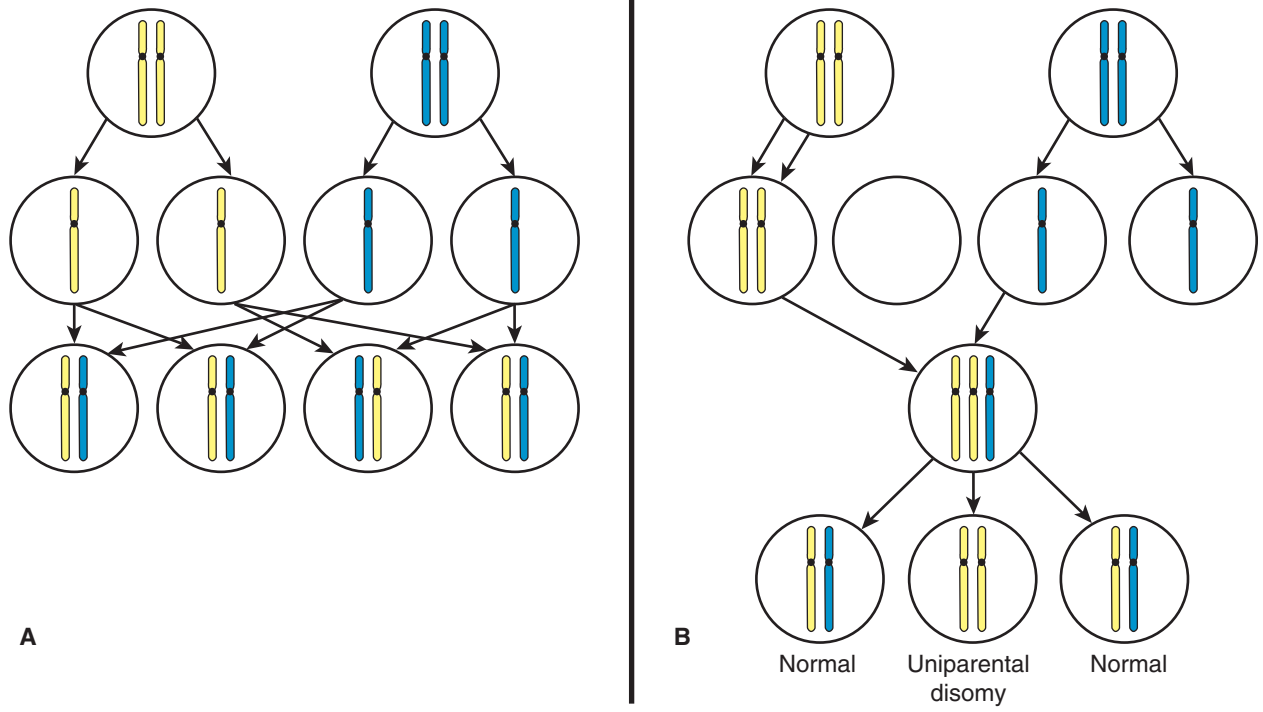

FIGURE 12-8 Mechanism of uniparental disomy arising from trisomic "rescue." **A.** In normal meiosis, one member of each pair of homologous chromosomes is inherited from each parent. **B.** If nondisjunction results in a trisomic conceptus, one homologue is sometimes lost. In a third of cases, loss of one homologue leads to uniparental disomy.

conditions that may manifest: late-onset neurodegenerative disorder with tremor and ataxia, particularly in males; premature ovarian failure in 20 to 30 percent of females; and autism or autistic-like behavior among children (Hagerman and Hagerman, 2004).

Whether a fetus will inherit the full mutation for fragile X syndrome depends on the gender of the transmitting parent and the number of CGG repeats in that parental gene. When transmitted by a male, the number of repeats usually remains stable—the premutation is transmitted without expanding to a full mutation. When transmitted by a female with a premutation, the FMR1 gene can expand during meiosis, particularly if the CGG repeat number exceeds 90. If a woman carries a premutation that increases in size as she transmits it to her offspring, then her child is at risk to have the full fragile X syndrome (Cutillo, 1994). If she carries an intermediate repeat number—41 to 60 repeats—expansion to a full mutation is unlikely.

Prenatal diagnosis of fragile X may be accomplished using Southern blot analysis and polymerase chain reaction to determine the CGG repeat number and the gene methylation status. These tests are discussed subsequently. Amniocentesis is preferred, because gene methylation status may not be reliably assessed from chorionic villi. It is reasonable to refer individuals with a history of mental retardation, developmental delay of unknown etiology, or autism for genetic evaluation because 2 to 6 percent will be determined to have fragile X (Curry and colleagues, 1997; Wenstrom and associates, 1999).

Uniparental Disomy

In this situation, both members of one pair of chromosomes are inherited from the *same* parent, instead of one member being inherited from *each* parent. Often, uniparental disomy does not have clinical consequences. Some exceptions are when it involves chromosomes 6, 7, 11, 14, or 15. These offspring are at increased risk for an abnormality that results from parent-of-origin differences in gene expression (Shaffer and colleagues, 2001). Although several genetic mechanisms may cause uniparental disomy, the most common is "trisomic rescue" as shown in **Figure 12-8**. After a nondisjunction event produces a trisomic conceptus, one of the three homologues may be lost. This will result in uniparental disomy for that chromosome in a third of cases.

Isodisomy is the unique situation in which an individual receives two identical copies of one chromosome in a pair from one parent. This mechanism explains some cases of cystic fibrosis, in which only one parent is a carrier but the fetus inherits two copies of the same abnormal chromosome from that parent (Spence and co-workers, 1988; Spotila and colleagues, 1992). It also has been implicated in abnormal growth related to placental mosaicism (Robinson and colleagues, 1997).

Imprinting

This term describes the process by which certain genes are inherited in an inactivated or *transcriptionally silent* state at one of the parental loci in the offspring (Hall, 1990). This type of gene inactivation is determined by the gender of the transmitting parent and may be reversed in the next generation. Imprinting affects gene expression by *epigenetic control*; that is, it changes the phenotype by altering gene expression and not by permanently altering the genotype. When a gene is inherited in an imprinted state, gene function is directed by the co-gene inherited

TABLE 12-7. Some Disorders That Can Involve Imprinting

Disorder	Chromosomal Region	Parental Origin
Angelman	15q11-q13	Maternal
Beckwith-Wiedemann	11p15.5	Paternal
Myoclonic-dystonia	7q21	Maternal
Prader-Willi	15q11-q13	Paternal
Pseudohypoparathyroidism	20q13.2	Depends on type
Russell-Silver syndrome	7p11.2	Maternal

from the other parent, so imprinting exerts an effect by controlling the "dosage" of specific genes.

Selected diseases that can involve imprinting are shown in Table 12-7. A useful example includes two very different diseases that may be caused by microdeletion, uniparental disomy, or imprinting for the 15q11-q13 region of DNA:

1. *Prader–Willi syndrome* is characterized by obesity and hyperphagia; short stature; small hands, feet, and external genitalia; and mild mental retardation. In over 70 percent of cases, Prader-Willi is caused by microdeletion or disruption for the *paternal* 15q11-q13. The remainder of cases are due to *maternal* uniparental disomy or due to imprinting—with the *paternal* genes inactive (Online Mendelian Inheritance in Man, 2008).
2. *Angelman syndrome* includes normal stature and weight; severe mental retardation; absent speech; seizure disorder; ataxia and jerky arm movements; and paroxysms of inappropriate laughter. In approximately 70 percent of cases, Angelman syndrome is caused by microdeletion or disruption for the *maternal* 15q11-q13. In 2 percent, the syndrome is caused by *paternal* uniparental disomy, and another 2 to 3 percent are due to imprinting—with the *maternal* genes inactivated (Online Mendelian Inheritance in Man, 2008).

There are a number of other examples of imprinting important to obstetricians. A *complete hydatidiform mole,* which has a paternally derived diploid chromosomal complement, is characterized by the abundant growth of placental tissue with no fetal structures (see Chap. 11, p. 257). Conversely, an *ovarian teratoma,* which has a maternally derived diploid chromosomal complement, is characterized by the growth of various fetal tissues but no placental structures (Porter and Gilks, 1993). It thus appears that paternal genes are vital for placental development, and maternal genes are essential for fetal development, but both must be present in every cell for normal fetal growth and development.

Multifactorial and Polygenic Inheritance

Polygenic traits are determined by the combined effects of more than one gene, and *multifactorial traits* are determined by multiple genes and environmental factors. Most inherited traits are multifactorial or polygenic. Birth defects caused by such inheritance are recognized by their tendency to recur in families, but not according to a mendelian inheritance pattern. The empirical recurrence risk for first-degree relatives usually is quoted as 3 to 5 percent. Multifactorial traits can be classified in several ways, but the most logical is to categorize them as continuously variable traits, threshold traits, or complex disorders of adult life.

Continuously Variable Traits

A trait is continuously variable if it has a normal distribution in the general population, such as height or head size. Abnormalcy for a trait is defined as a measurement greater than two standard deviations above or below the population mean. Continuously variable traits are believed to result from the individually small effects of many genes combined with environmental factors. They tend to be less extreme in the offspring of affected individuals, because of the statistical principle of regression to the mean.

Threshold Traits

These traits do not appear until a certain threshold is exceeded. Factors that create liability or propensity for the trait are normally distributed, and only individuals at the extreme of this distribution exceed the threshold and have the trait or defect. The phenotypic abnormality is thus an all-or-none phenomenon. Individuals in high-risk families have enough abnormal genes or environmental influences that their liability is close to the threshold, and in certain family members, the threshold is crossed. Cleft lip and palate and pyloric stenosis are examples of threshold traits.

Certain threshold traits have a predilection for one gender, indicating that males and females have a different liability threshold (Fig. 12-9). An example is pyloric stenosis, which is more common in males. If a female has pyloric stenosis, it is likely that she inherited even more abnormal genes or predisposing factors than are usually necessary to produce pyloric stenosis in males. The recurrence risk for her children or siblings is thus higher than the expected 3 to 5 percent. Her male siblings or offspring would have the highest liability, because they not only will inherit more than the usual number of predisposing genes but also are the more susceptible sex.

Finally, the recurrence risk of threshold traits is also higher if the defect is severe, again suggesting the presence of more abnormal genes or influences. For example, the recurrence risk after the birth of a child with bilateral cleft lip and palate is 8 percent, compared with only 4 percent for unilateral cleft lip without cleft palate (Melnick and associates, 1980).

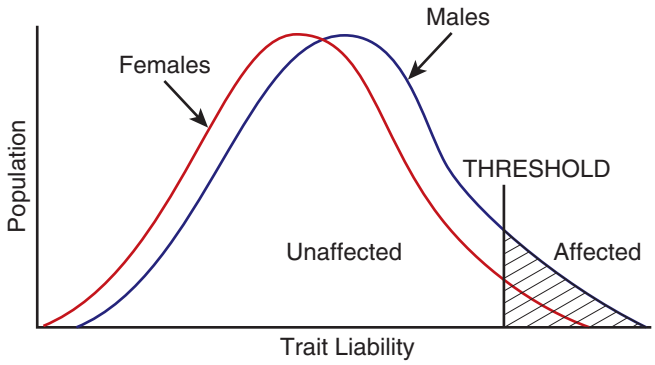

FIGURE 12-9 Schematic example of a threshold trait such as pyloric stenosis that has a predilection for males. Each gender is normally distributed, but at the same threshold, more males than females will develop the condition.

Complex Disorders of Adult Life

These are traits in which many genes determine the susceptibility to environmental factors, with disease resulting from the most unfavorable combination of both. Examples include common disorders such as heart disease or hypertension. These are usually familial and behave as threshold traits, but with environmental influence as an important cofactor. In recent years, many specific gene mutations have been characterized that may cause these common conditions. For example, as of April 2009, the OMIM website listed more than 700 specific entries for "Diabetes." In some diseases, the identity of the associated gene provides a clue to pathogenesis, whereas in others the related gene may simply serve as a disease marker.

Examples of Multifactorial or Polygenic Defects

Various birth defects and common diseases exhibit multifactorial or polygenic inheritance. These diseases have certain inherent characteristics that help to distinguish them from disorders with other modes of inheritance (Table 12-8). When assessing risks for a familial multifactorial trait, it is important to consider the degree of relatedness of the affected relative to the fetus, not the parents. An affected first-degree relative—parents or siblings of the fetus—results in a substantial risk increase, but risk declines exponentially with successively more distant relationships. Two examples are cardiac defects and neural-tube defects.

TABLE 12-8. Characteristics of Multifactorial Diseases

There is a genetic contribution
- No mendelian pattern of inheritance
- No evidence of single-gene disorder

Nongenetic factors are also involved in disease causation
- Lack of penetrance despite predisposing genotype
- Monozygotic twins may be discordant

Familial aggregation may be present
- Relatives are more likely to have disease-predisposing alleles

Expression more common among close relatives
- Becomes less common in less closely related relatives, fewer predisposing alleles
- Greater concordance in monozygotic than dizygotic twins

Adapted from Nussbaum and colleagues (2007).

Cardiac Defects. Structural heart anomalies are the most common birth defects worldwide, with an incidence of 8 per 1000 births. More than 100 genes believed to be involved in cardiovascular morphogenesis have been identified, including those directing production of various transcription factors, secreted proteins, extracellular proteins, and protein receptors (Olson, 2006; Weismann and Gelb, 2007). These gene products are likely involved in the development of specific cardiac tissues and structures. For example, folic acid and the methylene tetrahydrofolate reductase (MTHFR) mutation influence the development of cardiac defects (Wenstrom and co-workers, 2001). Importantly, periconceptional folic acid-containing multivitamin supplementation may reduce their incidence (Czeizel, 1998).

Observed recurrence risks for common congenital heart defects are shown in Table 12-9. If the exact nature of the defect is known, the most specific risk should be quoted when counseling. Otherwise, couples can be informed of the empirical risk of having a child with a cardiac defect. This is 5 to 6 percent if the mother has the defect and 2 to 3 percent if the father has the defect (Burn and associates, 1998). Specific defects, which may have recurrence risks four- to sixfold higher, include hypoplastic left heart, bicuspid aortic valve, and aortic coarctation (Lin and Garver, 1988; Nora and Nora, 1988).

Neural-Tube Defects. Isolated, that is, nonsyndromic, neural-tube defects are the second most common congenital structural abnormalities after cardiac defects. Their prenatal diagnosis and sonographic features are described in Chapters 13 (p. 287) and 16 (p. 354), respectively.

Neural-tube defects are classic examples of multifactorial inheritance. Their development is influenced by environment, diet, physiological abnormalities such as hyperthermia or hyperglycemia, teratogen exposure, family history, ethnic origin, fetal gender, amnionic fluid nutrients, and various genes. Neural-tube defects associated with type 1 diabetes mellitus are more likely to be cranial or cervical-thoracic; with valproic acid exposure, lumbosacral defects; and with hyperthermia, anencephaly (Becerra and colleagues, 1990; Hunter, 1984; Lindhout and associates, 1992).

Hibbard and Smithells (1965) postulated more than 40 years ago that abnormal folate metabolism was responsible for many neural-tube malformations. Decades later, a thermolabile variant of the enzyme 5,10-methylene tetrahydrofolate reductase (MTHFR), which plays a key role in folate metabolism, was shown to be associated with neural-tube defects. This enzyme transfers a methyl group from folic acid to convert homocysteine to methionine. One abnormal form of MTHFR carries a mutation at position 677 of its gene and has reduced enzymatic activity. Folic acid supplementation likely works by overcoming this relative enzyme deficiency. Because some defects develop in fetuses with normal 677 C→T alleles, and because

TABLE 12-9. Recurrence Risk (percent) for Congenital Heart Defects If Siblings or Parents Are Affected

	Father	Mother	1 Sibling	2 Siblings
Ventricular septal defects	2	6–10	3	10
Atrial septal defects	1.5	4–4.5	2.5	8
Fallot tetralogy	1.5	2.5	2.5	8
Pulmonary stenosis	2	4–6.5	2	6
Aortic stenosis	3	13–18	2	6
Coarctation	2	4	2	6

Adapted from Nora and Nora (1988), with permission.

folic acid supplementation does not prevent all cases, other unknown genes or factors are presumed to be involved.

Without folic acid supplementation, the empirical recurrence risk after one affected child is 3 to 4 percent, and after two affected children it is 10 percent. With supplementation, the risk after one affected child decreases by 70 percent to less than 1 percent (Czeizel and Dudas, 1992; MRC Vitamin Study Research Group, 1991).

Importantly, prenatal folic acid supplementation in all women may also significantly decrease the incidence of first occurrences of neural-tube defects. Since 1998, the Food and Drug Administration has required fortification of cereal grain products calculated so that the average woman ingests daily an extra 200 μg of folic acid. In the United States, the incidence of neural-tube defects has decreased by a fourth following folic acid fortification (Centers for Disease Control and Prevention, 2004; De Wals and associates, 2003).

GENETIC TESTS

Cytogenetic Analysis

Any tissue containing dividing cells or cells that can be stimulated to divide is suitable for cytogenetic analysis. The dividing cells are arrested in metaphase, and the chromosomes are stained to reveal light and dark bands. The most commonly used technique is Giemsa staining, which yields the G-bands shown in Figure 12-3. The unique banding pattern of each chromosome aids its identification as well as detection of deleted, duplicated, or rearranged segments. The accuracy of cytogenetic analysis increases with the number of bands produced. High-resolution metaphase banding routinely yields 450 to 550 visible bands per haploid chromosome set. Banding of prophase chromosomes generally yields 850 bands.

Because only dividing cells can be evaluated, the rapidity with which results are obtained correlates with the rapidity of cell growth in culture. Fetal blood cells often produce results in 36 to 48 hours. Amnionic fluid, which contains epithelial cells, gastrointestinal mucosal cells, and amniocytes usually yields results in 5 to 14 days. If fetal skin fibroblasts are evaluated postmortem, stimulation of cell growth can be more difficult, and cytogenetic analysis may take 2 to 3 weeks.

Fluorescence In Situ Hybridization (FISH)

This procedure provides a rapid method for determining numerical changes of selected chromosomes and confirming the presence or absence of a specific gene or DNA sequence. FISH is particularly useful for the rapid identification of a specific aneuploidy that may alter clinical management—for example, detection of trisomy 18 or verification of suspected microdeletion or duplication syndromes.

The cells are fixed onto a glass slide, and fluorescently labeled chromosome or gene probes are allowed to hybridize to the fixed chromosomes as shown in **Figures 12-10** and **12-11**. Each probe is a DNA sequence that is complementary to a unique region of the chromosome or gene being investigated, thus preventing cross reaction with other chromosomes. If the DNA sequence of interest is present, hybridization is detected as a bright signal visible by microscopy. The number of signals indicates the number of chromosomes or genes of that type in the cell being analyzed. FISH does not provide information about the entire chromosomal complement, merely the specific chromosomal region or gene of interest.

The most common prenatal application of FISH involves probing interphase chromosomes with DNA sequences specific to chromosomes 21, 18, 13, X, and Y. Probes are also available to aid identification of a number of microdeletion syndromes. Shown in Figure 12-11 is an example of interphase FISH using α-satellite probes for chromosomes 18, X, and Y, in this case demonstrating three signals for chromosome 18—trisomy 18. In a review by Tepperberg and colleagues (2001) of more than 45,000 cases, the concordance between FISH analysis for these chromosomes and a standard cytogenetic karyotype was 99.8 percent. Whenever a FISH analysis is performed, confirmation with standard cytogenetic evaluation is recommended by the American College of Medical Genetics (2000).

Southern Blotting

Named for its inventor, Edward Southern, this technique allows identification of one or several DNA fragments of interest

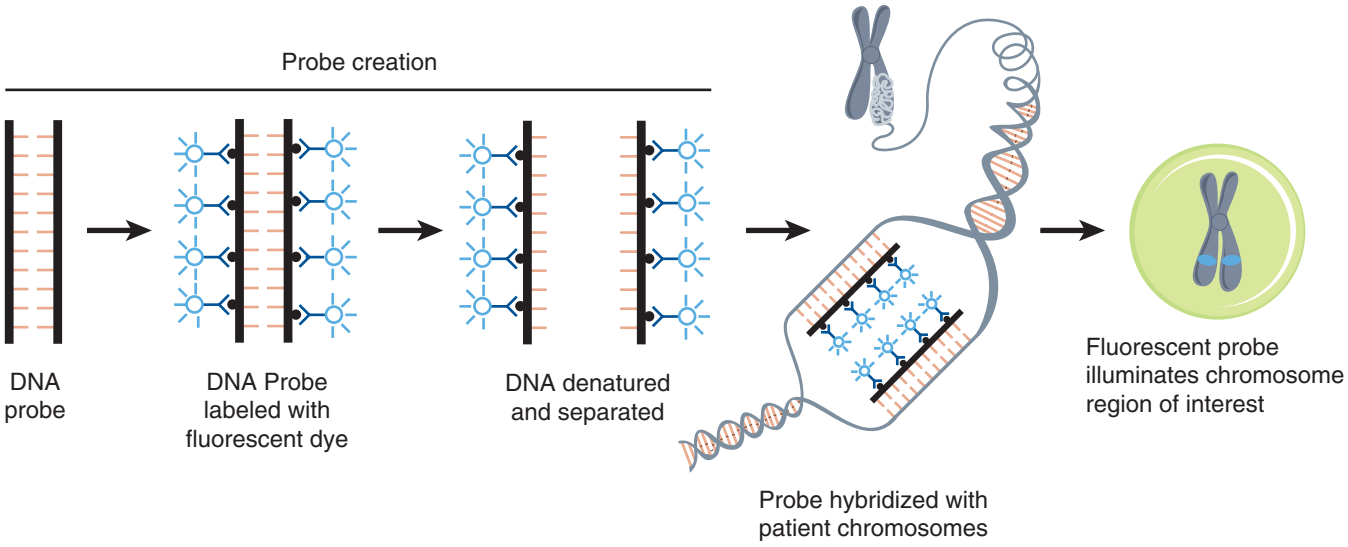

FIGURE 12-10 Steps in fluorescence in situ hybridization (FISH).

from among the million or so typically obtained by enzyme digestion of the entire human genome. As illustrated in **Figure 12-12**, DNA is digested with a restriction endonuclease enzyme, the resulting fragments are separated from each other using agarose gel electrophoresis, and then the fragments are transferred to a nitrocellulose membrane that binds DNA. Probes homologous for the DNA segment of interest are then hybridized to the DNA already bound to the membrane, with a marker that permits their identification. Basic principles of the Southern blot technique also can be applied to RNA, in which case it is called *Northern blotting,* and to proteins—*Western blotting.*

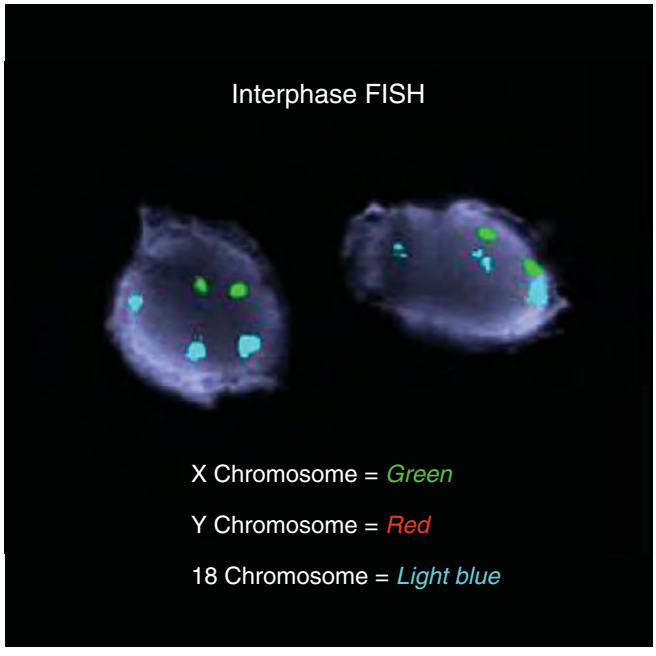

FIGURE 12-11 Interphase fluorescence in situ hybridization (FISH) using α-satellite probes for chromosomes 18, X, and Y. In this case, the three light blue signals, two green signals, and absence of red signals indicates that this is a female fetus with trisomy 18. (Used with permission from Dr. Frederick Elder.)

Polymerase Chain Reaction (PCR)

PCR enables the rapid synthesis of large amounts of a specific DNA sequence or gene. For this, the entire gene sequence or the sequences at the beginning and end of the gene must be known. PCR involves three steps that are repeated many times. First, double-stranded DNA is denatured by heating. Then, oligonucleotide primers corresponding to the target sequence on each separated DNA strand are added and anneal to either end of the target sequence. Finally, a mixture of nucleotides and heat-stable DNA polymerase is added to elongate the primer sequence, and new complementary strands of DNA are synthesized. The procedure is repeated over and over with exponential amplification of the DNA segment.

Linkage Analysis

If a specific disease-causing gene has not been identified, linkage analysis may be helpful. In such cases, the likelihood that an individual, for example, a fetus, has inherited the abnormal trait can be estimated. Linkage analysis allows the location of different genes to be determined, along with their approximate distances from each other. Limitations of this technique are that it is imprecise, that it depends on family size and availability of family members for testing, and that it relies on the presence of informative markers near the gene.

Specific scattered markers are selected for study, based on the suspected location of the gene responsible for the condition. DNA from each family member is next analyzed to determine whether any of the selected markers are transmitted along with the disease gene. If individuals with the disease have the marker and individuals without the disease do not, the gene causing the disease is said to be linked to the marker, suggesting that they are close to each other on the same chromosome.

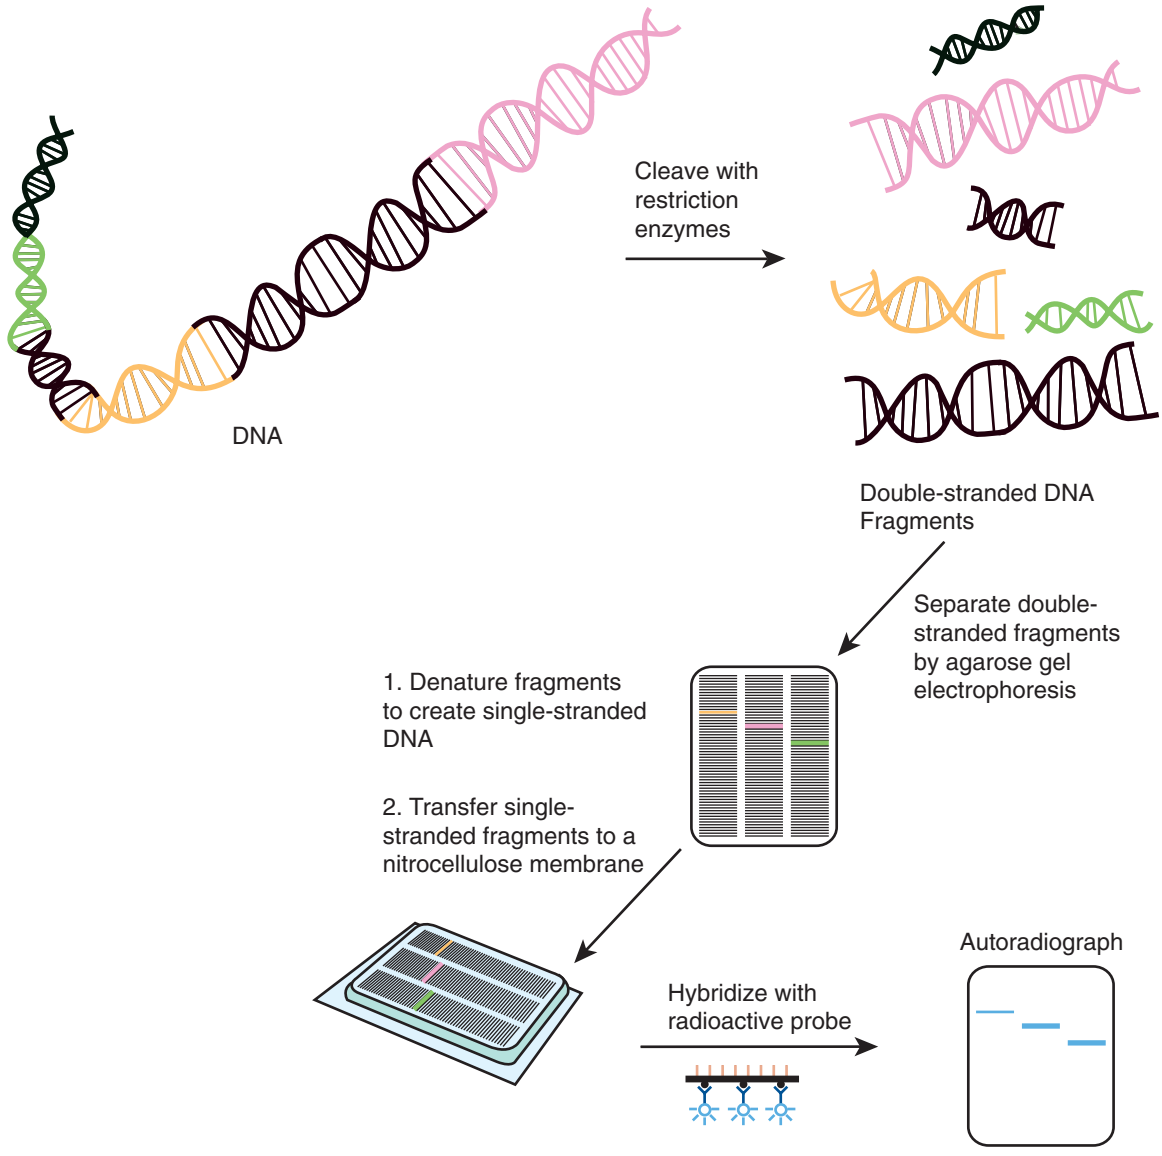

FIGURE 12-12 Southern blotting analysis. Genomic DNA is isolated from leukocytes or amniocytes and digested with a restriction enzyme. This procedure yields a series of reproducible fragments that are separated by agarose gel electrophoresis. The separated DNA fragments are then transferred ("blotted") to a nitrocellulose membrane that binds DNA. The membrane is treated with a solution containing a radioactive single-stranded nucleic acid probe, which forms a double-stranded nucleic acid complex at membrane sites when homologous DNA is present. These regions are then detected by autoradiography.

Comparative Genomic Hybridization (CGH) Arrays

CGH arrays take advantage of the principles of PCR and nucleic acid hybridization to screen DNA for many genes or mutations simultaneously. A microarray platform contains DNA fragments of known sequence. DNA from the tested individual is labeled with a fluorescent dye and exposed to the DNA fragments fixed on the chip. Normal control DNA is labeled with a different fluorescent probe. The intensity of fluorescent probe signals is then read by a laser scanner.

There are important limitations of this technology in its present form. It cannot detect balanced structural chromosomal rearrangements such as balanced translocations or inversions. Genetic polymorphisms identified with it may or may not be clinically significant. Although the use of CGH arrays is currently investigational, it is anticipated that this technology will one day revolutionize genetic screening for prenatal diagnosis.

FETAL THERAPY 302

The incidence of major abnormalities apparent at birth is 2 to 3 percent. These anomalies cause a significant portion of neonatal deaths, and more than a fourth of all pediatric hospital admissions result from genetic disorders (Lee and colleagues, 2001). *Prenatal diagnosis* is the science of identifying structural or functional abnormalities—birth defects—in the fetus. With this information, clinicians hope to provide appropriate counseling and optimize outcome. In some cases, fetal therapy can be used to improve the intrauterine environment. Therapy may include blood product transfusion, administration of medication transplacentally or via the fetal circulation, laser or radiofrequency ablation of vascular anastomoses, amnioreduction, shunt placement, or more extensive fetal surgery.

ETIOLOGY OF BIRTH DEFECTS

Birth defects can arise in at least three ways. The most common type of structural fetal abnormality is a *malformation*—an intrinsic abnormality "programmed" in development, regardless of whether a precise genetic etiology is known. An example is spina bifida. The second type is a *deformation* caused when a genetically normal fetus develops abnormally because of mechanical forces imposed by the uterine environment. An example is an otherwise normal limb that develops contractures because of prolonged oligohydramnios. The third type is a *disruption,* which is a more severe change in form or function that occurs when genetically normal tissue is modified as the result of a specific insult. An example is damage from an amnionic band causing a cephalocele or limb-reduction abnormality.

Sometimes multiple structural or developmental abnormalities occur together in one individual. A cluster of several anomalies or defects can be a *syndrome,* meaning that all the abnormalities have the same cause—for example, trisomy 18 (see Chap. 12, p. 269). Anomalies also may comprise a *sequence,* meaning that all developed sequentially as result of one initial insult—for example, oligohydramnios leading to pulmonary hypoplasia, limb contractures, and facial deformities. Finally, a group of anomalies may be considered an *association,* in which particular anomalies occur together frequently but do not seem to be linked etiologically—for example, *VATER*, association of vertebral defects, anal atresia, tracheoesophageal fistula with esophageal atresia, and radial dysplasia. It is readily apparent that classification of fetal anomalies can be challenging, and reclassification may be required.

PRENATAL DIAGNOSIS OF NEURAL-TUBE DEFECTS

Neural-Tube Defects (NTDs)

The open neural-tube defects include *anencephaly*, *spina bifida*, *cephalocele*, and other rare spinal fusion (*schisis*) abnormalities. Features of these anomalies are reviewed in Chapter 16 (p. 354). As a class, these defects of neurulation occur in 1.4 to 2 per 1000 pregnancies and are the second most common class of birth defect after cardiac anomalies (American College of Obstetricians and Gynecologists, 2003). In the 1970s, Brock and associates (1972, 1973) observed that pregnancies complicated by a NTD had higher levels of alpha-fetoprotein (AFP) in

maternal serum and amnionic fluid. This formed the basis for the first maternal serum screening test for a birth defect.

The results of a landmark trial were reported by Wald and associates (1977), who described the United Kingdom Collaborative Study on Alpha-Fetoprotein in Relation to Neural-Tube Defects. This study demonstrated the efficacy of maternal serum AFP screening for NTDs. Maternal serum AFP concentration at 16 to 18 weeks was found to exceed 2.5 multiples of the median (MoM) in 88 percent of women carrying fetuses with anencephaly and in 79 percent with spina bifida (Wald and co-workers, 1977). These benefits were subsequently confirmed by others and adopted in the United States and Europe by the mid-1980s (Burton, 1983; Haddow, 1983; Milunsky, 1980, and all their co-workers).

Risk Factors for Neural-Tube Defects

Almost 95 percent of NTDs occur in the absence of recognized risk factor or family history—hence the need for routine screening. There are, however, specific risk factors, some of which are listed in Table 13-1. Genetic causes are the largest category, and NTDs are multifactorial disorders (Chap. 12, p. 281). The recurrence risk is approximately 4 percent if a couple has previously had a child with either anencephaly or spina bifida, 5 percent if either parent was born with a NTD, and as high as 10 percent if a couple has two affected children. One etiology for this in some populations is a common mutation in the methylene tetrahydrofolate reductase (MTHFR) gene—677C→T—which leads to impaired homocysteine and folate metabolism and increases the risk for NTDs and probably cardiac malformations (Dalal, 2007; Grandone, 2006; Munoz, 2007, and all their colleagues). NTDs are also a component of more than 80 genetic syndromes, many of which include other fetal anomalies amenable to prenatal diagnosis (Milunsky and Canick, 2004).

Other risk factors for NTD include environmental exposures, such as hyperthermia; certain medications, especially those that disturb folic acid metabolism; and hyperglycemia from insulin-dependent diabetes. Although the exact mechanism by which diabetes causes a NTD is unknown, research in rodents has focused on the role of embryonic hyperglycemia causing increased oxidative metabolism (Loeken, 2005; Zhao and Reece, 2005). In mice, oxidative stress leads to decreased expression of one or more genes involved in neuroepithelial and neural crest development, effectively arresting the process of neural-tube closure.

There are also certain racial/ethnic groups, as well as populations living in high-risk geographical regions, that have an increased incidence of NTDs. For example, the United Kingdom has the highest frequency of NTDs—1 percent, whereas the overall incidence in the United States is only 0.2 percent. Within the U.S., Mexican-born women have an unexplained twofold increased risk (Velie and colleagues, 2006). The frequency of defects in high-risk populations is probably related to both ethnic-genetic background and environmental influences such as diet (see Chap. 12, p. 281).

Many women at increased risk for NTD benefit from taking 4 mg of folic acid daily before conception and through the first trimester (see also Chap. 7, p. 177). These include individuals with one or more prior affected children or if either the pregnant woman or her partner *has* a NTD. Although data are limited, folic acid supplementation may not decrease the NTD risk in women with valproic acid exposure, high temperature in the first trimester or hot tub exposure, or diabetes (American College of Obstetricians and Gynecologists, 2003). The role of lower doses of folic acid supplementation to reduce the first occurrence of NTDs in low-risk women is reviewed in Chapter 8, p. 204).

TABLE 13-1. Some Risk Factors for Neural-Tube Defects

Genetic cause
- Family history—multifactorial inheritance
- MTHFR mutation—677C→T
- Syndromes with autosomal recessive inheritance
  - Meckel-Gruber
  - Roberts
  - Joubert
  - Jarcho-Levin
  - HARDE—hydrocephalus–agyria–retinal dysplasia–encephalocele
- Aneuploidy
  - Trisomy 13
  - Trisomy 18
  - Triploidy

Exposure to certain environmental agents
- Diabetes—hyperglycemia
- Hyperthermia
  - Hot tub or sauna
  - Fever (controversial)
- Medications
  - Valproic acid
  - Carbamazepine
  - Coumadin
  - Aminopterin
  - Thalidomide
  - Efavirenz

Geographical region—ethnicity, diet, other factor
- United Kingdom
- India
- China
- Egypt
- Mexico
- Southern Appalachian United States

MTHFR = methylene tetrahydrofolate reductase.

Alpha-Fetoprotein (AFP)

This glycoprotein is synthesized early in gestation by the fetal yolk sac and later by the fetal gastrointestinal tract and liver (see Chap. 4, p. 79). It is the major serum protein in the embryo-fetus and is analogous to albumin. As shown in Figure 13-1, its concentration increases steadily in both fetal serum and amnionic fluid until 13 weeks, after which, levels rapidly decrease. Conversely, AFP is found in steadily increasing quantities in maternal serum after 12 weeks. The normal concentration

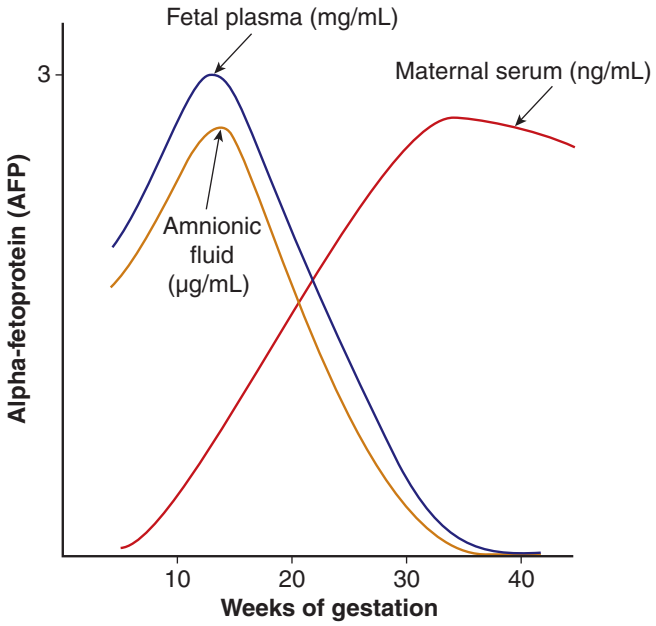

FIGURE 13-1 Diagram of alpha-fetoprotein (AFP) concentration across gestational age in fetal plasma, amnionic fluid, and maternal serum. The scale refers to the fetal plasma level, which is approximately 150 times greater than the amnionic fluid concentration and 50,000 times greater than the maternal serum concentration.

gradient between fetal plasma and maternal serum is on the order of 50,000:1. Fetal body wall defects uncovered by integument, such as NTDs and ventral wall defects, permit AFP to leak into the amnionic fluid, resulting in maternal serum AFP levels that may be dramatically increased.

Maternal Serum AFP Screening

The American College of Obstetricians and Gynecologists (2003) recommends that all women be offered second-trimester AFP screening. This is a component of multiple marker serum screening and is generally offered between 15 and 20 weeks. It should be performed within a protocol that includes quality control, counseling, and follow-up. Maternal serum AFP is measured in nanograms/milliter (ng/mL) and reported as a multiple of the median (MoM) of the unaffected population. Converting the results to MoM normalizes the distribution of AFP levels and permits comparison of results from different laboratories and populations. Using a maternal serum AFP level of 2.0 or 2.5 MoM as the upper limit of normal, most laboratories report a sensitivity—detection rate—of at least 90 percent for anencephaly and 80 percent for spina bifida, at a screen-positive rate of 3 to 5 percent (Milunsky and Canick, 2004). The positive-predictive value, those with AFP elevation who have an affected fetus, is only 2 to 6 percent. Thus, an abnormal screening test should be followed by counseling and consideration for a diagnostic test. The reason that the detection rate is not higher is explained by the overlap in AFP distributions in affected and unaffected pregnancies as shown in Figure 13-2.

Several factors influence the maternal serum AFP level and are taken into consideration when calculating the AFP MoM:

1. Maternal weight—Because AFP is a fetal product measured in the maternal circulation, accurate maternal weight reflects the volume of distribution
2. Gestational age—Maternal serum AFP concentration increases by approximately 15 percent per week during the second trimester, thus accurate gestational age is essential (Knight and Palomaki, 1992)
3. Race or ethnicity—African-American women have at least 10-percent higher serum AFP concentrations despite having a lower NTD risk (Benn and colleagues, 1997)
4. Diabetes—Women with overt diabetes have a three- to fourfold increased risk for an NTD, but their serum AFP levels may be as much as 20 percent lower than those of nondiabetics (Greene and colleagues, 1988). Although most laboratories continue to adjust for diabetes, it is unclear at this time if this is necessary for those with tight glycemic control (Sancken and Bartels, 2001)
5. Multifetal gestation—A higher screening threshold value is used in twin pregnancies, and the detection rate as well as false-positive rate will depend on the threshold selected (Cuckle and colleagues, 1990). For example, at Parkland Hospital, AFP is considered elevated in a twin pregnancy if greater than 3.5 MoM, but other laboratories use 4.0 or even 5.0 MoM.

One algorithm for evaluating maternal serum AFP is shown in Figure 13-3. With an elevated value, if not already performed, evaluation begins with a standard sonographic examination, which can reliably exclude three common causes of AFP elevation: underestimation of gestational age, multifetal gestation, and fetal demise. Most cases of neural-tube defects may be detected or suspected during this initial examination (Dashe and colleagues, 2006). Once the screening test is confirmed to be abnormal, the patient is offered diagnostic evaluation as subsequently discussed.

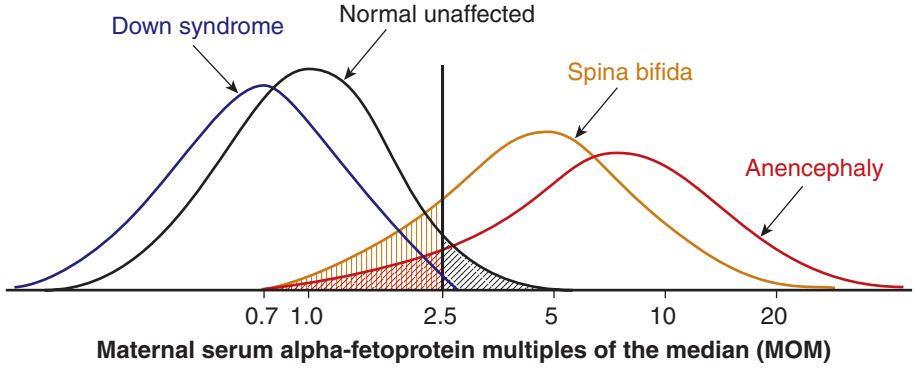

FIGURE 13-2 Maternal serum alpha-fetoprotein distribution for singleton pregnancies at 15 to 20 weeks. The screen cut-off value of 2.5 multiples of the median is expected to result in a false-positive rate of up to 5 percent (*black hatched area*) and false-negative rates of up to 20 percent for spina bifida (*tan hatched area*) and 10 percent for anencephaly (*red hatched area*).

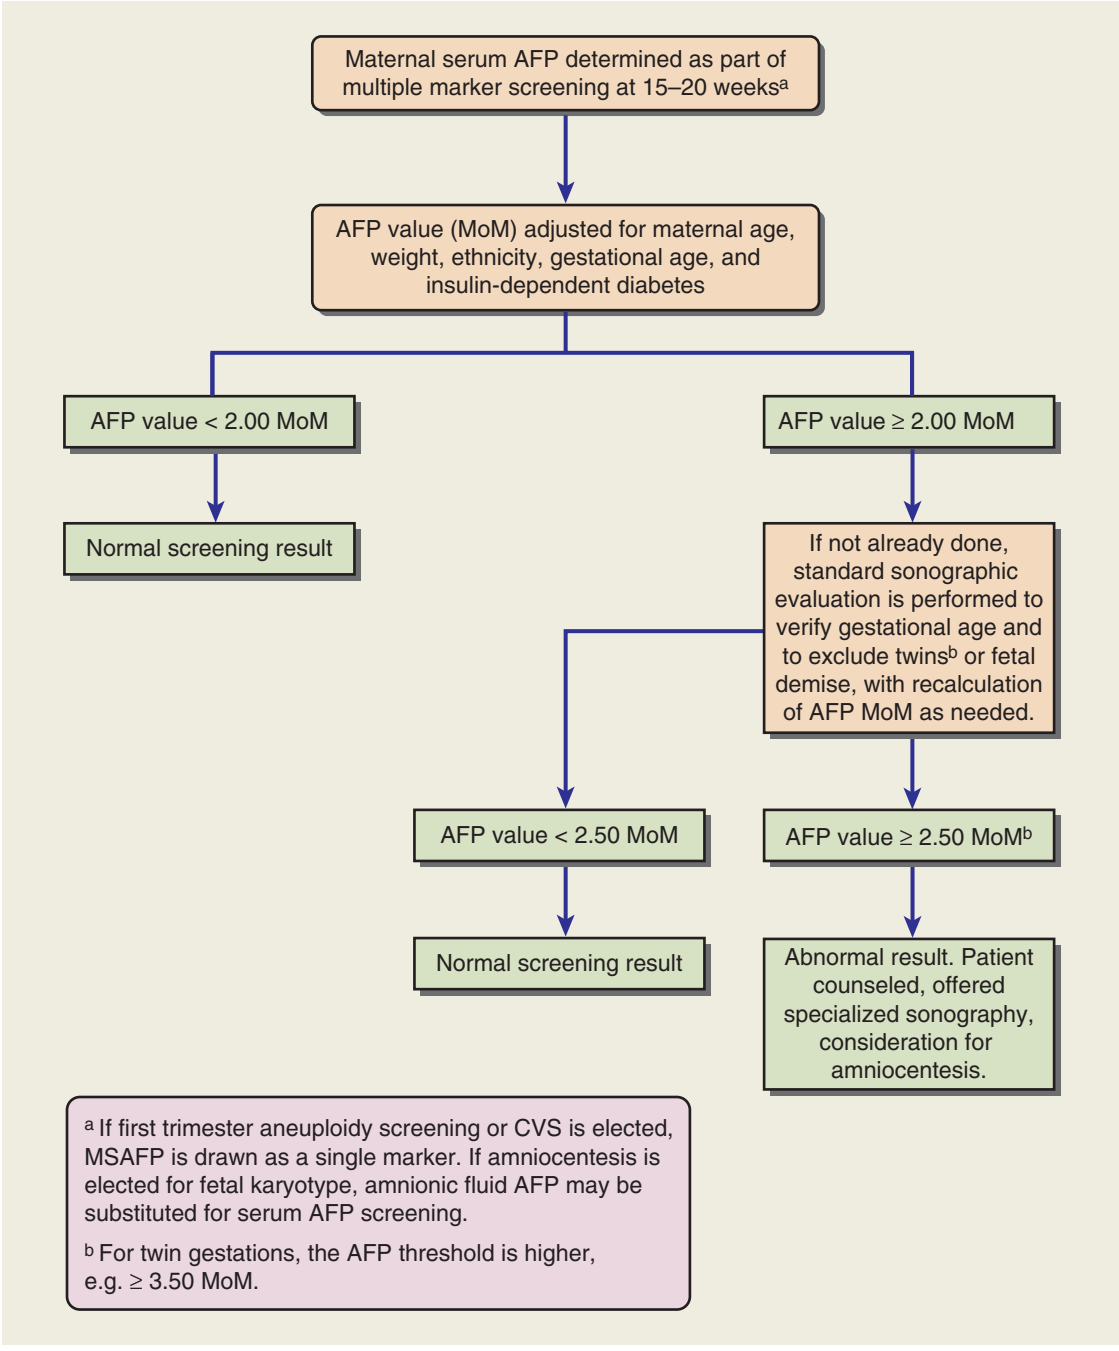

FIGURE 13-3 Example of an algorithm for evaluating maternal serum alpha-fetoprotein screening values (MSAFP).

In addition to NTDs, many other types of birth defects and placental abnormalities are associated with AFP elevation (Table 13-2). The likelihood that a pregnancy is affected by a fetal or placental abnormality increases in proportion to the AFP level. Greater than 40 percent of pregnancies are abnormal if the AFP level is greater than 7 MoM (Reichler and co-workers, 1994).

Evaluation of Maternal Serum AFP Elevation

Women with abnormally elevated serum AFP levels should be referred for genetic counseling and offered a diagnostic test, such as specialized sonographic evaluation and amniocentesis. Those with certain risk factors and normal AFP levels are also offered diagnostic testing. Risk factors include a personal history of NTD, a first-degree relative with NTD, insulin-dependent diabetes, and first-trimester exposure to medication associated with increased NTD risk.

Specialized Sonography. More than two decades ago, Nicolaides and associates (1986) described frontal bone scalloping—the "lemon sign"—shown in Figure 13-4, and bowing of the cerebellum with effacement of the cisterna magna—the "banana sign" shown in Figure 13-5—in second-trimester fetuses with open spina bifida. These investigators also noted that small biparietal diameter and ventriculomegaly frequently were present in such cases. In their review, Watson and associates

Elevated Levels
Underestimated gestational age
Multifetal gestation
Fetal death
Neural-tube defects
Gastroschisis
Omphalocele
Low maternal weight
Pilonidal cysts
Esophageal or intestinal obstruction
Liver necrosis
Cystic hygroma
Sacrococcygeal teratoma
Urinary obstruction
Renal anomalies—polycystic kidneys, renal agenesis
Congenital nephrosis
Osteogenesis imperfecta
Congenital skin defects
Cloacal exstrophy
Chorioangioma of placenta
Placental abruption
Oligohydramnios
Preeclampsia
Low birthweight
Maternal hepatoma or teratoma
Low Levels
Obesity[a]
Diabetes[a]
Chromosomal trisomies
Gestational trophoblastic disease
Fetal death
Overestimated gestational age

[a]Adjustments in formula used to calculate risk.

(1991) reported that 99 percent of fetuses with open spina bifida had one or more of these findings.

Transverse and sagittal images of the spine are increasingly used to characterize the size and location of spinal defects (see Fig. 16-9, p. 355). Indeed, experienced investigators have described nearly 100-percent detection of open NTDs (Nadel, 1990; Norem, 2005; Sepulveda, 1995, and all their colleagues). Overall NTD risk may be reduced by at least 95 percent when no spine or cranial abnormalities is observed (Hogge, 1989; Morrow, 1991; Van den Hof, 1990, and all their associates).

Many centers now use specialized sonography as the primary method of evaluating an elevated serum AFP. And although amniocentesis is offered, many women no longer opt for it. Importantly, as recommended by the American College of Obstetricians and Gynecologists (2003), women should be counseled regarding risks and benefits of both diagnostic tests, the risk associated with their degree of AFP elevation or with other risk factors, and the quality and findings of the sonographic examination before making a decision.

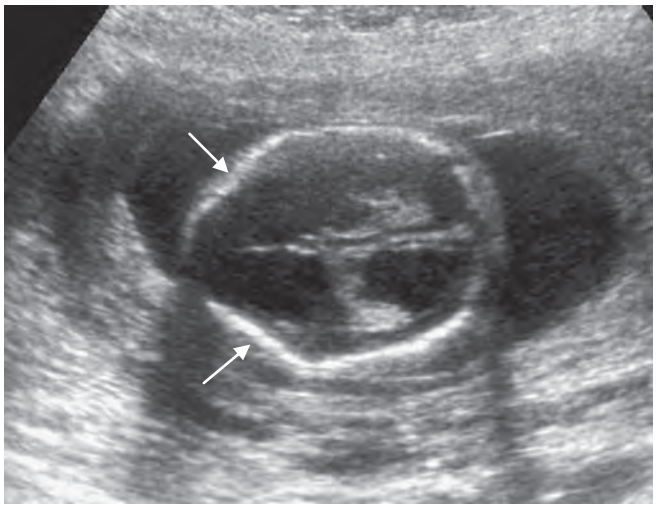

FIGURE 13-4 In this axial image of the fetal head at the level of the lateral ventricles, inward bowing or scalloping of the frontal bones (*arrows*) in the setting of spina bifida produces the "lemon sign." The image also depicts ventriculomegaly.

Amniocentesis. Until relatively recently, an elevated maternal serum AFP level prompted amniocentesis to determine the amnionic fluid AFP level. If this was also elevated, an assay for acetylcholinesterase was performed, and if positive, it was considered diagnostic of a NTD. The overall sensitivity is about 98 percent for open NTDs, with a false-positive rate of 0.4 percent (Milunsky and Carick, 2004). In one series of nearly 10,000 pregnancies, amniocentesis for AFP and acetylcholinesterase detected 100 percent of anencephaly and open spina bifida cases, with a false-positive rate of only 0.2 percent (Loft and colleagues, 1993). However, other fetal abnormalities may be

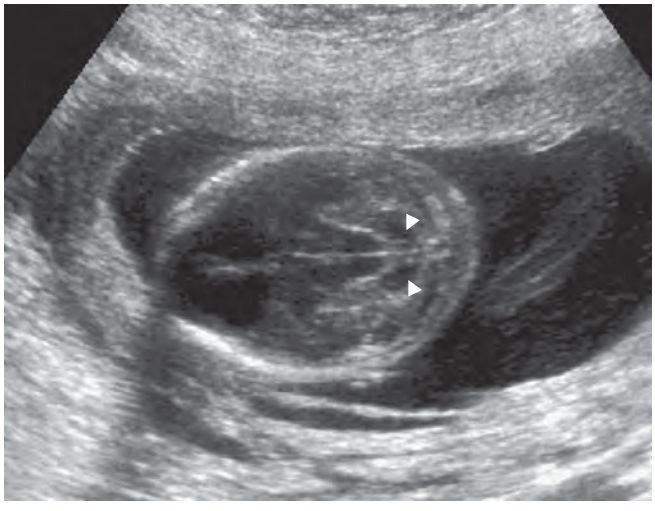

FIGURE 13-5 In this image of the fetal head at the level of the posterior fossa, downward herniation of the cerebellum (*white arrows*), with effacement of the cisterna magna, produces the "banana sign."

associated with both elevated amnionic fluid AFP and positive assay for acetylcholinesterase, including ventral wall defects, esophageal atresia, fetal teratoma, cloacal exstrophy, and skin abnormalities such as epidermolysis bullosa. And although amniocentesis was once considered the "gold standard" for diagnosis of open NTDs, in many centers it has been replaced by, or used in conjunction with, specialized sonography.

If amniocentesis is elected, it is somewhat controversial whether concurrent fetal karyotyping should be offered. If the maternal serum AFP level is elevated, but with *normal* amnionic fluid AFP level and no sonographically detectable fetal anomaly, Thiagarajah and colleagues (1995) found no increased risk for an abnormal karyotype in more than 600 pregnancies. Conversely, Feuchtbaum and associates (1995) reported a 1.1-percent rate of chromosomal anomalies in 8097 pregnancies—twice the expected prevalence. Gonzalez and associates (1996) reported that in women with an elevated serum and an elevated amnionic fluid AFP level but no visible fetal anomaly, the risk for chromosomal abnormalities was fivefold above background risk. The risk for chromosomal defects is higher whenever a NTD is *diagnosed*. In a review of more than 17,000 prenatal diagnosis cases, Hume and associates (1996) observed a aneuploidy rate in the 106 fetuses with an isolated NTD. At Parkland Hospital, amniocentesis for fetal karyotype is offered following sonographic diagnosis of NTD.

Unexplained Maternal Serum AFP Elevation

When no fetal or placental abnormality is detected after a specialized sonographic evaluation, with or without amniocentesis, the AFP elevation is considered *unexplained.* These pregnancies are at increased risk for a variety of subsequent adverse pregnancy outcomes (see Table 13-2). Some include a fetal anomaly not detectable prenatally, fetal-growth restriction, oligohydramnios, placental abruption, preterm membrane rupture, preterm birth, and even fetal death (Katz, 1990; Simpson, 1991; Waller, 1991, and all their associates). Many of these complications are assumed to result from placental damage or dysfunction. However, often neither the etiology nor optimal management is clear. No specific program of maternal or fetal surveillance has been found to favorably affect pregnancy outcomes (Cunningham and Gilstrap, 1991). At Parkland Hospital, prenatal care for these women is not altered unless a specific complication arises. Despite the extensive list of *possible* adverse outcomes, most women with unexplained AFP elevation have normal outcomes.

Management of the Fetus with a Neural-Tube Defect

The optimal timing and method of delivery for an affected fetus are controversial. Reports are retrospective and suffer from various biases. That said, an equal number of reports support cesarean versus vaginal delivery (Bensen and co-workers, 1988; Luthy and colleagues, 1991; Sakala and Andree, 1990). Cesarean delivery might reduce the risk of mechanical trauma and fetal spinal infection. Moreover, delivery can be scheduled to allow precise timing so that the appropriate management team can be assembled. It is best that the delivery time and method be determined on a case-by-case basis. Fetal surgical repair of meningomyelocele is being studied in a multicenter trial as described on page 306.

PRENATAL DIAGNOSIS OF DOWN SYNDROME AND OTHER ANEUPLOIDIES

Aneuploidy Screening Protocols

As discussed in Chapter 12, the risk of fetal trisomy increases considerably with maternal age and rises most rapidly beginning at age 35 (see Fig. 12-1, p. 268). Traditionally, age 35 has been selected as the threshold for "advanced maternal age." Thus, until the mid-1980s, prenatal diagnostic testing for fetal aneuploidy was offered only to women who would be 35 or older at delivery. After Merkatz and colleagues (1984) reported that pregnancies with fetal Down syndrome were characterized by low maternal serum AFP levels at 15 to 20 weeks, screening for Down syndrome became available to younger women. If the serum screening test identified a younger woman as having the same or greater risk for fetal trisomy 21 as a woman 35 years of age at delivery—about 1 in 375—the result was considered abnormal, and amniocentesis was offered.

During the past two decades, the field of prenatal diagnosis has undergone major advances. The addition of other serum analytes to second-trimester screening has improved trisomy 21 detection by three- to fourfold, and as high as 80 percent with the quadruple marker test (Malone and colleagues, 2005). Perhaps more impressive, comparable results can be achieved at 11 to 14 weeks by using a combination of the fetal nuchal translucency measurement and serum markers (American College of Obstetricians and Gynecologists, 2007b). These screening tests have even greater detection rates in older women because the prevalence of aneuploidy is higher.

Because of these improved detection rates with screening technology, the American College of Obstetricians and Gynecologists (2007b) recommends that *all* women who present for prenatal care before 20 weeks be offered screening. Thus, regardless of age, all women are counseled regarding the differences between screening and diagnostic tests, and they are given the option of invasive diagnostic testing.

There are a number of approaches to fetal aneuploidy screening as shown in **Table 13-3**. Sonography and maternal serum markers can be used in the first trimester, second trimester, or as a combination of first- and second-trimester tests. Of the screening options currently available, each has its own advantages (Reddy and Mennuti, 2006). The College thus recommends that, depending on available tests, physicians should determine which strategies best meet the needs of their patients. Screening tests such as those presented in Table 13-3 typically have false-positive rates of approximately 5 percent.

Second-Trimester Screening

As discussed above, it was discovered in the 1980s that multiple maternal serum markers could reliably differentiate pregnancies affected by trisomy 18 and 21 from unaffected pregnancies. At 15 to 20 weeks, Down syndrome pregnancies are characterized by an AFP value of approximately 0.7 MoM, human chorionic

TABLE 13-3. Selected Down Syndrome Screening Strategies

Strategy	Analytes	Detection Rate[a] (Percent)
First-trimester screen	NT, PAPP-A, hCG or free β-hCG	79–87
NT (First trimester)	NT	64–70
Triple test	MSAFP, hCG or free β-hCG, uE3	60–69
Quadruple (Quad) test	MSAFP, hCG or free β-hCG, uE3, inh	67–81
Integrated screen	First-trimester screen & Quad test—results withheld until Quad test completed	94–96
Stepwise sequential screen	First-trimester screen & Quad test — 1% offered diagnostic test after first trimester screen — 99% proceed to Quad test, results withheld until Quad test completed	90–95
Contingent sequential screen	First-trimester screen & Quad test — 1% offered diagnostic test after first-trimester screen — 15% proceed to Quad test, results withheld until Quad test completed — 84% have no additional test after first-trimester screen	88–94

[a]Based on a 5-percent positive screen rate.
Free β-hCG = free β-subunit hCG; hCG = human chorionic gonadotropin; inh = dimeric inhibin α; MSAFP = maternal serum alpha-fetoprotein; NT = nuchal translucency; PAPP-A = pregnancy-associated plasma protein-A; uE3 = unconjugated estriol.
Data from Cuckle (2005), Malone (2005), Wapner (2003), and all their colleagues.

gonadotropin (hCG) level of approximately 2.0 MoM, and unconjugated estriol concentration of approximately 0.8 MoM (Bogart, 1987; Merkatz, 1984; Wald, 1988a, b, and all their coworkers). This "triple test" can detect as many as 65 to 70 percent of trisomy 21 cases. The test is also used to screen for trisomy 18, in which all three serum markers are decreased. A fourth marker, dimeric inhibin alpha, was subsequently added to make the quadruple or "quad" test. Values of about 1.8 MoM are reported in Down syndrome pregnancies (Spencer and colleagues, 1996).

Accurate gestational age is essential for expected detection rates when multiple markers are used. For example, Wald and colleagues (1996) found that for a 5-percent false-positive rate, the quad test could detect 70 percent of Down syndrome fetuses in pregnancies dated by last menstrual period alone compared with 77 percent in pregnancies dated by second-trimester sonography. In a large study of pregnancies dated by first-trimester sonography, the sensitivity of the quad test exceeded 80 percent (Malone and colleagues, 2005).

Multiple-marker screening tests are based on a composite likelihood ratio determined by levels of all analytes. The maternal age-related risk is then multiplied by this ratio. A positive screening test indicates *increased risk,* but it is not diagnostic of Down syndrome or another aneuploidy. Conversely, a negative screening test indicates that the *risk* is not increased, but it does not guarantee a normal fetus. After gestational age is confirmed by sonography, women with a positive screening test result should be offered amniocentesis or fetal blood sampling for fetal karyotyping (American College of Obstetricians and Gynecologists, 2007b).

First-Trimester Screening

This is performed between 11 and 14 weeks. Protocols in current use include maternal serum analyte screening, sonographic evaluation, or a combination of both. Two maternal serum analytes are tested, hCG (or free βhCG) and pregnancy-associated plasma protein A (PAPP-A) (Haddow and associates, 1998). In the first trimester, serum hCG levels are higher, approximately 2.0 MoM, and PAPP-A levels are lower, approximately 0.4 MoM, with a Down syndrome fetus.

The most commonly used first-trimester screening protocol combines these two serum markers with the sonographic *nuchal translucency,* which is discussed below. Using this protocol, Down syndrome detection in large prospective trials ranges from 79 to 87 percent with a false-positive rate of 5 percent (see Table 13-3). These results are comparable to second-trimester quad screening (American College of Obstetricians and Gynecologists, 2007b). All screening tests for fetal aneuploidy are less sensitive in younger women because of lower prevalence rates. Gestational age also affects the accuracy of Down syndrome detection. Testing sensitivity is approximately 5 percent lower if performed at 13 instead of 11 weeks (Malone and colleagues, 2005).

In addition to trisomy 21, other abnormalities are also identified by first-trimester screening. For example, Nicolaides (2004) reported approximately 90-percent sensitivity for trisomies 18 and 13 with a 1-percent false-positive rate. Moreover, results may be abnormal in the setting of a number of structural fetal anomalies (Souka and colleagues 2001). There is also strong association between increasing nuchal translucency, which is detailed subsequently, and fetal cardiac anomalies (Atzei and colleagues, 2005; Simpson and colleagues, 2007). Because of this, the American College of Obstetricians and Gynecologists (2007b) recommends that when the nuchal translucency measurement is 3.5 mm or greater with a normal fetal karyotype, then targeted sonographic examination, fetal echocardiography, or both should be considered.

There are several logistical concerns with first-trimester screening. One is that because fewer than 10 percent of maternal-fetal medicine specialists perform chorionic villus sampling (CVS), the advantage of early diagnosis may be lost. A second is that women still require serum AFP testing in the second trimester. Another is that second-trimester screening will need to be provided for the one third of women who present for prenatal care after the first trimester.

Combined First- and Second-Trimester Screening

As first-trimester screening has become incorporated into practice, research efforts have focused on whether screening efficacy may be even further improved by combining the currently available first- and second-trimester screening technologies. A number of strategies have been developed (see Table 13-3):

1. *Integrated screening* combines results of both the first- and second-trimester screening tests into a single risk. Integrated screening has the highest Down syndrome detection rate—90 to 96 percent. The disadvantage, however, is that results are not available until the second-trimester screening test has been completed. A form of integrated screening, *serum integrated screening*, incorporates the serum markers of the first-trimester screening test with second-trimester quadruple marker testing. It may be offered if nuchal translucency measurement is not available, but it is significantly less effective than when nuchal translucency is included (American College of Obstetricians and Gynecologists, 2007b).
2. *Sequential screening* discloses results of first-trimester screening to women at highest risk, thus allowing them the option of earlier invasive testing. There are two testing strategies in this category:
   a. *Stepwise sequential screening* is for women with first-trimester screen results indicating particular risk for trisomy 21—for example, the top 1 percent, which may include 70 percent of trisomy 21 fetuses. These women are informed and offered invasive testing (Cuckle and associates, 2005). The remainder—about 99 percent—of women undergo second-trimester screening
   b. *Contingent sequential screening* is similar to stepwise screening, except that women are divided into three groups: high, moderate, and low risk. Those at highest risk—the top 1 percent—are counseled and offered invasive testing. Those at lowest risk—perhaps 80 to 85 percent—have no further testing. Only women at moderate risk—about 15 to 20 percent—go on to second-trimester screening (Cuckle and associates, 2005). This option is the most cost-effective for population screening because second-trimester screening is obviated in up to 85 percent of prenatal patients.

Integrated and sequential screening strategies require coordination between the practitioner and the laboratory to ensure that the second sample is obtained during the appropriate gestational window, sent to the same laboratory, and appropriately linked to first-trimester results. Not all laboratories are currently capable of integrating first- and second-trimester results because of laboratory inexperience or patent issues. Finally, the need for repeated visits at precise times may create special challenges for clinics serving indigent patients.

Sonographic Screening for Aneuploidy

Major Structural Defects

Because 2 to 3 percent of infants are found to have major birth defects, it is not uncommon for a major structural anomaly to be discovered during a routine sonographic examination. An isolated malformation may be multifactorial—for example, a cardiac defect or a NTD, or it may be part of a genetic syndrome. With a syndrome, the fetus may have other abnormalities that are undetectable by sonography but that affect the prognosis—for example, mental retardation. Aneuploidy is often associated with both major anatomical malformations and minor markers, which are discussed below. With few exceptions, the specific aneuploidy risk associated with most major anomalies is high enough to merit offering invasive fetal testing (**Table 13-4**).

Although the finding of a major anomaly often increases the aneuploidy risk, it should not be assumed that aneuploid fetuses will have a sonographically detectable major malformation. For example, only 25 to 30 percent of second-trimester fetuses with Down syndrome will have a major malformation that can be identified sonographically (Vintzileos and Egan, 1995). Most fetuses with trisomy 18, trisomy 13, and triploidy—aneuploidies much more likely to be lethal in utero—will have major sonographic abnormalities.

Second-Trimester Sonographic Markers—"Soft Signs"

For more than two decades, investigators have recognized that the sonographic detection of aneuploidy, particularly Down syndrome, may be increased by the addition of minor sonographic markers that are collectively referred to as "soft signs." In the absence of aneuploidy or an associated major malformation, these minor abnormalities usually do not significantly affect the fetal prognosis. A host of features seen sonographically in some Down fetuses are listed in **Table 13-5**. Six of these have been the focus of "genetic sonogram" studies, in which likelihood ratios have been calculated and are shown in **Table 13-6**. The aneuploidy risk increases with the number of markers identified.

TABLE 13-4. Aneuploidy Risk Associated with Selected Major Fetal Anomalies

Abnormality	Approximate Population Incidence	Aneuploidy Risk (Percent)	Common Aneuploidies[a]
Cystic hygroma	1/300 EU;1/2000 B	50	45X,21,18,13, triploidy
Nonimmune hydrops	1/1500–4000 B	10–20	21,18,13,45X triploidy
Ventriculomegaly	1/700–3000 B	5–25	13,18,21, triploidy
Holoprosencephaly	1/16,000 B	40–60	13,18,22, triploidy
Dandy Walker complex	1/30,000 B	30–50	18,13,21, triploidy
Cleft lip/palate	1/500–3000 B	5–15	18,13
Cardiac defects	5–8/1000 B	10–30	21,18,13,45X, 22q microdeletion
Diaphragmatic hernia	1/2500–10,000 B	5–15	18,13,21
Esophageal atresia	1/2000–4000 B	10–40	18,21
Duodenal atresia	1/5000 B	30–40	21
Jejunal/ileal atresia	1/3000 B	Minimal	None
Gastroschisis	1/2000–5000 B	Minimal	None
Omphalocele	1/4000 B	30–50	18,13,21, triploidy
Clubfoot	1/1000 B	5–20	18,13

[a]Numbers indicate autosomal trisomies except where indicated, for example, 45 X indicates monosomy X.
B = birth; EU = early ultrasound.
Data from Callen (2000); Malone (2005); Nyberg (2003); Santiago-Munoz (2007), and all their colleagues.

The incorporation of minor markers into second-trimester screening protocols has been studied largely in high-risk populations, with reported detection of Down syndrome of 50 to 75 percent (American College of Obstetricians and Gynecologists, 2007b). Unfortunately, at least 10 percent of unaffected pregnancies will have one of these markers, significantly limiting their utility for general population screening (Bromley and colleagues, 2002; Nyberg and Souter, 2003). Their use is also hampered by lack of standard measurement criteria and clear definition of what constitutes an abnormal finding. There are new markers, such as fetal nasal bone hypoplasia, which may hold promise (Gianferrari and colleagues, 2007). Currently the American College of Obstetricians and Gynecologists (2007b) recommends that risk adjustment based on second-trimester sonographic markers be limited to specialized centers and those conducting research in this area.

TABLE 13-5. Second-Trimester Markers or "Soft Signs" Associated with Some Down Syndrome Fetuses

Sonographic Marker
Nuchal fold thickening
Nasal bone absence or hypoplasia
Shortened frontal lobe or brachycephaly
Short ear length
Echogenic intracardiac focus
Echogenic bowel
Mild renal pelvis dilation
Widened iliac angle
Widened gap between first and second toes—"sandal gap"
Clinodactyly, hypoplastic mid-phalanx of fifth digit
Single transverse palmar crease
Short femur
Short humerus

First-Trimester Nuchal Translucency

The increased sonolucent area at the back of the fetal neck is termed the nuchal translucency, or NT (see Fig. 16-1, p. 351). During the 1990s, it became apparent that this sign was associated with Down syndrome and other aneuploidies, genetic syndromes, and birth defects (Souka and co-workers 1998). Specifically, if the NT measurement is abnormally increased, approximately a third of such fetuses will have a chromosome abnormality, and half of these are Down syndrome (Snijders and colleagues, 1998). Increased NT itself is not a fetal abnormality, but rather a marker or soft sign that confers increased risk. When expressed as a multiple of the median, the NT measurement can be combined with serum analytes to calculate an accurate composite risk.

The major drawbacks are that NT measurement requires specific training, standardization, use of appropriate ultrasound equipment, and ongoing quality assessment. For these reasons, the American College of Obstetricians and Gynecologists (2007b) recommends that this procedure be limited to centers and individuals who can meet these criteria. Used alone, and as shown in Table 13-3, NT measurement will identify 64 to 70 percent of cases of Down syndrome (Malone and colleagues, 2005). When combined with serum markers, and again shown

TABLE 13-6. Likelihood Ratios and False-Positive Rates for Isolated Second-Trimester Markers Used in Down Syndrome Screening Protocols

Sonographic Marker	Likelihood Ratio	Prevalence in Unaffected Fetuses (Percent)
Nuchal fold thickening	11–17	0.5
Mild renal pelvis dilation	1.5–1.9	2.0–2.2
Echogenic intracardiac focus	1.4–2.8	3.8–3.9[a]
Echogenic bowel	6.1–6.7	0.5–0.7
Short femur	1.2–2.7	3.7–3.9
Short humerus	5.1–7.5	0.4
Any 1 marker	1.9–2.0	10.0–11.3
2 markers	6.2–9.7	1.6–2.0
3 or more markers	80–115	0.1–0.3

[a]Higher in Asian individuals
Data from Bromley (2002), Nyberg (2001), Smith-Bindman (2001), and all their co-workers.

in Table 13-3, NT measurement detects 79 to 87 percent of Down fetuses. For this reason, the use of NT alone is recommended only in selected circumstances—for example, multifetal gestation (American College of Obstetricians and Gynecologists, 2007b).

Absent Nasal Bone

This first-trimester marker is also much more common in fetuses with Down syndrome. Cicero and colleagues (2001) examined 701 women at high risk for a Down fetus at 11 to 14 weeks. They were studied prior to amniocentesis for advanced maternal age or an abnormal fetal NT measurement. The investigators reported the nasal bone to be absent in 73 percent of Down syndrome fetuses, but in only 0.5 percent of karyotypically normal fetuses. In the FASTER—First and Second Trimester Evaluation of Risk—trial of more than 6300 women of average risk, Malone and colleagues (2005) found *no* case of Down syndrome detected by nasal bone assessment. They concluded that nasal bone sonography is more difficult to accomplish than nuchal translucency. They further concluded that nasal bone assessment is a poor screening tool in the general population.

The Maternal Fetal Medicine Nuchal Translucency Oversight Committee recently recommended that nasal bone assessment should be used only as a secondary or contingency marker in screening protocols (Rosen and associates, 2007). The Committee emphasized that further evaluation in a low-risk population is needed. Further, it recommended that educational and credentialing procedures be established.

FETUSES AT INCREASED RISK FOR GENETIC DISORDERS

Fetal Aneuploidy

At least 8 percent of conceptuses are aneuploid, and these account for 50 percent of first-trimester abortions and 5 to 7 percent of all stillbirths and neonatal deaths. Some factors that increase the fetal aneuploidy risk are listed in **Table 13-7**. Individuals with these risk factors may be candidates for genetic counseling. Although maternal age of 35 years or older is no longer used as a threshold to determine who is offered prenatal diagnosis (American College of Obstetricians and Gynecologists, 2007b), it is the most common risk factor for fetal aneuploidy. Risks for Down syndrome and any aneuploidy according to maternal age are presented for singletons in **Table 13-8** and for dizygotic twins in **Table 13-9**. As discussed, many women 35 or older now elect prenatal aneuploidy screening in the first or second trimester, and this modifies their age-related risk. Aneuploidy risks associated with numerical chromosomal abnormalities and chromosomal rearrangements are discussed in Chapter 12 (p. 267).

TABLE 13-7. Women with Increased Risk of Fetal Aneuploidy

Singleton pregnancy and maternal age older than 35 at delivery[a]
Dizygotic twin pregnancy and maternal age older than 31 at delivery
Previous autosomal trisomy birth
Previous 47,XXX or 47,XXY birth
Patient or partner is carrier of chromosome translocation
Patient or partner is carrier of chromosomal inversion
History of triploidy
Some cases of repetitive early pregnancy losses
Patient or partner has aneuploidy
Major fetal structural defect by sonography

[a]All women, regardless of age, should have the option of invasive testing (American College of Obstetricians and Gynecologists, 2007a).

TABLE 13-8. Singleton Gestation—Maternal Age-Related Risk for Down Syndrome and Any Aneuploidy at Midtrimester and at Term

	Down Syndrome		Any Aneuploidy

Familial Genetic Disease

Couples with a personal or family history of a heritable genetic disorder should be offered genetic counseling and provided with a calculated or estimated risk of having an affected fetus. Specific molecular tests for a variety of common genetic diseases are available. The risk of a disease for which the responsible gene has not been identified can sometimes be estimated by comparing fetal DNA with that of affected and unaffected family members using *restriction fragment length polymorphism analysis.* For some diseases, no laboratory tests may be available. In some cases, risk may be refined by sonographic examination if there are associated fetal structural abnormalities or by determination of fetal gender if the disease is X-linked.

A major issue that remains unresolved for many genetic disorders is phenotype prediction. For example, the disease may have variable penetrance and expressivity, and the phenotype may be modified by pre- and postnatal environmental influences. For these reasons, identification of a specific disease gene often is not sufficient to allow prediction of the phenotype of an affected fetus, even when there have been other affected siblings or family members. The phenotype of cystic fibrosis, for example, can vary widely within a family as discussed subsequently. Phenotype prediction is especially difficult when there are no living affected family members, or when the disease gene is identified as the result of population screening (see Chap. 12, p. 276).

Ethnic Groups at High Risk

Some otherwise rare recessive genes are found with increased frequency in certain racial or ethnic groups—examples are

TABLE 13-9. Dizygotic Twin Pregnancy—Maternal Age-Related Risk for Down Syndrome and Any Aneuploidy at Midtrimester and at Term[a]

	Down Syndrome		Any Aneuploidy	
Maternal Age	Midtrimester	Term	Midtrimester	Term
32	1/256	1/409	1/149	1/171
33	1/206	1/319	1/116	1/151

[a]Risk applies to one or both fetuses.

TABLE 13-10. Autosomal Recessive Diseases Found with Increased Frequency in Certain Ethnic Groups

Disease	Heritage of Groups at Increased Risk
Hemoglobinopathies	African, Mediterranean, Caribbean, Latin American, Middle Eastern, Southeast Asian
Thalassemia	Mediterranean, Asian
Inborn errors of metabolism: Tay-Sachs disease, Canavan disease, familial dysautonomia, Fanconi anemia group C, Niemann-Pick disease type A, mucolipidosis IV, Bloom syndrome, Gaucher disease	Ashkenazi Jewish
Cystic fibrosis	Caucasians of North European descent, Ashkenazi Jewish, Native American (Zuni, Pueblo)
Tyrosinemia, Morquio syndrome	French Canadian

given in Table 13-10. This increased frequency results from generations who procreate only within their own groups because of religious or ethnic prohibitions or geographical isolation. A phenomenon called the *founder effect* occurs when an otherwise rare gene that is found with increased frequency within a certain population can be traced back to a single family member or small group of ancestors. Some autosomal recessive conditions for which it is recommended that carrier screening be offered to individuals at increased risk are discussed below.

Cystic Fibrosis (CF)

This autosomal recessive disorder is caused by a mutation in a gene on the long arm of chromosome 7 that encodes a protein termed the *cystic fibrosis conductance transmembrane regulator (CFTR)*. More than 1500 mutations in this large gene had been described by the Cystic Fibrosis Consortium (2008) in their database. As shown in Table 13-11, the CF carrier frequency is about 1 in 25 in Caucasian and Native Americans and those of Ashkenazi Jewish (Eastern European) descent, 1 in 46 Hispanic Americans, 1 in 65 African Americans, and 1 in 94 Asian Americans. Some individuals have mild disease or only a single affected organ—for example, chronic pancreatitis (see Chap. 46, p. 1007). This tremendous range of clinical expression likely reflects both the degree to which protein function is changed by the mutation and the variation in exposure and susceptibility to environmental factors.

Carrier Screening. The American College of Obstetricians and Gynecologists (2007c) recommends that information about CF screening be made available to all couples. The current screening panel contains 23 pan-ethnic CF gene mutations. The panel can detect 88 percent of CF carriers who are Caucasian and 94 percent who are Ashkenazi Jewish. However, the test detects only 72 percent in Hispanic Americans and 65 percent in African Americans. Although a negative screening test result does not preclude the possibility of carrying a less-common mutation, it does reduce the risk substantively from the background rate (see Table 13-11). When both partners are from higher-risk groups, including Caucasian, European, or Ashkenazi Jewish ethnicity, carrier screening should be offered before conception or early in pregnancy. For individuals with a family history of CF, it is helpful to obtain records of the CFTR mutation. If the mutation has not been identified, screening with an expanded mutation panel or even complete CFTR gene sequencing may be necessary.

TABLE 13-11. Cystic Fibrosis Detection and Carrier Rates Before and After Testing

Racial or Ethnic Group	Detection Rate (Percent)	Carrier Rate Before Test	Carrier Risk After Negative Test
Ashkenazi Jewish	94	1/24	~1 in 400
Non-Hispanic Caucasian	88	1/25	~1 in 208
Hispanic American	72	1/46	~1 in 164
African American	65	1/65	~1 in 186
Asian American	49	1/94	~1 in 184

Reprinted, with permission, from Update on carrier screening for cystic fibrosis. ACOG Committee Opinion No. 325. American College of Obstetricians and Gynecologists. Obstet Gynecol 2005; 106:1465–8.

Fetal Testing. If both parents are carriers, the fetus can be tested using chorionic villus sampling or amniocentesis to determine whether it inherited either or both parental mutations. Phenotype prediction is fairly accurate if the mutations are ΔF508 or W1282X. Other mutations are less closely associated with disease symptoms, and thus phenotype prediction and pregnancy management are difficult. Prognosis is determined primarily by pulmonary status, and there is poor genotype–phenotype correlation between these other mutations and the severity of pulmonary disease.

Autosomal Recessive Diseases in Individuals of Ashkenazi Jewish Descent

The carrier rate among individuals of Ashkenazi Jewish heritage is approximately 1 in 30 for Tay-Sachs disease, 1 in 40 for Canavan disease, and 1 in 32 for familial dysautonomia. Fortunately, the detection rate of screening tests for each is at least 98 percent in this population. Because of their relatively high prevalence and consistently severe and predictable phenotype, the American College of Obstetricians and Gynecologists (2008) recommends that carrier screening for these three conditions be offered to Ashkenazi Jewish individuals, either before conception or during early pregnancy (see Chap. 7, p. 178). There are a number of other autosomal recessive diseases that are also more common in Ashkenazi Jews and are amenable to carrier screening, with detection rates of at least 95 percent (American College of Obstetricians and Gynecologists, 2008). These include Fanconi anemia group C, Niemann-Pick disease type A, mucolipidosis IV, Bloom syndrome, and Gaucher disease. Patient education materials can be made available so that those who are interested can request additional information or carrier screening if desired.

DIAGNOSTIC TECHNIQUES

Second-Trimester Amniocentesis

Amniocentesis for genetic diagnosis usually is performed between 15 and 20 weeks. In the United States, it is the procedure most commonly used to diagnose fetal aneuploidy and other genetic disorders. The safety of amniocentesis has been confirmed in several multicenter studies (Canadian Early and Mid-Trimester Amniocentesis Trial Group, 1998; NICHD National Registry for Amniocentesis Study Group, 1976). As shown in **Figure 13-6**, sonographic guidance is used to pass a 20- to 22-gauge spinal needle into the amnionic sac while avoiding the placenta, umbilical cord, and fetus. Because the initial 1 or 2 mL of fluid aspirate may be contaminated with maternal cells, it is either discarded or used for amnionic fluid AFP testing. Another approximately 20 mL of fluid is then collected for fetal karyotyping, and the needle is removed. Sonographically the uterine puncture site is observed for bleeding, and fetal cardiac motion is documented at the end of the procedure.

Complications are infrequent and include transient vaginal spotting or amnionic fluid leakage in 1 to 2 percent and chorioamnionitis in less than 0.1 percent. Needle injuries to the fetus are rare. Fetal cells obtained during amniocentesis rarely fail to grow in culture. However, this is more likely if the fetus is abnormal (Persutte and Lenke, 1995). Digital PCR of uncultured amniocytes and chorionic villous tissue provides rapid detection of aneuploidy and may prove promising for expanded clinical use (Fan and associates, 2009).

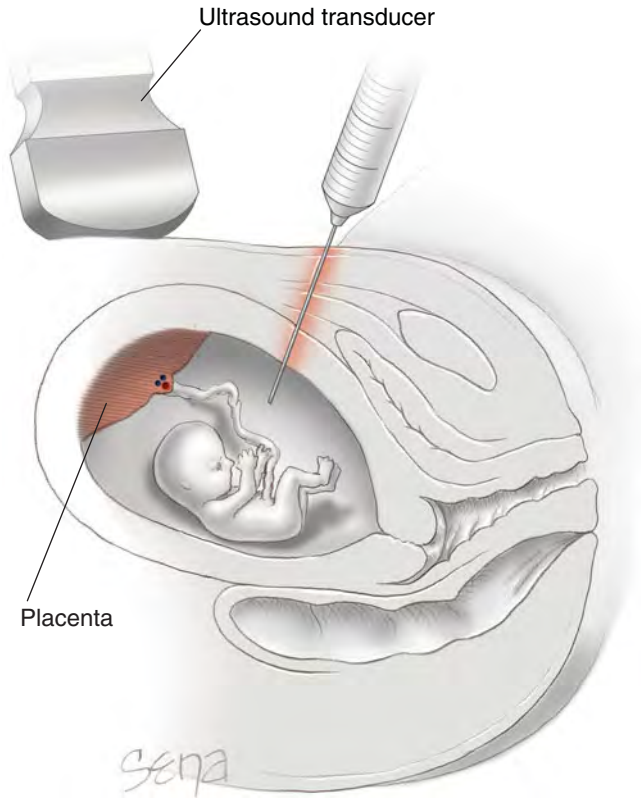

FIGURE 13-6 Amniocentesis.

Although early studies reported a fetal loss of about 0.5 percent, a large trial involving 35,003 women cited the procedure-related fetal loss rate to be 0.06 percent (Eddleman and colleagues, 2006). Based on recent studies, the American College of Obstetricians and Gynecologists (2007a) concluded that the procedure-related loss is approximately 1 in 300 to 500. Some losses are unrelated to amniocentesis but instead due to preexisting abnormalities such as placental abruption, abnormal placental implantation, fetal anomalies, uterine anomalies, and infection. Wenstrom and colleagues (1996) analyzed 66 fetal deaths following nearly 12,000 second-trimester amniocenteses and found that 12 percent were caused by preexisting intrauterine infection. A number of other postprocedural deaths have no apparent etiology.

Early Amniocentesis

These procedures are performed between 11 and 14 weeks. For a number of reasons, early amniocentesis is less satisfactory than standard second-trimester amniocentesis. The technique is the same as for traditional amniocentesis, although puncture of the sac may be more challenging due to lack of membrane fusion to the uterine wall. Less fluid is typically withdrawn, approximately 1 mL for each week of gestation (Nicolaides, 1994; Shulman, 1994; Sundberg, 1997, and all their associates).

Early amniocentesis has higher rates of postprocedural complications. One fetal complication that stands out is talipes equinovarus—*clubfoot*. Data from the Canadian Early and Mid-Trimester Amniocentesis Trial (1998) that involved nearly 4400 women undergoing early amniocentesis showed that rates of amnionic fluid leakage, fetal loss, and talipes equinovarus were all significantly higher following early compared with traditional amniocentesis. A trial involving 3775 women found that early amniocentesis was associated with a fourfold increased rate of talipes equinovarus compared with chorionic villus sampling (Philip and colleagues, 2004). Another problem with early amniocentesis is that there are more cell culture failures, thus necessitating a second procedure. For all these reasons, the American College of Obstetricians and Gynecologists (2007a) recommends against the use of early amniocentesis.

Chorionic Villus Sampling (CVS)

Biopsy of chorionic villi is generally performed at 10 to 13 weeks. Samples may be obtained transcervically or transabdominally, depending on which route allows easiest access to the placenta (Fig. 13-7). Relative contraindications include vaginal bleeding or spotting, active genital tract infection, extreme uterine ante- or retroflexion, or body habitus precluding easy uterine access or clear sonographic visualization of its contents.

The indications for CVS are essentially the same as for amniocentesis, except for a few analyses that specifically require either amnionic fluid or placental tissue. The primary advantage of villous biopsy is that results are available earlier in pregnancy, which lessens parental anxiety when results are normal. It also allows earlier and safer methods of pregnancy termination when results are abnormal.

Complications of CVS are similar to those for amniocentesis. The incidence of amnionic fluid leakage or infection is less than 0.5 percent (American College of Obstetricians and Gynecologists, 2007a). In a randomized trial involving nearly 4000 women, Jackson and colleagues (1992) compared transcervical CVS with transabdominal CVS and found no significant difference in fetal safety. The American College of Obstetricians and Gynecologists (2007a) has concluded that the fetal loss rate is the same after either types of CVS.

Early reports of an association between CVS and limb-reduction defects and oromandibular limb hypogenesis caused a great deal of concern (Burton, 1992; Firth, 1991, 1994; Hsieh, 1995, and all their colleagues). Subsequently, it was shown that limb-reduction defects were associated with CVS performed earlier in gestation—typically around 7 weeks. Thus, when CVS is performed by an experienced operator after 10 weeks, the incidence of limb-reduction defects is the same as background (Evans and Wapner, 2005; Kuliev and co-workers, 1996).

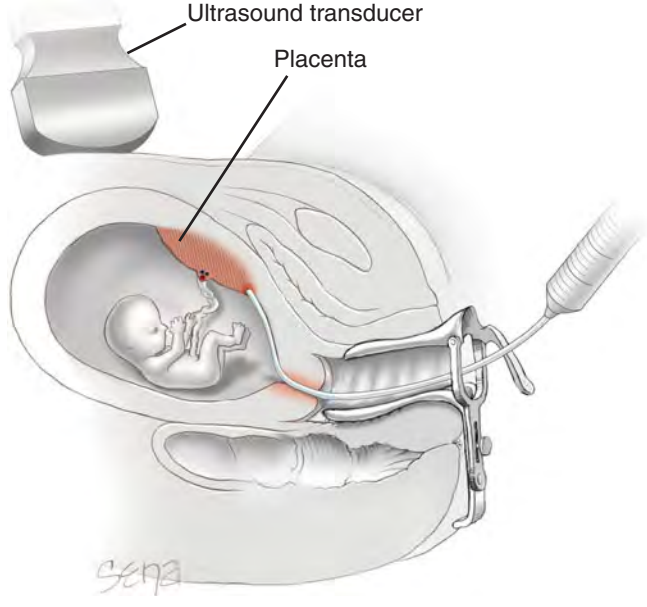

FIGURE 13-7 Transcervical chorionic villus sampling (CVS).

Laboratory Results

Midtrimester amniocentesis is associated with the lowest incidence of uninformative results—up to 0.8 percent. This compares with 0.8 to 1.5 percent for transcervical CVS and 0.7 to 1.9 percent for transabdominal CVS (Canadian Collaborative CVS–Amniocentesis Clinical Trial Group, 1989; Philip and coworkers, 2004; Rhoads and colleagues, 1989). Uninformative data usually are the result of an inadequate sample or the detection of mosaicism—more than one distinct cell line in a single chorionic villous sample. In these circumstances, such findings rarely represent true fetal mosaicism, but instead usually indicate *confined placental mosaicism*, or *pseudomosaicism* (see Chap. 12, p. 275).

Fetal Blood Sampling

Also called percutaneous umbilical blood sampling (PUBS) or cordocentesis, this procedure was first described by Daffos and colleagues (1983). It is performed primarily for assessment and treatment of confirmed red cell or platelet alloimmunization and in the evaluation of nonimmune hydrops (see Chap. 29, p. 623). Often, when severe fetal anemia is suspected, Doppler evaluation of the fetal middle cerebral artery peak systolic velocity is first performed. This is a noninvasive method of detecting severe fetal anemia, used prior to proceeding with fetal blood sampling and/or intrauterine transfusion**.** Fetal blood sampling also can be used to obtain cells for genetic analysis when CVS or amniocentesis results are confusing or when rapid diagnosis is necessary. Karyotyping of fetal blood usually can be accomplished within 24 to 48 hours. Blood can also be analyzed for metabolic and hematological studies, acid–base analysis, viral and bacterial cultures, polymerase chain reaction and other genetic techniques, and immunological studies.

Technique

Under direct sonographic guidance, the operator uses a 22-gauge spinal needle to puncture the umbilical vein, usually at or near its placental origin, and blood is withdrawn. This is shown in Figure 13-8. A free loop of cord also can be accessed for

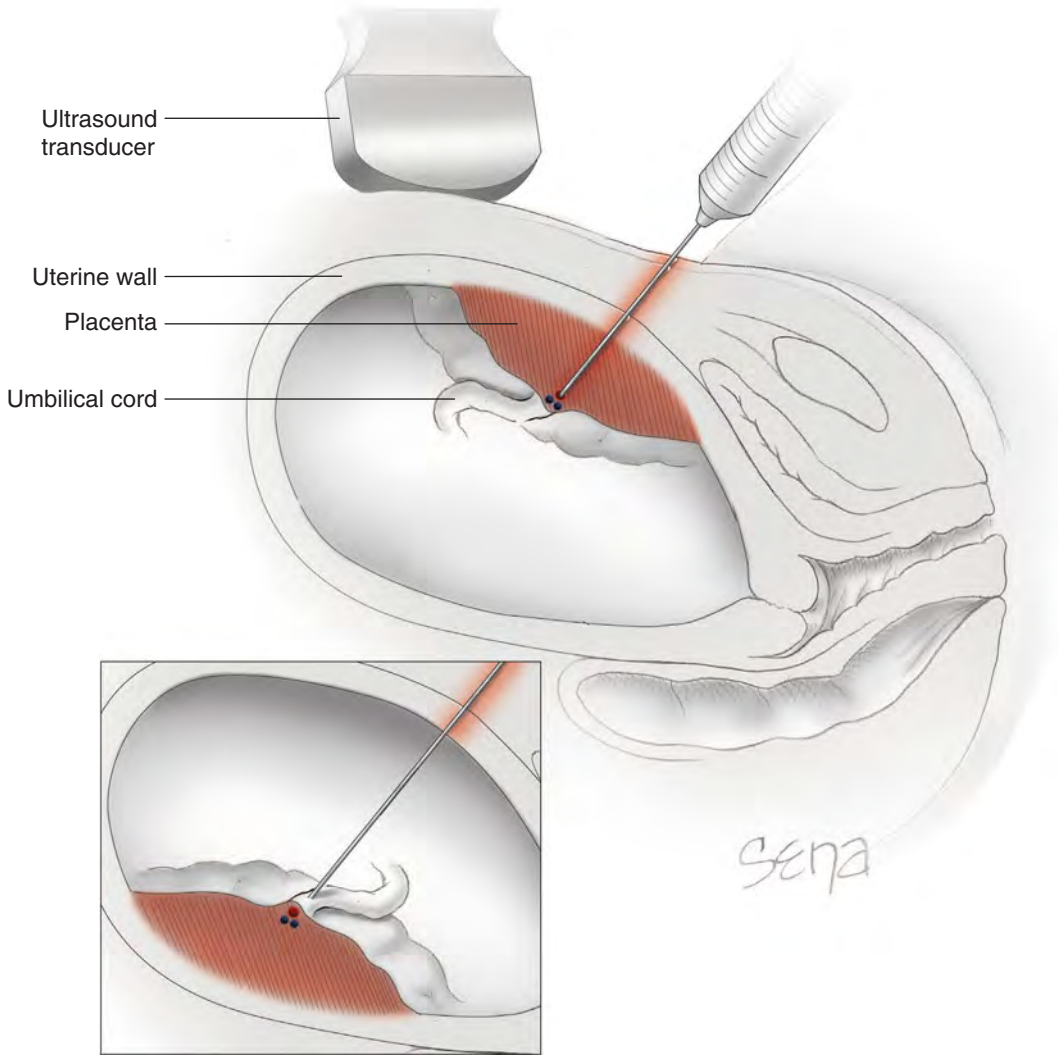

FIGURE 13-8 Fetal blood sampling. Access to the umbilical vein varies depending on placental location and cord position. With an anterior placenta, the needle may traverse the placenta. **Inset:** With posterior placentation, the needle passes through amniotic fluid before penetrating the umbilical vein. Alternately, a free loop of cord may be accessed.

venipuncture. Arterial puncture should be avoided because it may result in vasospasm and fetal bradycardia.

Complications

These may include cord vessel bleeding—50 percent, cord hematoma—17 percent, fetal-maternal hemorrhage—66 percent with an anterior placenta and 17 percent with a posterior placenta, and fetal bradycardia—3 to 12 percent (Ghidini and associates, 1993). Most complications are transitory with complete fetal recovery, but some result in fetal death. The procedure-related fetal death rate is cited to be 1.4 percent, but varies according to the indication as well as fetal status (Ghidini and colleagues, 1993; Maxwell and associates, 1991).

Fetal Tissue Biopsy

There are many genetic conditions for which there is no specific molecular test. Sometimes, prenatal diagnosis can only be accomplished by direct analysis of fetal tissue obtained by sonographically guided biopsy. Linkage analysis has been used for the diagnosis of familial disorders, but it is possible only if there are living, informative, affected family members (see Chap. 12, p. 283). The technique has been used for muscle biopsy to diagnose muscular dystrophy or mitochondrial myopathy (Evans and colleagues, 1994). And skin biopsy has been used to diagnose epidermolysis bullosa (Elias and co-workers, 1994).

Preimplantation Genetic Diagnosis

With the use of assisted reproductive technologies, zygotes affected with a severe genetic disorder can be identified so that they are not used for in vitro fertilization. As a result, only unaffected embryos are selected for implantation. The technique has been performed to diagnose nearly 200 different single-gene disorders such as cystic fibrosis, sickle-cell disease, or β-thalassemia;

to determine gender in X-linked diseases; and although controversial, to match for human leukocyte antigens for potential umbilical cord stem cell transplant for an affected sibling (de Wert, 2007; Flake, 2003; Fragouli, 2007; Grewal, 2004; Jiao, 2003; Rund and Rachmilewitz, 2005; Xu, 2004, and all their colleagues).

Several techniques have been reported. *Polar body analysis* is attractive because the first and second polar bodies normally are expelled, and their removal should not affect fetal development. Because most biopsied polar bodies are in metaphase, the chromosomes in these cells also are suitable for fluorescence in situ hybridization (FISH) analysis, which is discussed in Chapter 12 (p. 282) (Munne, 2001). A second technique is *blastomere biopsy* of the 3-day-old embryo at the 6- to 10-cell stage. One cell is removed through a hole made in the zona pellucida. Loss of one totipotent cell at this stage supposedly has little or no effect on the developing embryo. Even so, in a report by El-Toukhy and co-workers (2003), there was a lower implantation rate when previously biopsied frozen embryos were thawed and transferred. This technique is complex and still under development. New techniques such as whole-genome multiple displacement amplification from single cells may allow even more broad diagnoses (Spits and colleagues, 2006).

The American College of Obstetricians and Gynecologists (2009) recently reviewed the topic of preimplantaton genetic *screening* for aneuploidy using FISH. The College concluded that current data does not support use of this technology solely for advanced maternal age, that it does not improve in vitro fertilization success, and that it may be detrimental.

Fetal Cells in the Maternal Circulation

More than 50 years ago, various types of fetal cells were identified in the maternal circulation (Douglas and colleagues, 1959). It is now known that fetal cells likely are present in all pregnant women, although the concentration is very low—only 2 to 6 cells per mL of maternal blood (Bianchi and Hanson, 2006). Isolation of these cells for prenatal analysis might obviate the need for invasive procedures (Ober-Berman and associates, 2009). Most research in this area focuses on cell sorting techniques, which take advantage of unique cell surface proteins and other characteristics that distinguish fetal from maternal cells. These techniques include density gradient or protein separation, fluorescence-activated cell sorting, and magnetic-activated cell sorting (Bianchi and Hanson, 2006).

Nucleated red blood cells are most easily isolated. Fetal cells obtained this way have been evaluated for genetic diseases such as β-thalassemia as well as for fetal red cell D-antigen typing (Geifman-Holtzman and colleagues, 1996; Rund and Rachmilewitz, 2005). Karyotyping using FISH techniques may also be possible in some cases (Poon and co-workers, 2000). In a National Institutes of Health (NIH)-sponsored trial of fetal cell isolation, 1292 pregnant women with male fetuses were evaluated. In 41 percent, at least one XY male cell was detected using FISH (Bianchi and colleagues, 2002). The sensitivity was higher if a chromosomal abnormality was present—at least one aneuploid cell was detected by FISH in 74 percent of aneuploid fetuses.

The study of fetal cells in the maternal circulation is fascinating from the perspective of autoimmune disease as well. Fetal cells may persist in the maternal circulation for decades following delivery. There is evidence that persistent fetal cells play a role in the development of maternal autoimmune diseases, such as scleroderma and thyroiditis, possibly through a graft-versus-host phenomenon (see Chap. 53, p. 1127, and Chap. 54, p. 1146). Remarkably, there is even some evidence that fetal cells acquired during pregnancy might have a therapeutic role (Bianchi, 2004).

Several problems have hampered clinical implementation of this technology. There has been no universal fetal cell surface or cytoplasmic marker that identifies cells as being from the fetus. However, the maspin gene, a tumor suppressor gene that is hypomethylated in the placenta, has shown promise (Chim and colleagues, 2005). It still remains difficult to isolate a quantity of fetal cells sufficient for analysis or to isolate a pure sample devoid of maternal cells. And because some fetal cells appear to be immortal in the maternal circulation, it may not be possible to determine whether isolated cells are from the current or a past pregnancy. A recent NIH workshop concluded that there is need for standardization of techniques used for cell-free fetal DNA analysis (Bianchi and Hanson, 2006). The panel also noted that direct-to-consumer early fetal gender detection has become widely available, but that the accuracy is controversial. Noninvasive Rh CDE genotyping is now clinically available in several European countries and will likely soon be available in the United States.

FETAL THERAPY

Although prenatal treatment is currently not feasible for most fetal abnormalities, interventions have been developed during the past two decades that have dramatically altered the course of selected fetal anomalies and conditions. The 2004 NIH-sponsored multidisciplinary workshop on fetal treatment was designed to develop a plan for evaluation of such in-utero therapy (Chescheir and Socol, 2005).

Even when treatment is not available, there may be significant benefit from prenatal diagnosis of an anomaly or aneuploidy. For example, diagnosis may allow psychological preparation, and findings may alter delivery plans. Some neonates will benefit from delivery at a specialized center with immediate access to pediatric surgery or other subspecialists. In other cases, knowledge of a severe or lethal anomaly may allow for an informed decision about pregnancy termination or a decision not to perform cesarean delivery for fetal indications. Along with a maternal-fetal medicine or genetics referral, consultation with pediatric subspecialist(s) is often helpful.

Fetal Transfusion

The intrauterine transfusion of red blood cells has radically altered the natural history of fetal anemia due to alloimmunization and other causes. In many cases, a morbid and even lethal condition now is almost always treatable. Transfusions have also been used to treat fetal thrombocytopenia.

Fetal Anemia

There are many causes of fetal anemia, including alloimmunization, infection, genetic diseases such as thalassemia, and fetal-to-maternal hemorrhage. Anemia may be identified by fetal blood sampling as discussed, or in many cases, by Doppler evaluation of the fetal middle cerebral artery peak systolic velocity (see Chap. 16, p. 364). In the past, maternal *CDE alloimmunization* was the most common cause of hemolytic disease affecting the fetus (see Chap. 29, p. 619). Anti-D immunoglobulin given antepartum and at delivery has significantly diminished its incidence, but many other red cell antigens can also produce hemolytic anemia. The natural history of severe anemia usually is development of heart failure, hydrops, and ultimately death. The advent of fetal transfusion therapy has resulted in survival rates that exceed 90 percent with severe anemia without hydrops, and 70 percent if hydrops has developed (Schumacher and Moise, 1996).

Fetuses with *parvovirus B19 infection*, especially those infected before 20 weeks, may develop severe anemia from red cell hypoplasia. Although the fetus may spontaneously recover, most recommend transfusion if severe anemia is detected (see Chap. 58, p. 1215). Unfortunately, some fetuses develop viral myocarditis in addition to anemia and may not respond to transfusion therapy. Moreover, others may have sequelae of infection despite timely treatment. Surveillance of 24 fetuses given transfusions for anemia from parvovirus infection was provided by Nagel and colleagues (2007). Of 16 survivors aged 6 months to 8 years, neurodevelopmental status was abnormal in a third. These investigators found that neurological disability was not related to the severity of anemia or acidemia and proposed an infection-related cause.

Other causes of fetal anemia may be amenable to therapy. *Fetal-to-maternal hemorrhage* may be treated with fetal transfusion if the hemorrhage is significant but not ongoing. Unfortunately, it is not possible to determine whether irreversible neurological injury from cerebral hypoperfusion has already occurred (see Chap. 29, p. 617). Transfusions have also been used to treat fetal anemia from *hemoglobin Bart disease* (see Chap. 51, p. 1090).

Platelet transfusions for fetal *alloimmune thrombocytopenia* has been well described. Unfortunately, there is significant morbidity associated with the frequent transfusions required, and procedure-related fetal loss rates average approximately 5 percent per pregnancy (Berkowitz and co-workers, 2006). For this reason, most reserve platelet transfusions for cases refractory to medical therapy with high-dose immunoglobulin G, with or without corticosteroids (see Chap. 29, p. 629).

Technique. Using sonographic guidance, intravascular transfusion into the umbilical vein is generally considered the preferred method of fetal transfusion, although some employ intraperitoneal transfusion. In the setting of hydrops, peritoneal absorption is impaired, and intravascular transfusion is considered the optimal method (Moise, 2002). The red cells are generally type O, D-negative, cytomegalovirus negative, packed to a hematocrit of about 80 percent, irradiated, and leukocyte-poor. The fetal-placental volume allows a relatively rapid infusion of a relatively large quantity of blood. Prior to blood infusion, a paralytic agent such as vecuronium may be given to the fetus to minimize movements and potential trauma. The target hematocrit is approximately 40 to 50 percent in the nonhydropic fetus. The volume transfused may be estimated by multiplying the estimated fetal weight by 0.02 for each 10 percent increase in hematocrit needed (Giannina and colleagues, 1998). In the severely anemic fetus, less blood is transfused initially, and the next transfusion is planned 2 days later. Subsequent transfusions usually take place every 2 to 4 weeks, depending on the hematocrit.

Fetal Medical Therapy

There are several fetal conditions that have been shown to be amenable to maternal-fetal therapy. In such cases, medication administered to the mother is transported transplacentally and exerts beneficial effects on the fetus.

Thyrotoxicosis

Some euthyroid women with Graves thyrotoxicosis who have undergone radioiodine thyroid ablation will continue to produce IgG thyroid-stimulating antibodies that cross the placenta to cause fetal thyrotoxicosis (see Chap. 53, p. 1127). Fetal thyroid status can be assessed by cordocentesis for thyroid hormones. If hyperthyroidism is confirmed, propylthiouracil administered to the mother is carried transplacentally to suppress the fetal thyroid (Wenstrom and associates, 1990).

Congenital Adrenal Hyperplasia

Several autosomal recessive enzyme deficiencies cause congenital adrenal hyperplasia (CAH) characterized by impaired synthesis of cortisol from cholesterol by the adrenal cortex (see Chap. 4, p. 102). The 21-hydroxylase deficiency accounts for more than 90 percent of cases. The classic form has a population incidence of approximately 1:15,000. In selected populations, however, it is higher—for example, 1:300 in Yupik Alaskan Eskimos and 1:5000 in Saudi Arabians (New and Nimkarn, 2007). Due to excessive fetal adrenal androgen production, the condition can cause female virilization (see Chap. 4, p. 102). These newborns may be at risk for salt-wasting adrenal crises, and all states require newborn testing.

Treatment to prevent virilization must begin early, ideally prior to 9 weeks, *before it is known whether the fetus will be affected or even its gender.* One regimen is dexamethasone, given orally to the mother at a dosage of 20 μg/kg/d in three divided doses. Typically, treatment is begun and prenatal diagnosis with either CVS or amniocentesis is performed later. If testing shows that the fetus has a male karyotype, dexamethasone is stopped. If molecular genetic testing demonstrates that a female fetus is affected or if testing is indeterminate, treatment is continued until term. In affected families, clinically available molecular genetic testing can identify 80 to 98 percent of cases (New and Nimkarn, 2007).

Arrhythmias

As many as 1 percent of pregnancies are complicated by a fetal arrhythmia (Copel and associates, 2000). Fetal M-mode

sonography is used to clarify the relationship between atrial and ventricular beats and thereby diagnose the type of rhythm disturbance. Most are benign atrial extrasystoles (premature atrial contractions), which usually resolve before delivery with maturity of the conduction system.

Sustained tachyarrhythmias—most commonly from supraventricular tachycardia or atrial flutter—can lead to cardiac decompensation and hydrops if untreated. Maternal administration of antiarrhythmic drugs that cross the placenta is used to convert to a normal rhythm or to lower the baseline heart rate and thereby forestall failure. A variety of medications have been used, most commonly digoxin, sotalol, flecainide and procainamide. Their selection depends on the type of tachyarrhythmia as well as provider familiarity and experience with the drug, but digoxin is usually the first-line agent. Amiodarone therapy has been associated with neonatal hypothyroidism, which may be severe (Niinikoski and co-workers, 2007; Simpson, 2006).

Antiarrhythmic medications may have significant maternal and fetal risks, particularly because therapy may require dosages at the upper end of the therapeutic range for adults. A maternal electrocardiogram should be performed before and during therapy. If the fetus has become hydropic, the drug may need to be administered directly via the umbilical vein (Mangione and coworkers, 1999; Simpson, 2006).

Congenital Infections

A number of infectious agents cross the placenta and cause fetal infection with serious consequences. Prompt maternal treatment—and thus fetal treatment—may prevent or mitigate associated fetal morbidity. One dramatic example is timely treatment of maternal syphilis. Many causes of treatment "failures" are due to recognition *after* fetal infection is too advanced to respond. Diagnosis and treatment of sexually transmitted and other infectious diseases that may infect and affect the fetus are discussed throughout Chapters 58 and 59.

Metabolic Disorders

A number of inherited metabolic disorders have been treated in utero with impressive outcomes. Fetal *methylmalonic acidemia* has been treated with maternal oral and intramuscular vitamin B_{12} therapy, which is continued after birth and is associated with normal development into adulthood (Ampola and coworkers, 1975; O'Brien and Bianchi, 2005). Fetal umbilical vein and intraperitoneal transfusions of fresh-frozen plasma have been used to treat *Smith-Lemli-Opitz syndrome* (Irons and colleagues, 1999). And maternal oral L-serine supplementation has been used to treat fetal *3-phosphoglycerate-dehydrogenase deficiency* (de Koning and colleagues, 2004.)

Fetal Stem Cell Transplantation

In theory, stem cell transplantation could be used to treat a variety of hematological, metabolic, and immunological diseases and could serve as a delivery vehicle for gene transfer to treat other genetic conditions. The fetal period is ideal for this because in the first and early second trimesters, the fetus does not have an adaptive immune response to foreign antigens and has therefore been described as *preimmune* (Tiblad and Westgren, 2008). Other advantages are that pretreatment chemotherapy or radiation is not necessary prior to transplantation and that there is less risk for graft-versus-host disease.

Animal models have been developed to study fetal bone marrow transplantation. Studies have focused on identifying the optimal gestation age for transplantation, as well as the best source of hemopoietic stem cells such as fetal blood or liver, cord blood, parental bone marrow or circulating hemopoietic progenitor cells, or mesenchymal stem cells (Le Blanc and associates, 2005).

To date, human fetal stem cell transplantation has been most successful in the treatment of immunodeficiency syndromes, which suggests that even the early fetus has some degree of immunocompetence. Engraftment has been achieved in fetuses with severe combined immunodeficiency and bare lymphocyte syndrome and had a benign clinical course (Tiblad and Westgren, 2008). Treatment of other immunodeficiencies, including chronic granulomatous disease and Chediak-Higashi syndrome, and treatment of some storage diseases have not been successful. Stem cell transplantation has been used to treat some hemoglobinopathies. Fetuses with sickle-cell anemia have not achieved engraftment. In some with α- and β-thalassemia, despite achieving engraftment, children have remained transfusion dependent (Tiblad and Westgren, 2008; Westgren and colleagues, 1996). A fetus with osteogenesis imperfecta type II who was transplanted with fetal mesenchymal stem cells developed both engraftment and chimerism (Le Blanc and colleagues, 2005). Although long-term outcome of such cases remains uncertain, the technology holds a great deal of promise.

Fetal Gene Therapy

With advances in genetic technologies and progress in the identification of genes responsible for inherited disease, efforts have focused on therapeutic gene transfer. This has been attempted only in animal models, with limited success and significant challenges (David and Peebles, 2008). Certain inherited metabolic conditions in which tissue damage begins shortly after or even before birth would be ideal for early therapy by gene transfer. In Tay-Sachs disease, for example, central nervous system cells exhibit the characteristic pathology as early as 9 weeks after conception (Grabowski and colleagues, 1984). Early gene therapy also has the potential of requiring only one treatment, which would be definitive and would span a lifetime.

A number of criteria—not yet met—are considered requisite for the development of therapeutic gene transfer:

1. The normal gene can be inserted into the target cells and remain there long enough to have the desired effect. Potential types of vectors include nonviral agents, such as cationic polymers and cationic liposomes, and viruses—adenovirus, retrovirus, and lentiviruses (David and Peebles, 2008)
2. The level of expression of the new gene will be appropriate after a single application
3. The new gene will not harm the cell or the individual (Anderson, 1984). For example, two children who received gene therapy for severe combined immunodeficiency disease developed T-cell leukemia. Leukemia was a

consequence of the gene vector inserting near an oncogene, thereby activating the oncogene and increasing leukemia susceptibility (Berns, 2004).

Other unresolved issues include the timing of the procedure, that is, preconceptional, at the time of fertilization, prior to implantation, or during embryogenesis or fetal development. Which are the ideal recipient or target cells? Finally, which are the safest methods? Efficient techniques for in vivo gene targeting have yet to be developed, and the possibility of ex vivo gene transfer raises ethical considerations.

Fetal Surgery

The prospect of treating severe fetal anomalies in utero has been a topic of intense interest for more than two decades. Pioneering work in animals led to the development of *open fetal surgery*, in which maternal hysterotomy and partial exteriorization of the fetus are performed to permit surgery for selected life-threatening anomalies. Currently, such expertise is available at only a few centers in the United States and for only a few fetal conditions. Because it entails substantive fetal and maternal risks, these procedures are considered only when they might reasonably be expected to improve fetal outcome and when withholding them would undoubtedly be catastrophic.

Although the indications for open fetal surgery are limited, the number of conditions amenable to less invasive therapy has expanded, particularly during the past decade. These procedures are not without risk, but maternal morbidity and fetal preterm delivery may be reduced. A number of fetal abnormalities treatable antepartum or intrapartum are shown in **Table 13-12**. For any fetal therapy, it is important that appropriate selection criteria be established and verified, that each procedure be perfected and tested successfully in experimental animals, and that its efficacy in human pregnancy be rigorously evaluated prior to widespread implementation (Harrison and colleagues, 1980; Moise and associates, 1995). Chescheir (2009) further recommends that we must understand how fetal therapy is altered after a maternal-fetal intervention.

Open Fetal Surgery

These procedures require a highly skilled team from different disciplines, as well as extensive case management with education and counseling. To gain fetal access, the mother must undergo general endotracheal anesthesia to suppress both uterine contractions and fetal responses. Using sonographic guidance to avoid the placental edge, a hysterotomy incision is made with a stapling device that seals the edges to permit hemostasis. Warmed fluid is continuously infused into the uterus thorough a rapid infusion device. The fetus is gently manipulated to permit pulse oximetry monitoring and venous access in case fluids or blood are emergently needed (**Fig. 13-9**). At this point, fetal surgery is performed. The hysterotomy is then closed and tocolysis begun. Later in the pregnancy, delivery is completed by cesarean.

In a review of 87 open fetal surgery procedures from the Fetal Treatment Center of the University of California, San Francisco, Golombeck and colleagues (2006) reported the following morbidities: maternal pulmonary edema—28 percent, maternal blood transfusion—13 percent, preterm labor and delivery—33 percent, prematurely ruptured membranes—52 percent, chorion-amnion separation—20 percent, chorioamnionitis—9 percent, and placental abruption—9 percent. Other potential risks include later uterine rupture, maternal sepsis, and fetal death during or following the procedure.

Some conditions for which open fetal surgery is offered include thoracic masses with hydrops, such as *congenital cystic adenomatoid malformation* (CCAM) and *extralobar pulmonary sequestration*; *spina bifida; and sacrococcygeal teratoma* (SCT) with evidence of high-output cardiac failure (see Fig. 13-9). For fetuses with CCAM, Adzick and colleagues (1998) found that once hydrops had developed, none of 25 fetuses survived without treatment, whereas eight of 13 survived with fetal lobectomy. For 30 fetuses with a sacrococcygeal teratoma, Hendrick

TABLE 13-12. Some Abnormalities Amenable to Fetal Surgery

Open Fetal Surgery
- Cystic adenomatoid malformation
- Extralobar pulmonary sequestration
- Sacrococcygeal teratoma
- Spina bifida

Fetoscopic Surgery
- Twin-twin transfusion: laser of placental anastamoses
- Diaphragmatic hernia: fetal endoscopic tracheal occlusion (FETO)
- Posterior urethral valves: cystoscopic laser
- Congenital high airway obstruction: vocal cord laser
- Amnionic band release

Percutaneous Procedures
- Shunt therapy
  - Posterior-urethral valves/bladder outlet obstruction
  - Pleural effusion: chylothorax or sequestration
  - Dominant cyst in congenital cystic adenomatoid malformation (CCAM)
- Radiofrequency ablation
  - Twin-reversed arterial perfusion (TRAP) sequence
  - Monochorionic twins with severe anomaly(ies) of 1 twin
  - Chorioangioma
- Fetal intracardiac catheter procedures
  - Aortic or pulmonic valvuloplasty for stenosis
  - Atrial septostomy for hypoplastic left heart with restrictive atrial septum

Ex-utero-intrapartum-treatment(EXIT) procedures
- Congenital diaphragmatic hernia after FETO
- Congenital high airway obstruction sequence (CHAOS)
- Severe micrognathia
- EXIT-to-resection
  - Resection of fetal thoracic or mediastinal mass
  - Tumors involving airway/neck
- EXIT-to-extracorporeal membrane oxygenation (ECMO)
  - Congenital diaphragmatic hernia (if no fetal surgery)

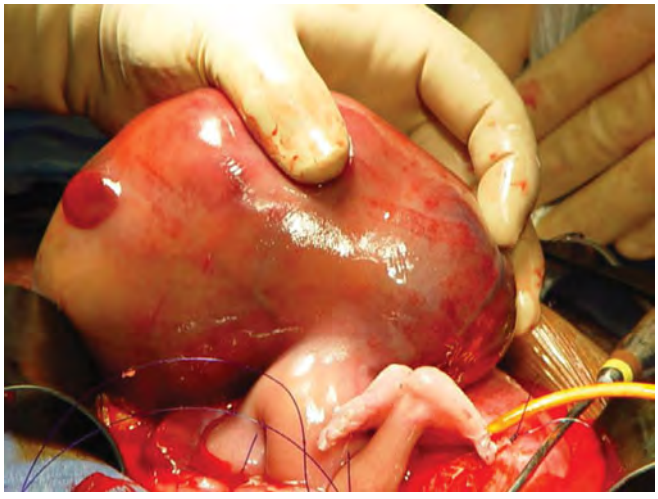

FIGURE 13-9 Photograph of open fetal surgery for resection of a sacrococcygeal teratoma. Hysterotomy has been completed, and the caudal portion of the fetus has been delivered onto the surgical field. The tumor is held by the surgeon's hand. (Used with permission from Dr. Timothy M. Crombleholme of the Fetal Care Center of Cincinnati.)

and colleagues (2004) reported that only four were amenable to tumor debulking—three survived following delivery at mean gestational age of 29 weeks.

Unlike open fetal surgery for other abnormalities, surgery for *spina bifida* is controversial, because the condition itself is not lethal. However, isolated open spinal defects usually result in permanent neurological damage, and in-utero repair can potentially limit the damage from chronic exposure to amnionic fluid (Heffez and associates, 1990). Proponents report that early experience suggests a decreased need for ventriculoperitoneal shunting and resolution of hindbrain herniation (Johnson and colleagues, 2003). As of 2009, prenatal surgical closure of fetal spine defects is available as part of an NIH-sponsored multicenter research trial entitled *Management of Myelomeningocele Study—MOMS* (moms@biostat.bsc.gwu.edu).

In the past, open fetal surgery was also attempted for cases of isolated *congenital diaphragmatic hernia*. The goal was to replace the liver within the abdominal cavity and repair the defect. Unfortunately, umbilical vein occlusion led to intraoperative fetal deaths, and overall survival was not improved. Efforts have since focused on fetoscopic tracheal occlusion for this anomaly, which is discussed subsequently.

Fetoscopic Surgery

Fetoscopy compares to open fetal surgery as laparoscopy does to laparotomy. To perform surgery using fiberoptic endoscopes only 1 to 2 mm in diameter and instruments such as lasers that fit through 3 to 5 mm cannulae has revolutionized treatments available for selected fetal conditions. These state-of-the-art procedures are performed almost exclusively at highly specialized centers, and most are considered investigational.

Risks are lower than with open fetal surgery but can still be formidable. For endoscopic procedures that entail minimally invasive laparotomy for access, Golombeck and colleagues (2006) reported complications of maternal pulmonary edema—25 percent, preterm delivery—27 percent, prematurely ruptured membranes—44 percent, chorion-amnion separation—65 percent, and placental abruption—6 percent. Other risks include maternal infection or injury and fetal death.

Examples of conditions treated by fetoscopy include twin-twin transfusion syndrome (TTTS), congenital diaphragmatic hernia—fetal tracheal occlusion, cystoscopic laser treatment of posterior urethral valves, laser therapy of vocal cord occlusion in congenital high-airway obstruction sequence, and release of amnionic bands.

Twin-Twin Transfusion Syndrome (TTTS). Laser therapy for TTTS has been the most commonly used example of fetoscopic surgery (Fig. 13-10). With this procedure, laser energy ablates

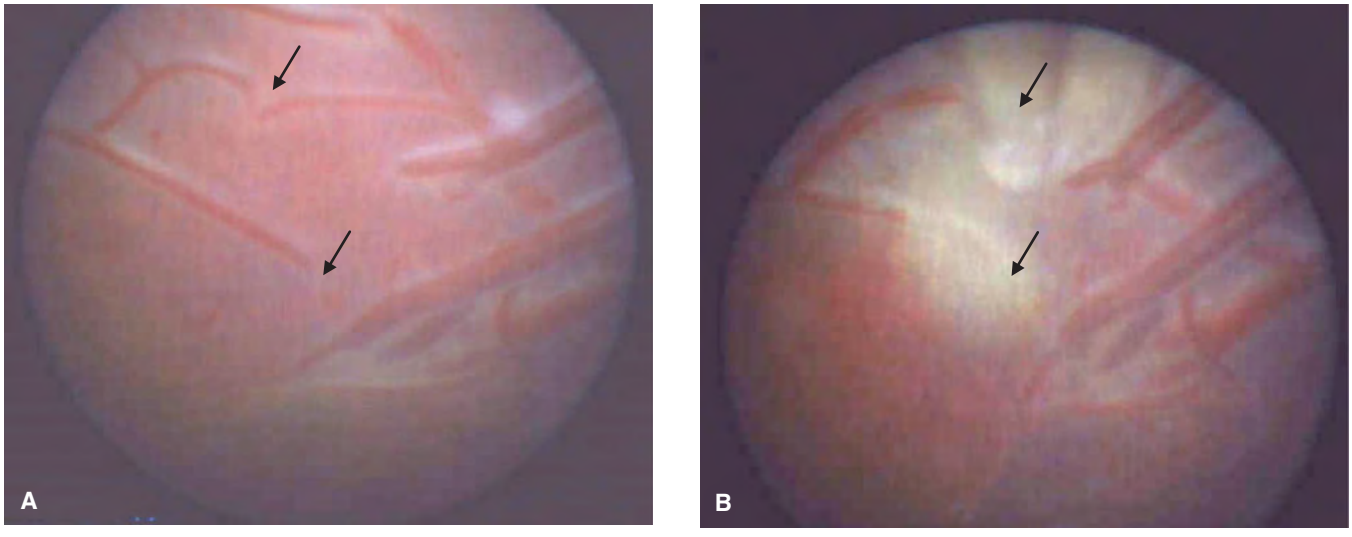

FIGURE 13-10 Laser therapy for twin-twin transfusion syndrome (TTTS). Fetoscopic photograph of the placental fetal surface. **A.** Vascular anastomoses (*arrows*) are shown before selective laser ablation. **B.** Sites of ablation are seen as blanched yellow-white areas (*arrows*). (Used with permission from Dr. Timothy M. Crombleholme of the Fetal Care Center of Cincinnati.)

pathological vascular anastomoses within a monochorionic twin placenta (see Chap. 39, p. 872). Even with such therapy, evaluation and management of TTTS remains challenging (Norton, 2007). For example, the relationship between placental angioarchitecture and pregnancy outcome is not fully understood, and neurological complications and preterm birth remain common. Treatment is even less likely to be successful in pregnancy after 26 weeks (Crombleholme and colleagues, 2007). Finally, fetal cardiovascular compromise plays a significant role in perinatal outcome (Rychik and associates, 2007; Van Mieghem and co-workers, 2009).

Fetal Endoscopic Tracheal Occlusion (FETO) for Congenital Diaphragmatic Hernia (CDH). Fetoscopic therapy has been rigorously evaluated in infants with this condition. With an isolated diaphragmatic hernia and with specialized care and postnatal surgery, mortality rates approximate 30 percent (Reickert and colleagues, 1998). The major prenatal findings used to identify candidates for fetal therapy—those at risk for lethal pulmonary hypoplasia—include a significant amount of liver within the thorax and a low lung-to-head ratio—the cross-sectional area of the right lung divided by the head circumference. The rationale for FETO is that by placing a silicone balloon between the fetal carina and vocal cords, the normal egress of lung fluid is halted, and the lungs will expand despite the presence of abdominal organs in the chest. The balloon is removed at delivery via the ex-utero-intrapartum-treatment (EXIT) procedure, which is discussed subsequently.

Although initial results were promising, FETO is currently controversial. Harrison and co-workers (2003) from the University of California Fetal Treatment Center conducted a randomized trial of FETO in 24 fetuses with a diaphragmatic hernia who had predicted survival of less than 40 percent with conventional neonatal surgical correction. Because there was approximately 75-percent survival in both groups at 90 days, the trial was discontinued. In other countries—particularly in Europe—FETO continues to be performed in fetuses with otherwise poor prognoses (Deprest and colleagues, 2006).

Percutaneous Procedures

Sonographic guidance can be used to permit therapy with a shunt, radiofrequency ablation needle, or angioplasty catheter. Although risks are lower than with open fetal surgery, risks include maternal infection, preterm labor or prematurely ruptured membranes, and fetal injury or loss. Fetal thoracic and urinary shunts have become increasingly available however, treatment with radiofrequency ablation and especially angioplasty remain investigational and largely confined to highly specialized centers.

Fetal Shunt Therapy. Percutaneous shunts have been used to drain fluid in cases of selected urinary and thoracic abnormalities. *Urinary shunts* are primarily used in cases of fetal *bladder-outlet obstruction*—for example, *posterior urethral valves*—that would otherwise be lethal. The rationale is that allowing urine to drain from the bladder into the amnionic cavity might preserve renal function and protect against pulmonary hypoplasia from oligohydramnios. Potential candidates are fetuses without other severe anomalies or aneuploidy and who have no sonographic features that confer poor prognosis, for example, renal cortical cysts. Only male fetuses are treated because in females the type of anomaly tends to be even more severe. Serial bladder drainage or vesicocentesis is performed to determine the urine electrolyte and protein content to classify the renal prognosis as good, borderline, or poor (**Table 13-13**). The procedure is performed by inserting a small trocar and cannula into the fetal bladder under sonographic guidance. This is followed by placement of a double-pigtail catheter (Freedman and colleagues, 2000). In their review of long-term outcomes of children treated with vesicoamnionic shunts, Biard and colleagues (2005) reported overall 1-year survival to be 90 percent. One third of surviving children required dialysis or renal transplantation.

TABLE 13-13. Optimal Fetal Urinary Electrolyte and Protein Values in Cases of Bladder Outlet Obstruction

Analyte	Threshold value
Sodium	<100 mmol/L
Chloride	<90 mmol/L
Calcium	<8 mg/dL
Osmolality	<200 mmol/L
β_2-microglobulin	<6 mg/L
Total protein	<20 mg/dL

Fetal renal status is assessed by 3 percutaneous bladder drainages at 48- to 72-hour intervals.
If all values are below the thresholds listed, good prognosis.
If 1 or 2 values exceed the thresholds, prognosis is borderline.
If 3 or more values exceed the thresholds, poor prognosis.

Adapted from Biard and colleagues (2005).

Thoracic shunts from the fetal pleural cavity into the amnionic cavity are performed to drain large pleural effusions. These may accrue with a *chylothorax,* or they may accompany *pulmonary sequestration.* Shunts have also been used to drain a dominant cyst in fetuses with *congenital cystic adenomatoid malformation.* These shunts are associated with fetal loss rates of 5 percent (Wilson and Johnson, 2003). In their review of controlled observational studies of these pulmonary drainage procedures in more than 600 fetuses, Knox and colleagues (2006) found that perinatal survival was significantly improved if there was fetal hydrops, but not in milder cases.

Radiofrequency Ablation Procedure (RFA). With this procedure, high-frequency alternating current is used to coagulate and desiccate tissue. Recently this has become a favored modality for the treatment of *twin-reversed arterial perfusion (TRAP) sequence* or *acardiac twin* (see Chap. 39, p. 872). It is

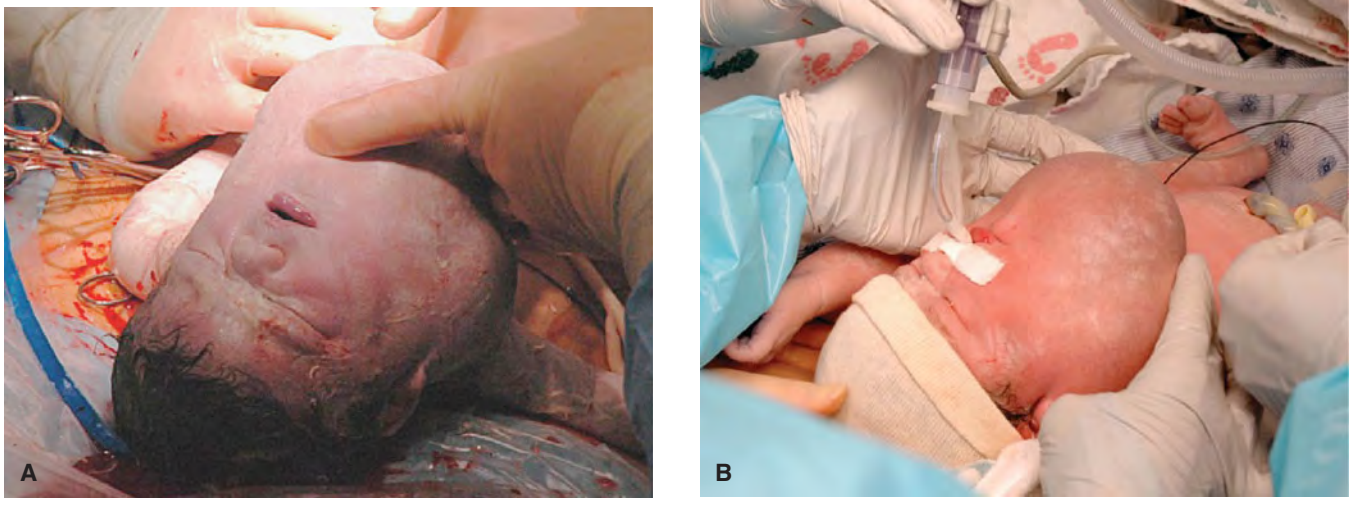

FIGURE 13-11 A. Ex-utero intrapartum treatment—EXIT—procedure. This fetus was diagnosed prenatally with large lymphatic abnormality of the neck, lower face, and mediastinum. The EXIT procedure was planned because of concern for tracheal compression and possibly deviation. Upon delivery of the head, with the placental circulation maintained, the surgeon evaluates the airway and prepares to attempt intubation. **B.** Infant following a controlled intubation, oxygenating well, and supported by the neonatal intensive care unit team. (Courtesy of Drs. Michael Zaretsky and Julie Y. Lo.)

also used for selective termination for other monochorionic twin complications. Without treatment, the mortality rate for the normal or pump twin in TRAP sequence exceeds 50 percent, and it is even higher with larger acardiac twins. Under sonographic guidance, a 17- or 19-gauge RFA needle is placed into the base of the umbilical cord of the acardiac twin, within the abdomen. After a 2-cm area of coagulation is achieved, color Doppler sonography is used to verify that there is no longer flow into the acardiac twin. Lee (2007) and Livingston (2007) and their colleagues performed this procedure in more than 20 pregnancies and reported nearly 90-percent survival of the normal twin. Recently, Lee and co-workers (2009) reported the largest series—83 patients—treated with RFA of the acardiac mass in TRAP sequence and confirmed the effectiveness of this technique.

Fetal Intracardiac Catheter Procedures. Selected fetal cardiac lesions are concerning because of their progression during gestation. For example, severe fetal aortic stenosis detected in the early second trimester may progress to a hypoplastic left heart by the third trimester (Simpson and Sharland, 1997). In 22 fetuses with critical aortic stenosis, Wilkins-Haug and associates (2006) performed aortic valvuloplasty by inserting a 19-gauge cannula into the left ventricle and passing a 0.014-inch guide wire with a coronary artery angioplasty catheter through the aortic valve orifice. Although initially attempted using sonographic guidance alone, maternal laparotomy was required in two thirds of cases to achieve optimal positioning. Of 18 live births, only three had biventricular circulation and did not require a Norword procedure to treat hypoplastic left heart (Wilkins-Haug and colleagues, 2006). This technique has also been used for pulmonic valvuloplasty and atrial septostomy. It remains investigational.

Ex Utero Intrapartum Treatment (EXIT)

This procedure is designed to allow the fetus/infant to remain perfused by the placental circulation after being partially delivered so that life-saving treatment can be performed prior to complete delivery. EXIT procedures have been performed for more than 15 years. As reviewed by Hirose and colleagues (2004), EXIT was initially used to treat airway obstruction after fetal surgery—FETO, as previously discussed. The technique has also been used to treat airway obstruction caused by neck masses and laryngeal or tracheal atresia or stenosis (**Fig. 13-11**) (Steigman and associates, 2009). More recently, Kunisaki and co-workers (2007) used the EXIT procedure as a bridge to extracorporeal membrane oxygenation (ECMO). This is used so that infants with large thoracic masses can undergo immediate resection. These investigators have also used EXIT-to-ECMO for managing infants with severe congenital diaphragmatic hernia (Morris and co-workers, 2009).

COUNSELING FOR TERATOGEN EXPOSURE 316
EXAMPLES OF KNOWN AND SUSPECTED TERATOGENS 317

In the United States, approximately 3 percent of infants have a major structural malformation that is detectable at birth. By age 5, another 3 percent have been diagnosed with a malformation, and another 8 to 10 percent are discovered to have one or more functional or developmental abnormalities by age 18. For most birth defects—approximately 65 percent, the etiology is unknown (Schardein, 2000). Importantly, chemically induced birth defects, which include those caused by medications, are believed to account for less than 1 percent of all birth defects (Center for Drug Evaluation and Research, 2005). Selected examples of confirmed teratogens are listed in Table 14-1.

Medications are commonly prescribed for pregnant women, and in France, Lacroix and colleagues (2000) found this to average 13.6 medications. Nearly all drugs in pregnancy are used off-label because of the paucity of research and clinical trials. The study of medication use in pregnancy is hampered at least in part by the difficulty of studying this special population given the vulnerability of the developing fetus. In addition, there are numerous physiological changes in pregnancy such as alterations in blood volume, plasma proteins, and gastric emptying and transit time that affect dosing and distribution of drugs.

TERATOLOGY

A *teratogen* is any agent—chemicals, viruses, environmental agents, physical factors, and drugs—that acts during embryonic or fetal development to produce a permanent alteration of form or function. The word *teratogen* is derived from the Greek *teratos,* meaning monster. A *hadegen*—after Hades, the god who possessed a helmet conferring invisibility—is an agent that interferes with normal maturation and function of an organ. A *trophogen* is an agent that alters growth. Hadegens and trophogens generally affect processes occurring after organogenesis or even after birth. Chemical or physical exposures that act as hadegens or trophogens are much harder to document. For simplification, most authors use the word *teratogen* to refer to all three types of agents.

Evaluation of Potential Teratogens

A birth defect in a newborn exposed prenatally to a certain drug, chemical, or environmental agent arouses concern that the agent is a teratogen. The two approaches used currently to identify teratogenicity after a drug is released for clinical use include follow-up studies and case-control surveillance (Mitchell, 2003). Before such culpability is established, specific criteria that follow the tenets in Table 14-2 must be considered:

- *The defect must be completely characterized.* This is preferably done by a geneticist or dysmorphologist. Many genetic and environmental factors produce similar anomalies. For example, although cleft lip and palate are associated with antenatal hydantoin exposure, there are also more than 200 known genetic causes (Murray, 1995). Identical defects with different etiologies are called *phenocopies.* It is easiest to prove causation when a rare exposure produces a rare defect, when at least three cases with the same exposure have been identified, and when the defect is severe.

TABLE 14-1. Selected Drugs or Substances Suspected or Proven to Be Human Teratogens

Alcohol	Methimazole
Angiotensin-converting enzyme inhibitors and angiotensin-receptor blockers	Methyl mercury
Aminopterin	Methotrexate
Androgens	Misoprostol
Bexarotene	Mycophenolate
Bosentan	Paroxetine
Carbamazepine	Penicillamine
Chloramphenicol	Phenobarbital
Chlorbiphenyls	Phenytoin
Cocaine	Radioactive iodine
Corticosteroids	Ribavirin
Cyclophosphamide	Streptomycin
Danazol	Tamoxifen
Diethylstilbestrol (DES)	Tetracycline
Efavirenz	Thalidomide
Etretinate	Tobacco
Isotretinoin	Toluene
Leflunomide	Tretinoin
Lithium	Valproate
	Warfarin

- *The agent must cross the placenta.* Although with few exceptions, all drugs cross the placenta, the drug must do so in sufficient *quantity* to directly influence fetal development or alter maternal or placental metabolism to exert an indirect fetal effect. Placental transfer depends on maternal metabolism; on specific characteristics of the drug, such as protein binding and storage, molecular size, electrical charge, and lipid solubility; and on placental metabolism, such as with cytochrome P_{450} enzyme systems. In early pregnancy, the placenta also has a relatively thick membrane that slows diffusion (Leppik and Rask, 1988).
- *Exposure must occur during a critical developmental period.* Syndromes resulting from teratogen exposure are named according to the time of exposure. Those within the first 8 weeks result in an *embryopathy,* and after 8 weeks, a *fetopathy.*
  1. The *preimplantation period* is the 2 weeks from fertilization to implantation and has traditionally been called the "all or none" period. The zygote undergoes cleavage, and an insult damaging a large number of cells usually causes death of the embryo. If only a few cells are injured, compensation is usually possible with continued normal development (Clayton-Smith and Donnai, 1996). Animal studies have shown that some insults—those that appreciably diminish the number of cells in the inner cell mass—can produce a dose-dependent diminution in body length or size (Iahnaccone and co-workers, 1987).
  2. The *embryonic period* is from the second through the eighth week. It encompasses organogenesis and is thus the most crucial with regard to structural malformations. The critical developmental period for each organ system is shown in **Figure 14-1**.
  3. Maturation and functional development continue after 8 weeks, and during this *fetal period,* certain organs remain vulnerable. For example, the brain remains susceptible throughout pregnancy to environmental influences such as alcohol exposure. Alteration in cardiac blood flow during the fetal period can result in deformations such as hypoplastic left heart or aortic coarctation (Clark, 1984).
- *There must be a biologically plausible association.* Because both birth defects and drug or environmental exposures are common, it is always possible that an exposure and a defect are temporally but not causally related. For example, pregnant women frequently express concern about ingesting food or drinks containing aspartame. This compound, however, is metabolized to aspartic acid, which does not cross the placenta; to phenylalanine, which is metabolized; and to methanol, which is produced from aspartame in quantities lower than those released from an equal amount of metabolized fruit juice. Thus, it is not biologically plausible that aspartame is a teratogen.
- *Epidemiological findings must be consistent.* The initial evaluation of teratogen exposure is usually retrospective and may be hampered by recall bias, inadequate reporting, and incomplete assessment of the exposed population. The investigation is often confounded by a variety of dosages, concomitant drug therapy, and maternal disease(s). Familial and environmental factors can also influence development of birth defects. Thus, an important criterion for proving teratogenicity is that two or more high-quality epidemiological studies should report similar findings. These studies should control for confounding factors, exclude positive and negative biases, include a sufficient number of cases, and be conducted prospectively. Additionally, a relative risk greater than 3 is generally

TABLE 14-2. Criteria for Proof of Human Teratogenicity

1. Careful delineation of clinical cases
2. Rare environmental exposure associated with rare defect, with at least three reported cases—easiest if defect is severe
3. Proof that the agent acts on the embryo or fetus, directly or indirectly
4. Proven exposure to agent at critical time(s) in prenatal development
5. The association must be biologically plausible
6. Consistent findings by two or more epidemiological studies of high quality:
   (a) Control of confounding factors
   (b) Sufficient numbers
   (c) Exclusion of positive and negative bias factors
   (d) Prospective studies, if possible
   (e) Relative risk of three or more
7. Teratogenicity in experimental animals, especially primates

Modified from Czeizel and Rockenbauer (1997), Shepard (2001), and Yaffe and Briggs (2003).

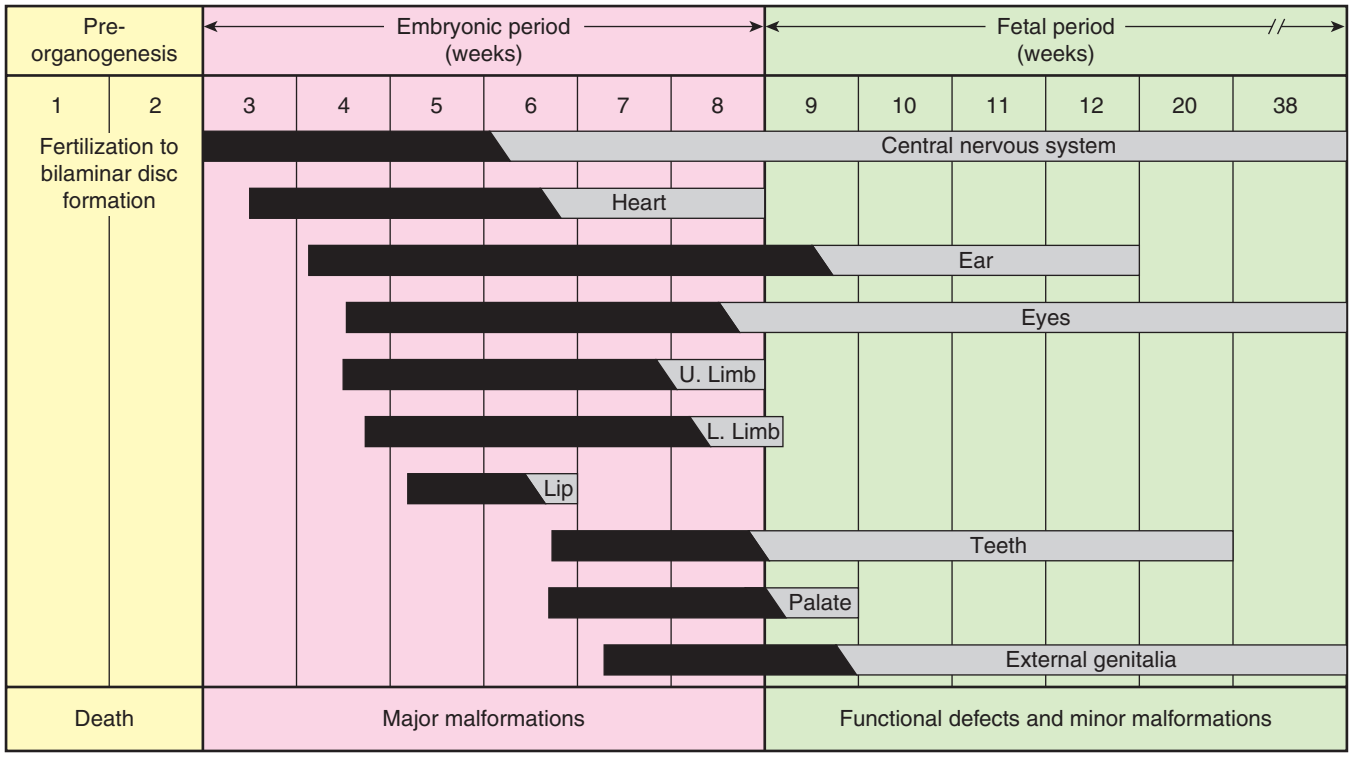

FIGURE 14-1 Timing of organogenesis during the embryonic period. (From Sadler, 1990, with permission.)

necessary to support the hypothesis, and a lesser risk should be interpreted with caution (Khouri and colleagues, 1992).

An illustration of the advantages of prospective evaluation is the Canadian multicenter study of lithium exposure (Jacobson and colleagues, 1992). Multiple case reports had associated lithium use with the rare *Ebstein anomaly* of the heart. When 148 exposed women were carefully evaluated prospectively, there was only one case of Ebstein anomaly, leading to the conclusion that lithium is not an important human teratogen, but that targeted sonography and fetal echocardiography are indicated following exposure. Suspected teratogens rarely are evaluated epidemiologically, and as a result, drug safety information frequently is derived from case reports and small series. Nonscientific and biased reporting has contributed to assertions—subsequently proven false—about the safety of widely used drugs. In many cases these assertions prompted litigation and cessation of manufacture of some very useful drugs. An example is *Bendectin,* a drug that was safe and effective for the treatment of nausea and vomiting in early pregnancy. More than 30 million women used this drug worldwide, and the 3-percent congenital anomaly rate among exposed fetuses was not different from the background rate (McKeigue and associates, 1994). Despite evidence that Bendectin was not teratogenic, it was the subject of numerous lawsuits, and the financial burden of defending these suits forced its withdrawal. Thereafter, hospitalizations for hyperemesis doubled (Koren and co-workers, 1998).

- *The suspected teratogen causes a defect in an animal.* If a drug or environmental exposure causes birth defects in experimental animals, it may be harmful to the human fetus (Brent, 2004a, 2004b). Human teratogenicity is more likely if the agent produces an adverse effect in many different species, especially subhuman primates.

The problems associated with reliance on animal data are illustrated by thalidomide. Although one of the most potent human teratogens was known, its teratogenicity was not recognized until thousands of infants had been born with thalidomide embryopathy because it produced no defects in several animal species studied.

Food and Drug Administration Classifications

To provide therapeutic guidance, a system for rating drug safety in pregnancy was developed in 1979 by the Food and Drug Administration (FDA). The system was designed to assist physicians by simplifying risk-benefit information with categories represented by letters that are listed in the classification shown in **Table 14-3**. The general consensus is that this system is not ideal. Many drug ratings are based on animal data, case reports, and limited or no human data, with information rarely updated. Because the manufacturer rates the product, discrepancies are common. This may be one reason why Lacroix and associates (2000) found that more than half of pregnant women in France were prescribed a medication from category D. Rather than simplifying counseling, this system places the onus on the clinician to interpret category information according to timing of exposure, dose, route, other medications used, and underlying medical condition(s).

The FDA acknowledges important limitations of the system. One is that drugs in categories D and X, and to a certain extent those in category C, may pose similar risks but are categorized

TABLE 14-3. Food and Drug Administration Categories for Drugs and Medications

Category A: Studies in pregnant women have not shown an increased risk for fetal abnormalities if administered during the first (second, third, or all) trimester(s) of pregnancy, and the possibility of fetal harm appears remote.
Fewer than 1 percent of all medications are in this category. Examples include levothyroxine, potassium supplementation, and prenatal vitamins, when taken at recommended doses.

Category B: Animal reproduction studies have been performed and have revealed no evidence of impaired fertility or harm to the fetus. Prescribing information should specify kind of animal and how dose compares with human dose.

or

Animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus during the first trimester of pregnancy, and there is no evidence of a risk in later trimesters.

Examples include many antibiotics, such as penicillins, macrolides, and most cephalosporins.

Category C: Animal reproduction studies have shown that this medication is teratogenic (or embryocidal or has other adverse effect), and there are no adequate and well-controlled studies in pregnant women. Prescribing information should specify kind of animal and how dose compares with human dose.

or

There are no animal reproduction studies and no adequate and well-controlled studies in humans.

Approximately two thirds of all medications are in this category. It contains medications commonly used to treat potentially life-threatening medical conditions, such as albuterol for asthma, zidovudine and lamivudine for human immunodeficiency viral infection, and many antihypertensives, including β-blockers and calcium-channel blockers.

Category D: This medication can cause fetal harm when administered to a pregnant woman. If this drug is used during pregnancy or if a woman becomes pregnant while taking this medication, she should be apprised of the potential hazard to the fetus.
This category also contains medications used to treat potentially life-threatening medical conditions, for example: systemic corticosteroids, azathioprine, phenytoin, carbamazepine, valproic acid, and lithium.

Category X: This medication is contraindicated in women who are or may become pregnant. It may cause fetal harm. If this drug is used during pregnancy or if a woman becomes pregnant while taking this medication, she should be apprised of the potential hazard to the fetus.
There are a few medications in this category that have never been shown to cause fetal harm but should be avoided nonetheless such as the rubella vaccine.

differently based on different risk-benefit considerations. Another drawback is that merely having categories creates the impression that drugs within a category pose similar risks, which is not the case. Concern has also been raised that reliance on the drug categories to make complex decisions about therapy for pregnant women may often be inappropriate.

Because of these problems, the FDA has proposed new rules for labeling drugs for use by pregnant women. Specifically, the Center for Drug Evaluation and Research (Food and Drug Administration, 2008) would remove the A-X categories and replace them with a narrative *fetal risk summary, clinical considerations,* and *inadvertent exposure* including registries available. This evidence-based rating system is currently under development. Meanwhile, the most current and accurate information can be obtained through online reproductive toxicity services such as *Reprotox* and *TERIS.*

GENETIC AND PHYSIOLOGICAL MECHANISMS OF TERATOGENICITY

Teratogens likely act by disturbing specific physiological processes, which leads to cell death, altered tissue growth, or abnormal cellular differentiation. Because abnormal physiological processes may be induced in many different cells or tissues, teratogenic exposure commonly results in multiple effects. Drugs may produce similar phenotypes if they disturb similar pathophysiological processes. The *fetal hydantoin syndrome*, subsequently discussed, illustrates this concept. Exposure may cause any combination of growth impairment, developmental delay, craniofacial abnormalities, hypoplasia of the distal phalanges, and widely spaced nipples. This phenotype shares features with that associated with prenatal exposure to carbamazepine and is similar to fetal alcohol syndrome (Vorhees and associates, 1988).

Disruption of Folic Acid Metabolism

Several congenital anomalies, including neural-tube defects, cardiac defects, cleft lip and palate, and even Down syndrome, are thought to arise, at least in part, from disturbance of folic acid metabolic pathways. Folic acid is essential for the production of methionine, which is required for methylation reactions and thus production of proteins, lipids, and myelin. Hydantoin, carbamazepine, valproic acid, and phenobarbital impair folate absorption or act as antagonists. They can lead to decreased periconceptional folate levels in women with epilepsy and to fetal malformations (Dansky and colleagues, 1987; Hiilesmaa and co-workers, 1983).

A study by Hernandez-Diaz and colleagues (2000) that included 5832 infants with birth defects and 8387 control infants is instructive. They showed that fetuses who were exposed during embryogenesis to anticonvulsant medications that act as folic acid

antagonists had a two- to threefold increased risk for oral clefts, cardiac defects, and urinary tract abnormalities. Although periconceptional folate supplementation lowers the malformation rate, women with epilepsy should be given the fewest number of drugs possible during pregnancy as well as folic acid supplementation (Lewis and co-workers, 1998; Zhu and Zhou, 1989).

Fetal Genetic Composition

It is believed that many multifactorial anomalies are caused by the interaction of environment and certain altered genes. One well-known example is mutation of the gene for *methylene tetrahydrofolate reductase—MTHFR 677C → T*. This mutation is associated with neural-tube defects and other malformations, but only when the mother has inadequate folic acid intake.

Another example is that fetuses exposed to hydantoin are most likely to develop anomalies if they are homozygous for a gene mutation resulting in abnormally low levels of *epoxide hydrolase* (Buehler and associates, 1990). Hydantoin, carbamazepine, and phenobarbital are metabolized by microsomes to arene oxides or epoxides. These oxidative intermediates normally are detoxified by cytoplasmic *epoxide hydrolase,* but because fetal epoxide hydrolase activity is weak, oxidative intermediates accumulate in fetal tissue (Horning and colleagues, 1974). These free oxide radicals have carcinogenic, mutagenic, and other toxic effects that are dose related and increase with multidrug therapy (Buehler and associates, 1990; Lindhout and co-workers, 1984).

There is also a reported association between cigarette smoking and isolated cleft palate, but only in individuals with an uncommon polymorphism in the gene for *transforming growth factor-1—TGF-1*. The risk of clefts in individuals with this allele is increased two- to sevenfold (Hwang and colleagues, 1995; Shaw and co-workers, 1996).

Homeobox Genes

These are highly conserved genes that share a region of homology. They are regulatory and encode nuclear proteins that act as transcription factors to control the expression of other developmentally important genes (Boncinelli, 1997). They are essential for establishing positional identity of various structures along the body axis from the branchial area to the coccyx. The arrangement of the genes along the chromosome corresponds to the arrangement of the body areas they control and the order in which they are activated (Faiella and collaborators, 1994).

An example of homeobox gene teratogenicity is retinoic acid. During embryogenesis, retinoids such as vitamin A activate genes essential for normal growth and tissue differentiation. Retinoic acid is a potent teratogen that can activate these genes prematurely, resulting in chaotic gene expression at sensitive stages of development (Soprano and Soprano, 1995). This mechanism has been linked to abnormalities in the hindbrain and limb buds. Another example is valproic acid, which is believed to preferentially alter the expression of the homeobox *Hox genes.* Disregulation of Hox-gene expression by valproic acid may prevent normal closure of the posterior neuropore (Faiella and colleagues, 1994). Interestingly, the affected Hox genes, *Hox d8, d10,* and *d11*, all control posterior structures. This corresponds with clinical observations that most neural-tube defects caused by valproic acid are in the lumbosacral area.

Paternal Exposures

In some cases, paternal exposures to drugs or environmental influences may increase the risk of adverse fetal outcome (Robaire and Hales, 1993). Several mechanisms are postulated. One is the induction of a gene mutation or chromosomal abnormality in sperm. Because the process by which germ cells mature into functional spermatogonia takes 64 days, drug exposure at any time during the 2 months prior to conception could result in a mutation. A second possibility is that during intercourse a drug in seminal fluid could directly contact the fetus. And a third is that paternal germ cell exposure to drugs or environmental agents may alter gene expression (Trasler and Doerksen, 1999).

Some studies support these hypotheses. For example, ethyl alcohol, cyclophosphamide, lead, and certain opiates have been associated with an increased risk of behavioral defects in the offspring of exposed male rodents (Nelson and colleagues, 1996). In humans, paternal environmental exposure to mercury, lead, solvents, pesticides, anesthetic gases, or hydrocarbons may be associated with early pregnancy loss (Savitz and associates, 1994). Offspring of men employed in the art or textile industries have been reported to be at increased risk for stillbirth, preterm delivery, and growth restriction. Others who may have an increased risk of having anomalous offspring include janitors, woodworkers, firemen, printers, and painters (Olshan and co-workers, 1991; Schnitzer and associates, 1995).

COUNSELING FOR TERATOGEN EXPOSURE

Questions regarding medication and illicit drug use should be part of routine preconceptional and prenatal care. Often women who request genetic counseling for prenatal drug exposure have misinformation regarding risk. Koren and colleagues (1989) reported that a fourth of women exposed to nonteratogenic drugs thought they had a 25-percent risk of fetal anomalies—that is, a risk equivalent to thalidomide exposure. Women also may underestimate the background risk of birth defects in the general population. Such misleading information can be amplified by the referral source, who may exaggerate risk—and even offer pregnancy termination—or by inaccurate reports in the lay press.

Counseling should include possible fetal risks from drug exposure, as well as possible teratogenic risks or genetic implications of the condition for which the drug was prescribed. Importantly, the manner in which information is presented affects the perception of risk. Jasper and colleagues (2001) showed that women given *negative information*—such as a 1- to 3-percent chance of having a malformed newborn—are more likely to perceive an exaggerated risk than women given *positive information*, that is, the 97- to 99-percent chance of having a child without a malformation. Ideally, women should be counseled preconceptionally as discussed throughout Chapter 7. In reality, however, patients often do not seek care or report possible adverse exposures until *after* conception.

With a few notable exceptions, most commonly prescribed drugs and medications can be used with relative safety during pregnancy.

For the few drugs believed to be teratogenic, counseling should emphasize *relative risk.* All women have an approximate 3-percent chance of having a neonate with a birth defect. Although exposure to a confirmed teratogen may increase this risk, it is usually increased by only 1 or 2 percent, or at most, doubled or tripled. The concept of *risk versus benefit* also should be introduced. Some untreated diseases pose a more serious threat to both mother and fetus than any theoretical risks from medication exposure.

EXAMPLES OF KNOWN AND SUSPECTED TERATOGENS

Fortunately, the number of drugs or medications strongly suspected or proven to be human teratogens is small (see Table 14-1). In addition, in nearly every clinical situation potentially requiring therapy with a known teratogen, there are several alternate drugs that can be given with relative safety. In general, because there are no adequate and well-controlled studies in pregnant women for most medications, and because animal reproduction studies are not always predictive of human response, the use of any medication in pregnancy must be carefully considered and only used if clearly needed.

Alcohol

Ethyl alcohol is one of the most potent teratogens known. As many as 70 percent of Americans drink alcohol socially, and its use during pregnancy varies by population. Ethen and associates (2009) published data from the National Birth Defects Prevention Study that 30 percent of women report drinking alcohol during pregnancy. This rate is approximately threefold higher than that found in a 2002 survey by the Centers for Disease Control and Prevention (2004).

The fetal effects of alcohol abuse have been recognized at least since the 1800s. Lemoine and associates (1968) categorized the wide spectrum of alcohol-related fetal defects, in what is now known as the *fetal alcohol syndrome* (Table 14-4). The Institute of Medicine (1996) has estimated that the prevalence of the syndrome ranges from 0.6 to 3 per 1000 births, and the prevalence of alcohol-related birth defects and neurobehavioral disorders is 9 per 1000 births. Thus, alcohol is one of the most frequent nongenetic causes of mental retardation as well as the leading cause of preventable birth defects in the United States.

Clinical Characteristics

Fetal alcohol syndrome has specific criteria, which are enumerated in Table 14-4. These were updated by a national task force of the Centers for Disease Control and Prevention and include dysmorphic facial features, pre- or postnatal growth impairment, and central nervous system abnormalities that may be structural, neurological, or functional (Bertrand and colleagues, 2005). The distinctive facial features are shown in Figure 14-2. Affected individuals may have other alcohol-related major and minor birth defects, including cardiac and renal anomalies, orthopedic problems, and abnormalities of the eyes and ears. *Fetal alcohol spectrum disorder* is an umbrella term that includes the full range of prenatal alcohol damage that may not meet the criteria for fetal alcohol syndrome and is estimated to occur in up to 1 in 100 children born in the United States (Burd, 2003; Guerri, 2009; Sampson, 1997, and all their associates).

TABLE 14-4. Fetal Alcohol Syndrome and Alcohol-Related Birth Defects

Fetal Alcohol Syndrome Diagnostic Criteria—all required

I. Dysmorphic facial features
   a. Small palpebral fissures
   b. Thin vermilion border
   c. Smooth philtrum
II. Prenatal and/or postnatal growth impairment
III. Central nervous system abnormalities
   a. Structural: Head size < 10th percentile, significant brain abnormality on imaging
   b. Neurological
   c. Functional: Global cognitive or intellectual deficits, functional deficits in at least three domains

Alcohol-Related Birth Defects

I. Cardiac: atrial or ventricular septal defect, aberrant great vessels, conotruncal heart defects
II. Skeletal: radioulnar synostosis, vertebral segmentation defects, joint contractures, scoliosis
III. Renal: aplastic or hypoplastic kidneys, dysplastic kidneys, horseshoe kidney, ureteral duplication
IV. Eyes: strabismus, ptosis, retinal vascular abnormalities, optic nerve hypoplasia
V. Ears: conductive or neurosensory hearing loss
VI. Minor: hypoplastic nails, clinodactyly, pectus carinatum or excavatum, camptodactyly, "hockey stick" palmar creases, refractive errors, "railroad track" ears

Modified from Bertrand and co-workers (2005) and Hoyme and colleagues (2005).

Dose Effect

Binge drinking has been linked to an increased risk of stillbirth (Strandberg-Larsen and co-workers, 2008). However, the minimum amount of alcohol required to produce adverse fetal consequences is unknown (Henderson and colleagues, 2007). Fetal vulnerability varies due to genetic factors, nutritional status, environmental factors, coexisting disease, and maternal age (Abel, 1995). Wass and colleagues (2001) monitored fetal brain growth sonographically in 167 pregnant women. They found that of the fetuses whose mothers drank an average of 8 ounces of alcohol per day, 23 percent had a frontal cortex measurement below the 10th percentile compared with only 4 percent of nonexposed fetuses. Unfortunately, fetal alcohol syndrome cannot be reliably diagnosed prenatally, although in some cases, major abnormalities or growth restriction may suggest it.

Anticonvulsant Medications

Women with epilepsy have an increased risk of fetal malformations that is usually estimated to be two to three times the

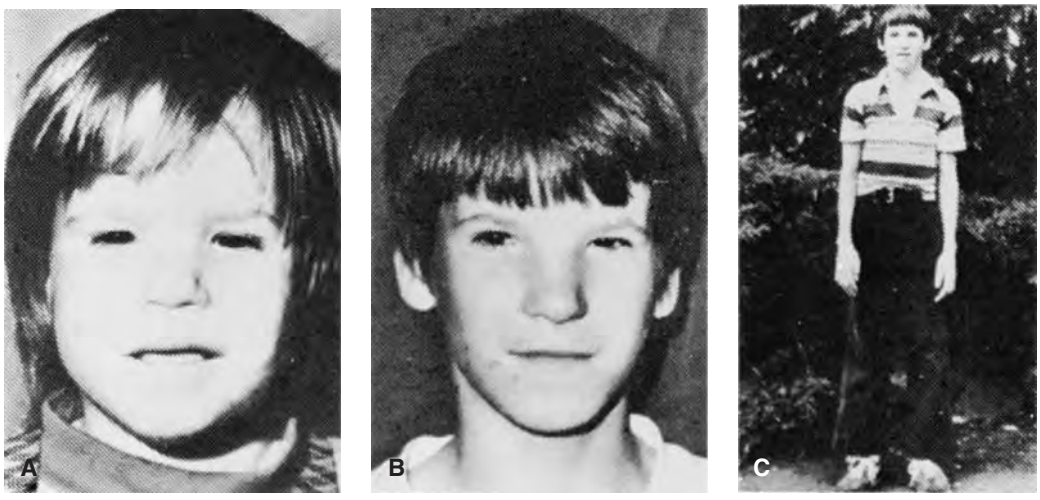

FIGURE 14-2 Fetal alcohol syndrome. **A.** At 2½ years. **B, C.** At 12 years. Note persistence of short palpebral fissures, epicanthal folds, flat midface, hypoplastic philtrum, and thin upper vermilion border. This individual also has the short, lean prepubertal stature characteristic of young males with fetal alcohol syndrome. (Reprinted from *The Lancet,* Vol. 326, AP Streissguth, SK Clarren, and KL Jones, Natural history of the fetal alcohol syndrome: A 10-year-follow-up of eleven patients, pp. 85–91, Copyright 1985, with permission from Elsevier.)

background rate. There has been controversy as to whether the increased risk is due to the underlying seizure disorder or the medication(s) used to treat it (Holmes and colleagues, 2001). Recent data suggest that the risks are not as great as once thought. For example, a meta-analysis by Fried and associates (2004) from the Toronto Motherisk Program showed that women with untreated epilepsy had a similar risk for major fetal malformations as did nonepileptic control women. And in the United Kingdom Epilepsy and Pregnancy Registry of 3400 women, the major fetal malformation rate was 3 percent with untreated epilepsy and 3 percent with epilepsy treated with monotherapy (Morrow and colleagues, 2006). In fact, only women who were treated with valproate had a significantly increased risk for malformations—the risk was 9 percent if valproate was part of polytherapy.

Malformations of all types are more prevalent with high serum anticonvulsant concentrations. Moreover, the need for drug therapy, for high serum levels, and for multiple medications also reflects severity of epilepsy. Thus, it is also possible that at least part of the increased risk is related to epilepsy itself or some other aspects of the maternal condition. The most frequently reported defects—whether or not the mother takes medication—are orofacial clefts, cardiac malformations, and neural-tube defects. For example, clefts develop almost 10 times more frequently than in the general population.

The most commonly used potentially teratogenic anticonvulsants and their fetal effects are listed in **Table 14-5**. Several of these produce a similar constellation of malformations, typified by the *fetal hydantoin syndrome* shown in

TABLE 14-5. Teratogenic Effects of Common Anticonvulsant Medications

Drug	Abnormalities Described	Affected	Pregnancy Category
Valproate	Neural-tube defects, clefts, skeletal abnormalities, developmental delay	1–2% with monotherapy, 9–12% with polytherapy	D
Phenytoin	Fetal hydantoin syndrome: craniofacial anomalies, fingernail hypoplasia, growth deficiency, developmental delay, cardiac defects, clefts	5–11%	D
Carbamazepine	Fetal hydantoin syndrome, spina bifida	1–2%	D
Phenobarbital	Clefts, cardiac anomalies, urinary tract malformations	10–20%	D
Lamotrigine	Inhibits dihydrofolate reductase, lowering fetal folate levels. Registry data suggest increased risk for clefts	4-fold with monotherapy, 10-fold with polytherapy	C
Topiramate	Registry data suggest increased risk for clefts	2%	C
Levetiracetam	Theoretical—skeletal abnormalities and impaired growth in animals at doses similar to or greater than human therapeutic doses	Too few cases reported to assess risk	C

From Cunningham (2005), Holmes (2008), Hunt (2006, 2008), Morrow (2006), UCB, Inc. (2008), and all their associates.

Figure 14-3. Other medications, such as *phenobarbital,* act by lowering fetal folate levels and may thereby cause defects associated with impaired folic acid metabolism, such as neural-tube defects, oral clefts, cardiac anomalies, and urinary tract malformations (see Chap. 12, p. 281).

There are limited data available for the newer anticonvulsants—*levetiracetam, lamotrigine*, and *topiramate*. Cases reported thus far through registries suggest that the risk for oral clefts may be increased with either lamotrigine or topiramate (Holmes and associates, 2008; Hunt and co-workers, 2008) (Table 14-5). But because most birth defects are so infrequent, even a severalfold increase would not necessarily be apparent with the relatively small number of cases reported. Given limitations of the available data, many obstetricians and neurologists choose to maintain the woman on whichever medication(s) had best stabilized her seizures prior to pregnancy.

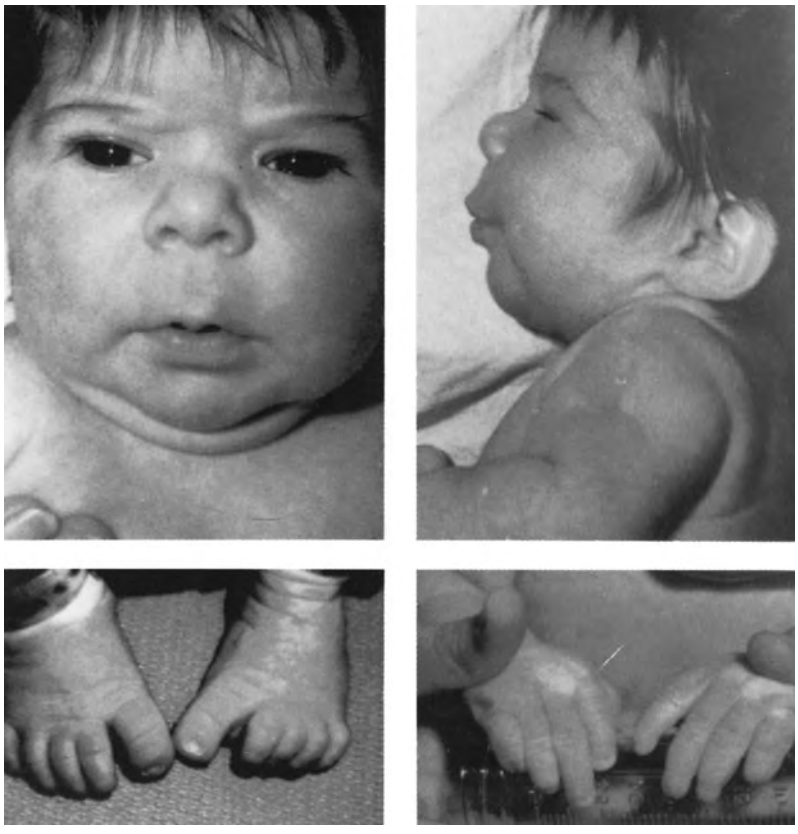

FIGURE 14-3 Fetal hydantoin syndrome. Upper: facial features including upturned nose, mild midfacial hypoplasia, and long upper lip with thin vermilion border. Lower: distal digital hypoplasia. (From Buehler BA, Delimont D, van Waes M, et al: Prenatal prediction of risk of the fetal hydantoin syndrome. *N Engl J Med* 322:1567, with permission. Copyright © 1990 Massachusetts Medical Society. All rights reserved.)

Angiotensin-Converting Enzyme (ACE) Inhibitors and Angiotensin-Receptor Blockers

It has been known for 20 years that ACE inhibitors are fetotoxic, and more recently they have also been associated with embryotoxicity. The most frequently associated agent is *enalapril,* although *captopril* and *lisinopril* have also been implicated. Because angiotensin-receptor blockers exert their effects through a similar mechanism, concerns about toxicity have been generalized to include this entire category of medications. These drugs disrupt the fetal renin-angiotensin system, which is essential for normal renal development (Guron and Friberg, 2000). In addition, they may provoke prolonged fetal hypotension and hypoperfusion, thus initiating a sequence of events leading to renal ischemia, renal tubular dysgenesis, and anuria (Pryde and colleagues, 1993; Schubiger and associates, 1988). The resulting oligohydramnios may prevent normal lung development and lead to limb contractures. Reduced perfusion also causes growth restriction, relative limb shortening, and maldevelopment of the calvarium (Barr and Cohen, 1991). Because these changes occur after organogenesis, and thus during the fetal period, they are termed *ACE inhibitor fetopathy* (see p. 313).

Cooper and colleagues (2006) recently described 209 children whose mothers were prescribed ACE inhibitors in the first trimester. They reported that 8 percent had major congenital anomalies—predominantly cardiovascular and central nervous system malformations—a rate 2.7 times higher than that observed in more than 29,000 control infants. Given the many therapeutic options for treating hypertension during pregnancy, it is recommended that ACE inhibitors and angiotensin-receptor blocking agents be avoided.

Antifungals

Fluconazole and Itraconazole

There have been several reports of congenital malformations associated with fluconazole. Exposed newborns had skull abnormalities, cleft palate, humeral-radial fusion, and other arm abnormalities (Aleck and Bartley, 1997). There have also been reports associating itraconazole with limb defects and other adverse outcomes. Despite this, large cohort studies suggest that neither drug is teratogenic (Bar-Oz, 2000; Carter, 2008; Sorenson, 1999, and all their colleagues).

Anti-inflammatory Agents

Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

These are not considered to be teratogenic, but they can have adverse fetal effects when used in the third trimester (Parilla, 2004; Rebordosa and colleagues, 2008). *Indomethacin* in particular is reported to cause constriction of the fetal ductus arteriosus with subsequent pulmonary hypertension (Marpeau and associates, 1994; Rasanen and Jouppila, 1995). It may also decrease fetal urine output and thereby reduce amnionic fluid volume, presumably by increasing vasopressin levels and responsiveness to it (van der Heijden and colleagues, 1994; Walker and associates, 1994). These complications appear to be more likely when the drug is taken for longer

than 72 hours. In one series of more than 60 pregnancies, ductal constriction developed in 50 percent, with a significantly increased incidence after 30 weeks (Vermillion and colleagues, 1997). Fortunately, ductal flow velocity returned to normal following discontinuation of therapy in all cases. There also are associations of indomethacin with intraventricular hemorrhage, bronchopulmonary dysplasia, and necrotizing enterocolitis. Some reports indicate that low-birthweight neonates who are delivered preterm within 48 hours of indomethacin exposure are at highest risk (Major and associates, 1994; Norton and co-workers, 1993). Studies conducted after neonatal surfactant treatment became available have not confirmed this association (Gardner and colleagues, 1996).

Leflunomide

This is a pyrimidine-synthesis inhibitor used to treat rheumatoid arthritis (see Chap. 54, p. 1157). It currently is considered contraindicated in pregnancy. This is because in animal studies with multiple species, hydrocephalus, eye anomalies, skeletal abnormalities, and embryo death have been reported with amounts given at or below human-equivalent exposure (Sanofi-aventis Pharmaceuticals, 2007). It can take 2 years after discontinuation for the active metabolite of leflunomide to return to nondetectable plasma levels. The manufacturer has developed a cholestyramine treatment/washout plan in the event of unintended pregnancy. There are also guidelines and a cholestyramine treatment plan available for men taking this medication who are contemplating fathering a child (Brent, 2001).

Antimalarials

Chloroquine is valuable as a first-line antimalarial treatment and for chemoprophylaxis. In high doses, it is also effective against rheumatoid arthritis and systemic lupus erythematosus (Ruiz-Irastorza and associates, 2009; Vroom and co-workers, 2006). *Quinine* and *quinidine* are reserved for severely ill women with chloroquine-resistant malaria. There has been no increased rate of congenital anomalies in the offspring of mothers given any of these antimalarial drugs during pregnancy (McGready and co-workers, 2001, 2002). Daily use of chloroquine for lupus and other connective-tissue diseases has been shown to cause maternal retinopathy but no adverse fetal effects (Araiza-Casillas and colleagues, 2004; Costedoat-Chalumeau and co-workers, 2003). Second- or third-trimester use of *mefloquine* for asymptomatic malaria treatment has been associated with a fivefold increased risk of stillbirth (Nosten and colleagues, 1999). According to Briggs and colleagues (2005), however, accumulated evidence supports its safety.

Antimicrobials

Aminoglycosides

Maternal administration can result in toxic fetal blood levels, but this can be avoided by using lower divided doses (Regev and colleagues, 2000). Although both nephrotoxicity and ototoxicity have been reported in preterm newborns and adults treated with *gentamicin* or *streptomycin,* congenital defects resulting from prenatal exposure have not been confirmed.

Chloramphenicol

This readily crosses the placenta and results in significant fetal blood levels. The incidence of congenital anomalies does not appear to be increased in exposed fetuses. When given to the preterm neonate, the *gray baby syndrome* may develop. This is manifested by cyanosis, vascular collapse, and death. It seems unlikely that fetal serum levels obtained from maternal administration would cause this syndrome.

Sulfonamides

Although these agents readily cross the placenta, fetal blood levels are lower than maternal levels. Sulfonamides do not appear to pose any significant teratogenic risk (Briggs and colleagues, 2005). They displace bilirubin from protein binding sites, raising theoretical concerns about hyperbilirubinemia in the preterm neonate if used near delivery (see Chap. 29, p. 625).

Tetracyclines

Tetracycline may cause yellow-brown discoloration of deciduous teeth or be deposited in fetal long bones when used after 25 weeks (Kutscher and associates, 1966). The risk of dental caries, however, is not increased in exposed children (Billing and associates, 2004). One acceptable use is treatment of maternal syphilis in penicillin-allergic women for whom desensitization is not feasible (see Chap. 59, p. 1238).

Antineoplastic Agents

Cyclophosphamide

In the first trimester, this alkylating agent inflicts a chemical insult on developing fetal tissues, resulting in cell death and heritable DNA alterations in surviving cells. The most common fetal anomalies are missing and hypoplastic digits, believed to be caused by necrosis of limb buds and DNA damage in surviving cells (Manson and associates, 1982). Other defects include cleft palate, single coronary artery, imperforate anus, and fetal-growth restriction with microcephaly (Kirshon and colleagues, 1988). Nurses who administer cyclophosphamide may be at increased risk for fetal loss, but there are no adequate epidemiological studies (Glantz, 1994).

Methotrexate and Aminopterin

These drugs alter folic acid metabolism, which is essential for normal cell replication (Sutton and co-workers, 1998). Methotrexate commonly is prescribed in gynecology for ectopic pregnancy or as an abortifacient (see Chap. 9, p. 232 and Chap. 10, p. 247). It is also used for psoriasis and some connective-tissue diseases (see Chap. 54, p. 1150 and Chap. 56, p. 1191). Principal features of fetal methotrexate-aminopterin syndrome are growth restriction, failure of calvarial ossification, craniosynostosis, hypoplastic supraorbital ridges, small posteriorly rotated ears, micrognathia, and severe limb abnormalities (Del Campo and associates, 1999). The critical period for their development is 8 to 10 menstrual weeks. After a review of 20 first-trimester exposures, Feldcamp and Carey (1993) calculated that a dosage of 10 mg/week is necessary to produce abnormalities. The standard 50 mg/m^2 dose for ectopic pregnancy or elective abortion easily exceeds this, and ongoing pregnancies after methotrexate treatment—especially if

used in conjunction with misoprostol—raise concerns for fetal malformations (Creinin and Vittinghoff, 1994).

Tamoxifen

This nonsteroidal selective estrogen-receptor modulator (SERM) is used as an adjuvant to treat breast cancer (see Chap. 57, p. 1195). Although not found to be teratogenic for all animals, it is *fetotoxic* in rats and marmosets, in which it produces deaths and impaired growth, and is *carcinogenic* in rats and mice. In rodents, tamoxifen causes changes similar to those seen following maternal diethylstilbestrol (DES) exposure as subsequently discussed. There are limited human data available. Tamoxifen is pregnancy category D, and it is recommended that exposed offspring be followed for up to 20 years to assess the risk of carcinogenicity (Briggs and colleagues, 2005).

Antivirals

Amantadine is used in pregnancy to prevent, modify, or treat influenza infections (see Chap. 46, p. 1003). This drug is embryotoxic and teratogenic in animals at high doses, but data regarding its safety in pregnancy are limited (Centers for Disease Control and Prevention, 2003). Several case reports and case series in which amantadine was given during the first trimester suggest a possible association with cardiac defects, but the information provided is too limited to allow risk assessment (Pandit and colleagues, 1994; Rosa, 1994).

Ribavirin is given by aerosol inhalation to treat respiratory syncytial virus infections in infants and young children. Pregnant women may be exposed to the drug while working in intensive care nurseries. The drug is highly teratogenic in all animal species studied and consistently produces skull, palate, eye, jaw, limb, skeleton, and gastrointestinal abnormalities in rodent models (Briggs and colleagues, 2005). Although human exposures are rare, the manufacturers consider it Category X and contraindicated for use in pregnancy.

As discussed in Chapter 59 (p. 1250), the use of antiviral medications for human immunodeficiency virus (HIV) infections during pregnancy is growing. These agents inhibit host intracellular viral replication through their action on RNA or DNA substrates. A registry chronicling their maternal and fetal effects has been established by several manufacturers, and it can be accessed for current information at http://www.apregistry.com/. Watts and associates (2004) reported that nearly 1400 first-trimester exposed pregnancies have been followed through this registry thus far, and no significant increase in birth defects has been noted following exposure to lamivudine, nelfinavir, nevirapine, stavudine, or zidovudine.

Another drug used to treat HIV infection is *efavirenz,* a nonnucleoside reverse transcriptase inhibitor. Three of 20 cynomolgus monkeys treated with doses of efavirenz comparable with human doses had birth defects—anencephaly, cleft palate, and microphthalmia (Bristol-Meyers Squibb, 2008). It is reassuring, however, that the Antiretroviral Pregnancy Registry Steering Committee (2004) reported 159 human pregnancies with first-trimester exposure and found neither an increased risk for birth defects nor a particular pattern of defects. At this time, data are limited and options for treating pregnant women are best individualized.

Bosentan

This is an endothelin-receptor antagonist used to treat pulmonary hypertension (see Chap. 44, p. 970). Bosentan is teratogenic in rats, causing abnormalities of the head, face, and large blood vessels, and it is also carcinogenic in rats and mice (Actelion Pharmaceuticals, 2005). No human data are available, but based on these concerning animal data, the manufacturer has rated bosentan category X (Briggs and associates, 2005). Moreover, the package insert recommends pregnancy be excluded before starting treatment and prevented with two concurrent forms of birth control thereafter. As any hormonal contraceptives—oral, injectable, or implantable—may not be completely effective in women on bosentan, it is recommended that they not be the sole means of contraception.

Hormones

The primordial structures that will become the external genitalia are bipotential for the first 9 weeks (see Chap. 4, p. 98). Between 9 and 14 weeks, the testis secretes androgen and the male fetus develops a male perineal phenotype. Because the ovaries do not secrete androgens, the female fetus continues to develop a female phenotype, which is completed by 20 weeks. Exposure to exogenous sex hormones before 7 completed weeks generally has no effect on external structures. Between 7 and 12 weeks, however, female genital tissue is responsive to exogenous androgens and exposure can result in full masculinization. The tissue continues to exhibit some response until 20 weeks, with exposure causing partial masculinization or genital ambiguity.

Those areas of the brain with high concentrations of estrogen and androgen receptors are also influenced by hormonal exposure. Hormones program the central nervous system for gender identity, sexual behavior, levels of aggression, and gender-specific play behaviors. The critical period for hormonal influence on behavior is much later than that for the external genitalia, with the degree of behavioral alteration proportional to dose and length of exposure.

Androgens

One example of the fetal effects from early exposure to androgens is autosomal recessive *congenital adrenal hyperplasia* (see Chap. 4, p. 102). Exposure to exogenous androgens can induce similar fetal effects, but masculinization from exogenous androgens does not progress after birth (Stevenson, 1993b).

Testosterone and Anabolic Steroids. Androgen exposure in reproductive-aged women occurs primarily as the result of anabolic steroids used to increase lean body mass and muscular strength. Synthetic testosterones are the most effective and are taken in doses 10 to 40 times higher than physiological doses. In adult women, these compounds cause extreme and irreversible virilization, liver dysfunction, and mood and libido disorders. Exposure of a female fetus results in varying degrees of virilization, including labioscrotal fusion after first-trimester exposure and phallic enlargement from later fetal exposure (Grumbach and Ducharme, 1960; Schardein, 1985). An example is shown in Figure 4-19 (p. 102). Normal female maturation usually occurs at puberty, although surgery may be necessary to give a more feminine appearance to the virilized genitalia.

Androgenic Progestins. These testosterone derivatives currently are used as contraceptives. In studies of rats and nonhuman primates, antenatal exposure to *medroxyprogesterone acetate* given as an intramuscular depot contraceptive has been associated with virilization of female fetuses and feminization of male fetuses. Fortunately, no association between this agent and any congenital defects in humans has been established (see Chap. 32, p. 682). *Norethindrone,* a progesterone-only contraceptive, is estimated to cause female fetus masculinization in 1 percent of exposures (Schardein, 1985).

Danazol. This ethinyl testosterone derivative has weak androgenic activity. It is prescribed primarily for endometriosis but also is used to treat immune thrombocytopenic purpura, migraine headaches, premenstrual syndrome, and some breast diseases. In a review of its inadvertent use during early pregnancy, Brunskill (1992) reported that 40 percent of 57 exposed female fetuses were virilized. There was a dose-related pattern of clitoromegaly, fused labia, and urogenital sinus malformation, most of which required surgical correction.

Estrogens

Most of the many available estrogen compounds do not affect fetal development. *Oral contraceptives,* as discussed in Chapter 32 (p. 675), have not been associated with congenital anomalies (Raman-Wilms and colleagues, 1995). *Tamoxifen* is a selective estrogen-receptor modulator and is discussed with other antineoplastic agents on page 321.

Diethylstilbestrol (DES). From 1940 to 1971, between 2 million and 10 million pregnant women took this synthetic estrogen to "support" high-risk pregnancies (Giusti and co-workers, 1995). The drug later was shown to have no beneficial effects, and its use for this purpose was abandoned. Herbst and colleagues (1971) reported a series of eight prenatally exposed women who developed vaginal clear-cell adenocarcinoma. Subsequent studies showed that the absolute cancer risk in prenatally exposed women is approximately 1 per 1000. A registry established by the National Institutes of Health reported that half of 384 cancer patients were exposed before 12 weeks and 70 percent before 17 weeks (Melnick and colleagues, 1987). Malignancy was not dose related, and there was no relationship between location of the tumor and timing of exposure. For these reasons and because its absolute risk is low, some authors categorize DES as an *incomplete carcinogen.*

The drug also produces both structural and functional abnormalities (Salle and colleagues, 1996). By 18 weeks, the müllerian-derived cuboidal-columnar epithelium lining the vagina should be replaced by squamous epithelium originating from the urogenital sinus. DES interrupts this transition in up to half of exposed female fetuses, resulting in excess cervical eversion—*ectropion*, and ectopic vaginal glandular epithelium—*adenosis.* These lesions have malignant potential, and DES-exposed women have a twofold increase in vaginal and cervical intraepithelial neoplasia (Vessey, 1989). Approximately a fourth of exposed females have structural abnormalities of the cervix or vagina (Robboy and associates, 1984). The most commonly reported abnormalities include a hypoplastic, T-shaped uterine cavity; cervical collars, hoods, septa, and coxcombs; and "withered" fallopian tubes (Goldberg and Falcone, 1999). As discussed in Chapter 40 (p. 897), these women are at increased risk for poor pregnancy outcomes related to uterine malformations, decreased endometrial thickness, and reduced uterine perfusion (Kaufman and colleagues, 2000). Exposed men have normal sexual function and fertility but are at increased risk for epididymal cysts, microphallus, cryptorchidism, and testicular hypoplasia (Stillman, 1982). Klip and associates (2002) reported that sons of women exposed in utero had an increased risk of hypospadias.

Immunosuppressants

Corticosteroids

Hydrocortisone, prednisone, and other corticosteroids are commonly used to treat serious medical conditions such as asthma and autoimmune disease. In animal studies, they have been associated with cleft palate. In a 10-year prospective cohort study by the Motherisk Program and the University of Toronto, corticosteroid exposure was not associated with an increased risk for major malformations (Park-Wyllie and colleagues, 2000). A meta-analysis by the same investigators, however, did demonstrate an increased incidence of facial clefts. The odds ratio for clefts in case-control series was increased approximately threefold—an absolute risk of 3 per 1000 (Park-Wyllie and colleagues, 2000). Based on these findings, systemic corticosteroids are category D if used in the first trimester, however, they are not considered to represent a major teratogenic risk.

Mycophenolate Mofetil

This inosine monophosphate dehydrogenase inhibitor, and a related agent, *mycophenolic acid,* are used to prevent rejection in recipients of kidney, liver, or heart transplantation. They have also been used in the treatment of autoimmune disease. In 2007, the FDA revised the prescribing information for these medications to pregnancy category D, based on reports of increased risks of spontaneous abortion and selected anomalies in exposed pregnancies (Food and Drug Administration, 2008). Of 33 pregnancies in the National Transplantation Pregnancy Registry exposed to *mycophenolate mofetil,* 45 percent experienced a spontaneous loss, and 22 percent of surviving infants had malformations. The majority of reported malformations have involved the ear and include bilateral microtia, anotia, and/or atresia of the external auditory canals. In addition, oral clefts have been described. Importantly, inosine monophosphate dehydrogenase inhibitors may decrease the efficacy of oral contraceptives. Because of these risks, the manufacturer states that women must use two different types of effective birth control for 1 month before starting use of these immunosuppressants, during their use, and for 6 weeks after stopping their use (Roche Laboratories, 2008).

Iodine Preparations

Radioactive iodine-131 is used to treat thyroid malignancies and hyperthyroidism, and it is used diagnostically for thyroid scanning. It is contraindicated during pregnancy because it

readily crosses the placenta and is avidly concentrated in the fetal thyroid by the end of the first trimester. High doses of radiation may ablate the fetal thyroid as well as increase the future risk for childhood thyroid cancer. Although fetal thyroid hormone production is believed to begin at approximately 10 weeks, it would seem prudent to avoid radioiodide at any gestational age (see also Chap. 41, p. 921 and Chap. 53, p. 1128).

Methyl Mercury

Although not a drug, methyl mercury is a known teratogen. Reports from Minimata, Japan, and from rural Iraq, the sites of two major methyl mercury industrial spills, indicate that the developing nervous system is particularly susceptible to the effects of mercury. Prenatal exposure causes disturbances in neuronal cell division and migration, resulting in a range of defects from developmental delay and mild neurological abnormalities to microcephaly and severe brain damage (Choi and colleagues, 1978).

Although there have been no recent episodes of large-scale methyl mercury contamination in the United States, pregnant women worldwide are currently at risk of exposure. Mercury enters the ecosystem through industrial pollution, which joins surface water and eventually reaches the ocean. Several varieties of older large fish, notably tuna, shark, king mackerel, and tilefish, absorb and retain mercury from the water or ingest it when they eat smaller fish and aquatic organisms. Women who eat these fish ingest mercury, which is metabolized to inorganic mercury by intestinal microflora and eliminated by demethylation and fecal excretion. The process is slow, with an elimination half-time of 45 to 70 days (Clarkson, 2002). Because large quantities of contaminated fish ingested during pregnancy may expose a fetus to unsafe mercury levels, the Environmental Protection Agency and the Food and Drug Administration (2008) currently recommend that pregnant women not eat shark, swordfish, king mackerel, or tilefish. Regarding other fish, a pregnant woman should eat each week no more than 6 ounces of albacore tuna or 12 ounces of fish or shellfish thought to be low in mercury (see Chap. 8, p. 206).

Psychiatric Medications

Lithium

This drug is used for manic-depressive illness (see Chap. 55, p. 1179). As discussed on page 314, it has been associated with the rare *Ebstein anomaly*, which is characterized by a downward or apical displacement of the tricuspid valve that leads to atrialization of the right ventricle. In the Lithium Baby Register, by 1977, there were five cases of Ebstein anomaly among 183 reported exposed pregnancies (Weinstein, 1977). Subsequently, in a prospective multicenter study of 148 exposed pregnancies, there was only one such case, leading to the conclusion that lithium may not be an important teratogen (Jacobson and colleagues, 1992). Currently, targeted sonography with fetal echocardiography is recommended for women who take lithium in the first trimester.

Lithium also may cause transient neonatal toxicity. Effects have included hypothyroidism, diabetes insipidus, cardiomegaly, bradycardia, electrocardiogram abnormalities, cyanosis, and hypotonia (Briggs and associates, 2005).

Selective Serotonin-Reuptake Inhibitors (SSRIs)

In a study of seven health plans including nearly 119,000 pregnant women, Andrade and co-workers (2008) reported that 8 percent were prescribed antidepressants. As a class, these are the most commonly used antidepressants in pregnancy (see Chap. 55, p. 1177). Included are citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline.

Teratogenicity. In 2005, data from a Swedish national registry and a U.S. insurance claims database raised concerns that the rate of congenital cardiac malformations was increased 1.5- to 2-fold following first-trimester paroxetine exposure (GlaxoSmithKline, 2008). The two studies included more than 12,000 pregnant women prescribed antidepressants, including approximately 1600 women who used paroxetine in the first trimester. The overall rate of infants with cardiovascular malformations among women who took paroxetine was increased approximately 0.5 to 1.0 percentage points above the rate for infants with other antidepressant exposure in utero. Most of these defects were atrial and ventricular septal defects, which are the most common congenital cardiac anomalies and are also among the most difficult to reliably detect with prenatal sonography. Based on these findings, the manufacturer changed the pregnancy category of paroxetine, but not other SSRIs, from C to D. Also, the American College of Obstetricians and Gynecologists (2007) recommended that paroxetine use be avoided in women who are either pregnant or planning pregnancy and that fetal echocardiography should be considered for women with early pregnancy paroxetine exposure.

Subsequent to these events, two large case-control studies from multisite surveillance programs have reported potential teratogenicity of paroxetine and other SSRI medications. From the National Birth Defects Prevention Study, Alwan and associates (2007) did not find an increased risk of cardiovascular anomalies but did identify a two- to threefold increased risk for omphalocele, craniosynostosis, and anencephaly. This risk—approximately 2 per 1000 infants—was primarily with paroxetine exposure. In the other study, Louik and colleagues (2007) from the Sloane Epidemiology Center did not identify a risk for any of these birth defects. They did, however, report an association with paroxetine and cardiac right outflow tract abnormalities as well as with sertraline and cardiac septal defects and omphalocele. Because of the large number of outcomes analyzed, the American College of Obstetricians and Gynecologists (2007) concluded that the absolute risk of any birth defect is very small and that SSRIs are not major teratogens.

Neonatal Effects. There are two types of neonatal effects that have been described following maternal SSRI use in pregnancy. A neonatal behavioral syndrome has been observed in up to a fourth of fetuses exposed in the last trimester (Chambers and associates, 2006; Costei and colleagues, 2002). In a review of 13 case reports and nine cohort studies that included 990 pregnancies with such exposure, Moses-Kolko and co-workers (2005) calculated a significant overall risk ratio of 3.0 for this syndrome. Most reported cases followed paroxetine or fluoxetine exposure. Common features are jitteriness or shivering, increased muscle tone, feeding or digestive disturbances, irritability or agitation, and respiratory distress.

Generally, the syndrome is considered to be mild and self-limited, lasting usually approximately 2 days. Management typically consists of supportive care. Jordan and colleagues (2008) found that affected infants were not more likely to be transferred to a special care nursery or to require longer hospitalization than infants of mothers whose depression was not treated with medication. Rarely, there may be a severe form of this syndrome—reported in only 0.3 percent of infants—manifested by seizures, hyperpyrexia, excessive weight loss, and need for intubation. These findings are similar to those in adults from SSRI toxicity or from drug discontinuation (Levin, 2004).

The second neonatal syndrome is rare and manifested by persistent pulmonary hypertension in the newborn (PPHN). It is characterized by high pulmonary vascular resistance, right-to-left shunting, and profound hypoxemia. Mortality rates are as high as 20 percent, and many survivors have long-term morbidity (Jankov and McNamara, 2005). In a case-control study, Chambers and colleagues (2006) compared 377 women whose infants had pulmonary hypertension with 836 women with unaffected infants. Fetuses exposed to maternal SSRIs after 20 weeks had a sixfold increased risk for pulmonary hypertension. The absolute risk among exposed infants was 6 to 12 per 1000—approximately 1 percent.

The American College of Obstetricians and Gynecologists (2007) has stressed that the potential risks of SSRI use in pregnancy must be considered in the context of the risk of depression relapse if their administration is discontinued. Thus, treatment with these medications during pregnancy should be individualized.

Retinoids

These compounds, especially vitamin A, are essential for normal growth, tissue differentiation, reproduction, and vision (Gudas, 1994). As discussed earlier, retinoids are believed to activate clusters of homeobox genes during embryogenesis (Soprano and Soprano, 1995).

Vitamin A

There are two natural forms of vitamin A. *Beta-carotene* is a precursor of provitamin A. It is found in fruits and vegetables and has never been shown to cause birth defects (Oakley and Erickson, 1995). *Retinol* is preformed vitamin A. Many foods contain vitamin A, but animal liver contains the most. Several reports of prenatal supplementation have associated high doses of vitamin A with congenital anomalies. However, they were clouded by small numbers, unknown daily dose, and absence of any recognizable pattern of observed defects. Two cohort studies have also been inconclusive (Conway, 1958; Rothman and coworkers, 1995). The only prospective study included 423 women who contacted European Teratology Services to report exposure (Mastroiacovo and associates, 1999). These women had ingested from 10,000 to 300,000 IU of vitamin A daily during the first 9 weeks of pregnancy. Only three exposed newborns had birth defects, and there was no relationship between vitamin dose and outcome. It seems reasonable to avoid doses higher than the recommended daily allowance of 5000 IU (American College of Obstetricians and Gynecologists, 1995). Nohynek and colleagues (2006) found that human topical exposure to retinol- or retinyl ester-containing cosmetic creams at 30,000 IU/day did not affect plasma levels of retinol, retinyl esters, or retinoic acids.

Bexarotene

This is a member of a subclass of retinoids used to treat refractory T-cell lymphoma. When given to rats in amounts comparable to human doses, eye and ear abnormalities, cleft palate, and incomplete ossification resulted (Eisai, 2007). This medication is considered contraindicated during pregnancy. Moreover, male patients who have partners who could become pregnant are advised to use condoms during sexual intercourse if they are taking bexarotene and for one month after discontinuing therapy.

Isotretinoin

Some isomers of vitamin A are used primarily for dermatological disorders because they stimulate epithelial cell differentiation (see Chap. 56, p. 1191). *Isotretinoin,* which is 13-*cis*-retinoic acid, is effective for treatment of cystic acne. **Isotretinoin is considered one of the most potent teratogens in common use.** First-trimester exposure is associated with a high rate of fetal loss, and the 26-fold increased malformation rate in survivors is similar to that for thalidomide (Lammer and coworkers, 1985). Abnormalities have been described only with first-trimester use. Because it is rapidly cleared—the mean serum half-life is 12 hours—anomalies are not increased in women who discontinue therapy before conception (Dai and colleagues, 1989).

Malformations typically involve the cranium and face, heart, central nervous system, and thymus. The craniofacial malformation most strongly associated with isotretinoin—microtia or anotia—is bilateral, but often asymmetrical. These defects frequently appear in conjunction with agenesis or stenoses of the external ear canal (Fig. 14-4). Other defects include cleft palate and maldevelopment of the facial bones and cranium. The most frequent cardiac anomalies are conotruncal or outflow tract defects, and hydrocephalus is the most common central nervous system defect. Thymic abnormalities include aplasia, hypoplasia, or malposition.

Dai and colleagues (1992) summarized 433 exposed pregnancies and did not find any safe first-trimester exposure period or dose. Despite the well-publicized hazards associated with prenatal isotretinoin use, as well as efforts by the manufacturer to highlight these reproductive risks, exposures continue to be reported. The FDA-mandated web-based pregnancy risk management system—the iPLEDGE program—requires that all patients, physicians, and pharmacies participate in an attempt to eliminate fetal exposure (www.ipledgeprogram.com).

Etretinate

This orally administered retinoid is used to treat psoriasis. **Etretinate is associated with severe anomalies similar to those with isotretinoin**. One important difference is that anomalies are observed even when conception occurs *after* discontinuation of etretinate. The drug is lipophilic, has a half-life of 120 days, and has been detected in serum almost 3 years after therapy

FIGURE 14-4 Isotretinoin embryopathy. **A**. Bilateral microtia or anotia with stenosis of external ear canal. **B**. Flat, depressed nasal bridge and ocular hypertelorism. (Photograph courtesy of Dr. Edward Lammer.)

(DiGiovanna and colleagues, 1984; Thomson and Cordero, 1989). It is unknown how long the teratogenic effects persist, but Lammer (1988) reported malformations up to 51 weeks after discontinuation! If possible, women who plan future childbearing should not use this drug. If etretinate is used, Geiger and associates (1994) suggest that women wait at least 2 years after concluding treatment before conceiving.

Tretinoin

This is all-*trans*-retinoic acid, and it most often is used as a gel preparation for topical treatment of acne vulgaris. When the gel is used, the skin metabolizes most of the drug with minimal apparent absorption. In two studies totaling 221 neonates born to women who used topical tretinoin during early pregnancy, there were no observed increases in rates of congenital anomalies (Jick and colleagues, 1993; Loureiro and colleagues, 2005). Four cases have been reported in which first-trimester topical use resulted in fetal defects similar to those associated with isotretinoin (Reprotox, 2008b). In all, however, the doses were unknown, and in one case, another medication was concurrently used.

Tretinoin is also available in an oral form for use as antineoplastic therapy for acute promyelocytic leukemia at doses 9000 to 14,000 times greater than those used topically. Like other retinoids, this form is likely to be highly teratogenic, although no affected fetuses have been reported to date (Briggs and colleagues, 2005).

Thalidomide

This anxiolytic and sedative drug is likely the most notorious human teratogen. It produces malformations in approximately 20 percent of fetuses exposed during the specific time window from 34 to 50 days menstrual age. Defects primarily are limited to structures derived from the mesodermal layer, such as limbs, ears, cardiovascular system, and bowel musculature. A wide variety of limb-reduction defects have been associated with thalidomide, with upper limbs usually more severely affected. Bone defects range from abnormal shape or size to total absence of a bone or limb segment—*phocomelia*. Limb-reduction defects may be the result of dysmorphogenesis—seen also with warfarin and phenytoin—or of vascular disruption of a normally formed limb—seen also with misoprostol, chorionic villus sampling, and phenytoin (Holmes, 2002).

Thalidomide was available from 1956 to 1960 before its teratogenicity was discovered. The ensuing disaster was instructive of a number of important teratological principles. First, the placenta had been believed to be a perfect barrier that was impervious to toxic substances unless given in maternally lethal doses (Dally, 1998). Second, the extreme variability in species susceptibility to drugs and chemicals had not yet been appreciated. Thus, because thalidomide produced no defects in experimental mice and rats, it was assumed to be safe for humans. Third, thalidomide demonstrated the close relationship between the timing of exposure and the type of defect (Knapp and co-workers, 1962). For example, upper limb phocomelia developed only after exposure during days 27 to 30—coincidental with appearance of the upper limb buds at day 27. Lower limb phocomelia was associated with exposure during days 30 to 33, gallbladder aplasia at 42 to 43 days, duodenal atresia at 40 to 47 days—and so on for a number of malformations.

Thalidomide was removed from the drug market, but in the past decade a number of immunomodulating uses were discovered (Franks and associates, 2004). It was approved in the United States in 1999 for the treatment of erythema nodosum leprosum (Ances, 2002). It also has been shown effective for the treatment of cutaneous lupus erythematosus, chronic graft-versus-host disease, prurigo nodularis, and certain malignancies (Maurer and co-workers, 2004; Pro and associates, 2004). For obvious reasons, it is recommended that reproductive-aged women taking thalidomide use two highly effective forms of birth control. However, despite ample warnings, thalidomide-affected children continue to be born in countries where the drug is available (Castilla and co-workers, 1996).

Warfarin (Coumadin Derivatives)

These anticoagulants, which include warfarin and dicumarol, are low molecular weight, readily cross the placenta, and can cause significant adverse teratogenic and fetal effects. Ginsberg and Hirsh (1989) reviewed 186 studies involving 1325 exposed pregnancies and reported that 9 percent of exposed fetuses suffered permanent deformity or disability, and 17 percent of these fetuses died. Schaefer and colleagues (2006) compared 666 women exposed to vitamin K antagonists—63 were exposed to

FIGURE 14-5 Warfarin embryopathy or fetal warfarin syndrome: nasal hypoplasia and depressed nasal bridge. (Courtesy of Dr. Mary Jo Harrod.)

warfarin—with 1094 nonexposed controls and found more structural defects and other adverse pregnancy outcomes. The rate of embryopathies, however, was less than 1 percent.

It was concluded that two distinct types of defects result from exposure during two different developmental periods. If exposed between the sixth and ninth weeks, the fetus is at risk for *warfarin embryopathy*. This is characterized by nasal and midface hypoplasia, such as shown in **Figure 14-5**, and stippled vertebral and femoral epiphyses. Importantly, vitamin K-dependent clotting factors are not demonstrable in the embryo, and it is thought that warfarin derivatives exert their teratogenic effect by inhibiting posttranslational carboxylation of coagulation proteins (Hall and associates, 1980). The syndrome is a phenocopy of *chondrodysplasia punctata*, a group of genetic diseases thought to be caused by inherited defects in osteocalcin. There are data that suggest that the risk of warfarin embryopathy is dose dependent. In a study of 43 women with mechanical heart valves treated with warfarin during 58 pregnancies, Vitale and colleagues (1999) found that warfarin embryopathy and fetal wastage developed only when a dose exceeding 5 mg daily was taken throughout the first trimester. In these women, the incidence of embryopathy was 8 percent, and that of spontaneous abortion was 72 percent.

During the second and third trimesters, the defects associated with fetal exposure to warfarin likely result from hemorrhage leading to disharmonic growth and deformation from scarring in any of several organs (Warkany, 1976). Defects may be regionally extensive and include dorsal midline central nervous system dysplasia, such as agenesis of the corpus callosum, Dandy-Walker malformation, and midline cerebellar atrophy; ventral midline dysplasia such as microphthalmia, optic atrophy, and blindness; and developmental delay and mental retardation (Hall and colleagues, 1980).

Herbal Remedies

It is difficult to estimate the risk or safety of various herbal remedies because they are not regulated by the FDA. Thus, the identity and quantity of all ingredients are frequently unknown. Few human or animal studies of their teratogenic potential have been reported, and knowledge of complications has essentially been limited to reports of acute toxicity (Hepner and co-workers, 2002; Sheehan, 1998). In general, because it is not possible to assess the effects of herbal remedies on the developing fetus, pregnant women should be counseled to avoid these substances.

A number of herbal preparations with possible adverse physiological or pharmacological effects are listed in **Table 14-6**. In addition, *Echinacea* causes fragmentation of hamster sperm (Ondrizek and associates, 1999). *Black cohosh,* used to speed labor and treat premenstrual symptoms, contains a chemical that acts similarly to estrogen. *Gingko,* touted as an aid to memory and mental clarity, can interfere with the effects of monoamine oxidase-inhibiting drugs and has anticoagulant properties. Real *licorice* contains *glycyrrhizin,* which has hypertensive and potassium-wasting effects. *Soy* products contain phytoestrogen.

Certain herbal remedies may act as abortifacients. For example, *blue* and *black cohosh* appear to directly stimulate uterine musculature. *Pennyroyal* appears to work by irritating the bladder and uterus and causing strong uterine contractions. The drug also can cause liver damage, renal failure, and disseminated intravascular coagulation and has been associated with several maternal deaths (Black, 1985).

Recreational Drugs

It is estimated that at least 10 percent of fetuses are exposed to one or more illicit drugs (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2007). As discussed on page 317, alcohol is a known significant teratogen, and because it is legally obtained and ubiquitous, its use confounds that of illicit drugs. Other confounding factors include poor maternal health, malnutrition, infectious diseases, and polydrug abuse. Several different drugs may be used at the same time, and the combination may cause a worse outcome than expected with drugs used alone. Furthermore, many illegal substances contain contaminants such as lead, cyanide, cellulose, herbicides, and pesticides. And, substances commonly added as diluents include fine glass beads, powdered sugar, finely ground sawdust, strychnine, arsenic, antihistamines, and even coumadin. Some of these diluents and impurities may independently have serious adverse perinatal effects.

Amphetamines

These sympathomimetic agents can be used as central nervous system stimulants, as anorectics, or as treatment of narcolepsy. Various amphetamines are teratogenic at very high doses in mice (Reprotox, 2008a). But in four cohort studies of 818 women who took amphetamines during early pregnancy, the frequencies of major and minor congenital anomalies were no greater than those for controls (Heinonen and colleagues, 1983; Little and associates, 1988; Milkovich and van den Berg, 1977). *Methamphetamines* are used to treat obesity and narcolepsy in adults and

TABLE 14-6. Possible Adverse Effects of Some Herbal Medicines

Herb and Common Name	Relevant Pharmacological Effects	Perioperative Concerns
Echinacea: *purple coneflower root*	Activation of cell-mediated immunity	Allergic reactions; decreased effectiveness of immunosuppressants; potential for immunosuppression with long-term use
Ephedra: *ma huang*	Tachycardia and hypertension through direct and indirect sympathomimetic effects	Hypertension, arrhythmias with myocardial ischemia and stroke; long-term use depletes endogenous catecholamines; life-threatening interaction with monoamine oxidase inhibitors
Garlic: *ajo*	Inhibition of platelet aggregation; increased fibrinolysis; equivocal antihypertensive activity	Increased risk of bleeding, especially when combined with other medications that inhibit platelet aggregation
Ginger	COX inhibitor	Increased risk of bleeding
Ginseng	Lowers blood glucose; inhibition of platelet aggregation; increased PT and aPTT in animals	Hypoglycemia; increased risk of bleeding; decreased anticoagulation effect of warfarin
Glucosamine and chondroitin		Worsening of diabetes
Kava: *awa, intoxicating pepper, kawa*	Sedation, anxiolysis	Increased sedative effect of anesthetics; effects of tolerance and withdrawal unknown
St. John wort: *amber, goat weed, hardhay, hypericum, klamatheweed*	Inhibition of neurotransmitter reuptake, monoamine oxidase inhibition unlikely	Induction of cytochrome P_{450} affecting cyclosporine, warfarin, steroids, protease inhibitors, and possibly benzodiazepines, calcium-channel blockers, and many other drugs
Valerian: *all heal, garden heliotrope, vandal root*	Sedation	Increased sedative effect of anesthetics; liver damage; benzodiazepine-like acute withdrawal; potential to increase anesthetic requirements with long-term use
Yohimbe		Hypertension, arrhythmias

aPTT = activated partial thromboplastin times; COX = cyclooxygenase; PT = prothrombin time.
From Ang-Lee and colleagues (2001), Briggs and associates (2005), and Consumer Reports on Health (2003).

hyperkinetic children. These drugs often are used to dilute other illicit drugs. Methamphetamine use has been associated with symmetrical fetal-growth restriction but does not appear to increase the frequency of congenital anomalies (Little and colleagues, 1988; Ramin and associates, 1992). Methylamphetamine, known as *speed, ice, crank,* and *crystal meth,* produces defects in mice, rats, and rabbits, but has not been associated with defects in humans. Methylenedioxymethamphetamine (MDMA)—known as *ecstasy*—is in the amphetamine family. In animal studies, it is not teratogenic, and limited data suggest no increased risk of human teratogenicity or fetal toxicity (Briggs and colleagues, 2005).

Cocaine

This alkaloid is derived from the leaves of the South American tree *Erythroxylon coca.* It is a highly effective topical anesthetic and local vasoconstrictor. It is also a central nervous system stimulant through sympathomimetic action via dopamine. It is one of the most widely abused drugs, and the National Survey on Drug Use and Health (2007) reported that it accounted for more than 10 percent of illicit drug use in the United States.

Most of the adverse outcomes associated with cocaine result from its vasoconstrictive and hypertensive effects. The risk of vascular disruption within the embryo, fetus, or placenta is highest *after* the first trimester and likely accounts for the increased incidence of stillbirth with this drug (Hoyme and associates, 1990). A number of cocaine-related congenital anomalies resulting from vascular disruption have been described. These include skull defects, cutis aplasia, porencephaly, subependymal and periventricular cysts, ileal atresia, cardiac anomalies, and visceral infarcts (Cohen and associates, 1994; Little and colleagues, 1989; Stevenson, 1993a). Results from the population-based Atlanta Birth Defects Case-Control Study showed that cocaine use increased the risk fourfold for urinary

tract defects (Chavez and colleagues, 1988). Prune-belly anomaly also has been reported (Bingol and co-workers, 1986; Chasnoff and colleagues, 1985, 1988).

Cocaine has been associated with microcephaly and behavioral abnormalities (Rivkin and associates, 2008). There are, however, few prospective studies of its effect on psychomotor development. Singer and colleagues (2002) reported a prospective study of 218 cocaine-exposed infants and 197 unexposed controls. At age 2 years, compared with control infants, the cocaine-exposed infants had significantly more cognitive defects and twice the rate of developmental delay. Cognitive impairments persisted at age 4 years (Singer and associates, 2004).

Not all studies, however, support the concept of cocaine as a major teratogen. Reports of cocaine-induced limb-reduction defects have been disputed (Hume and co-workers, 1997). One prospective longitudinal cohort study of 272 offspring of crack-cocaine users found no increase in the number or pattern of birth defects (Behnke and co-workers, 2001). Because few reports address dosage or total fetal exposure during pregnancy, it is difficult to estimate the ultimate fetal risk associated with antenatal cocaine use.

Opiates (Narcotics)

Heroin. In most studies, the frequency of congenital anomalies is not higher with heroin use (Little and associates, 1990b). In one cohort study of 830 exposed neonates, the frequency of anomalies was 2.4 percent, similar to the background risk (Ostrea and Chavez, 1979). Other types of morbidity, such as fetal-growth restriction, perinatal death, and several perinatal complications, are common in the offspring of narcotic-addicted mothers (Lifschitz and colleagues, 1983; Little and co-workers, 1990b). It is not clear whether these complications are due to fetal heroin exposure or to generally poor maternal health. Postnatal growth of these children appears to be normal in most cases, although the average head circumference is smaller than that of unexposed children. There also may be mild developmental delay or behavioral disturbances (Chasnoff and colleagues, 1986; Lifschitz and co-workers, 1983).

Withdrawal symptoms such as tremors, irritability, sneezing, vomiting, fever, diarrhea, and occasionally seizures are observed in 40 to 80 percent of newborns born to heroin-addicted women (Alroomi and colleagues, 1988). Although these symptoms may be prolonged, they usually persist for fewer than 10 days. Logically, higher doses of maternal methadone are associated with longer required lengths of neonatal abstinence syndrome treatment (Lim and co-workers, 2009). Abnormal respiratory function during sleep often persists and may be a factor in the increased incidence of sudden infant death syndrome in exposed newborns (Kandall and associates, 1993).

Methadone. This *synthetic* opioid narcotic structurally resembles propoxyphene and is used primarily as maintenance therapy for narcotic addiction. Although large doses are teratogenic in rodents, congenital anomalies were not increased above background in cohort studies and clinical series of neonates born to women on methadone maintenance therapy (Stimmel and Adamsons, 1976). Withdrawal symptoms, however, are frequent, and birthweights are often lower than expected (Briggs and colleagues, 2005). Chasnoff and co-workers (1987) compared 52 cocaine-using pregnant women with 73 former heroin addicts maintained on methadone. They found a significantly higher rate of preterm labor, rapid labor, placental abruption, and meconium staining among cocaine users. Withdrawal from methadone is more severe than from heroin and more protracted—up to 3 weeks—due to the much longer half-life of methadone. That said, the best maintenance agonist for pregnant women has not been found (Minozzi and associates, 2008).

Marijuana

Also known as *hashish,* in earlier studies, marijuana was used by nearly 15 percent of pregnant women (Abel and Sokol, 1988; Chasnoff and colleagues, 1990). The active ingredient is *delta-9-tetrahydrocannabinol (THC),* which in high doses is teratogenic for animals. There is no evidence, however, that marijuana is associated with human anomalies. The birthweight of exposed fetuses has been reported to be lower in some studies but not others (Greenland, 1983; Linn, 1983; Shiono, 1995, and all their colleagues).

Miscellaneous Drugs

Phencyclidine (PCP), known as *angel dust,* is not associated with congenital anomalies. Neonatal withdrawal, characterized by tremors, jitteriness, and irritability, is observed in more than half of exposed newborns. Golden and colleagues (1987) reported that the incidence of structural malformations was not increased in 94 phencyclidine-exposed infants, but confirmed an increased incidence of newborn behavioral and developmental abnormalities. "*T's and blues"* is a street mixture of the narcotic analgesic *pentazocine (Talwin)* and the over-the-counter antihistamine *tripelennamine (Pyribenzamine).* It has not been associated with an increased incidence of congenital anomalies (Little and co-workers, 1990a; von Almen and Miller, 1984).

Classically known as *lysergic acid diethylamide (LSD),* these are amine alkaloids obtained only through chemical synthesis. There is no evidence that this drug is a human teratogen. Some investigators have found increased frequencies of chromosomal breakage in somatic cells of mothers who used lysergic acid as well as in their prenatally exposed newborns. However, such breakage does not appear to correlate with an increased risk for congenital anomalies.

Toluene is present in paints and glue and when intentionally inhaled, can produce lightheadedness, dizziness, and loss of consciousness. Prenatal abuse is associated with *toluene embryopathy.* The phenotype has been compared with fetal alcohol syndrome and includes pre- and postnatal growth deficiency, microcephaly, and characteristic facial and hand findings—midface hypoplasia, short palpebral fissures, wide nasal bridge, and abnormal palmar creases (Pearson and colleagues, 1994). Developmental delays have been reported in approximately 40 percent of exposed children (Arnold and colleagues, 1994). Fortunately, the maximum occupational exposure is estimated to be only a fraction of that experienced by abusers and is not expected to cause significant fetal risk (Wilkins-Haug, 1997).

Tobacco

Cigarette smoke contains a complex mixture of substances including nicotine, cotinine, cyanide, thiocyanate, carbon monoxide, cadmium, lead, and various hydrocarbons (Stillerman and colleagues, 2008). In addition to being fetotoxic, many of these substances have vasoactive effects or reduce oxygen levels. The best-documented reproductive outcome related to smoking is a direct dose-response reduction in fetal growth. Newborns of mothers who smoke weigh an average of 200 g less than those of nonsmokers, and heavy smoking results in more severe weight reduction (D'Souza and associates, 1981). Smoking doubles the risk of low birthweight and increases the risk of fetal-growth restriction two- to threefold (Werler, 1997). Mercer and colleagues (2008) have shown that this disparity can be detected sonographically between 10 and 20 weeks. Women who stop smoking early in pregnancy generally have neonates with normal birthweights (Cliver and co-workers, 1995). Smoking also may cause a slightly increased incidence of subfertility, spontaneous abortion, placenta previa and abruption, and preterm delivery. These effects are discussed in more detail in Chapters 35 (p. 761), 36 (p. 811), and 38 (p. 848).

It is plausible that the vasoactive properties of tobacco smoke could produce congenital defects related to vascular disturbances. Martinez-Frias and colleagues (1999) observed in smokers a twofold risk of *Poland sequence*, which is caused by an interruption in the vascular supply to one side of the fetal chest and ipsilateral arm. Smoking was found associated with an increased risk for congenital heart disease in a dose-related manner (Malik and co-workers, 2008). Smoking at least 20 cigarettes a day combined with the use of vasoconstrictive drugs such as amphetamines and decongestants also appears to result in a fourfold risk of gastroschisis and small intestinal atresia (Werler and associates, 2003).

Smoking has been associated with cleft lip and palate in individuals heterozygous or homozygous for an uncommon polymorphism in the transforming growth factor gene (Shaw and colleagues, 1996). When exposed prenatally to cigarette smoke, these individuals have twice the risk of combined cleft lip and palate, and four to seven times the risk for cleft palate alone (Hwang and associates, 1995; Shaw and co-workers, 1996). A study that used the National Vital Statistics System natality data from more than 6 million live births in the United States found an association between maternal smoking and hydrocephaly, microcephaly, omphalocele, gastroschisis, cleft lip and palate, and hand abnormalities (Honein and colleagues, 2001).

Antepartum Assessment

FETAL MOVEMENTS 334
FETAL BREATHING 336
CONTRACTION STRESS TESTING 337
NONSTRESS TESTS 337
ACOUSTIC STIMULATION TESTS 340
BIOPHYSICAL PROFILE 341
AMNIONIC FLUID VOLUME 342
DOPPLER VELOCIMETRY 343
CURRENT ANTENATAL TESTING RECOMMENDATIONS 345

According to the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics (2007), the goals of antepartum fetal surveillance include prevention of fetal death and avoidance of unnecessary interventions. Current techniques employed to forecast fetal well-being focus on fetal physical activities, including heart rate, movement, breathing, and amnionic fluid production. In most cases, a negative, that is, normal test result is highly reassuring, because fetal deaths within 1 week of a normal test are rare. Indeed, negative-predictive values—a true negative test—for most of the tests described are 99.8 percent or higher. In contrast, estimates of the positive-predictive values—a true positive test—for abnormal test results are low and range between 10 and 40 percent. Importantly, the widespread use of antepartum fetal surveillance is primarily based on circumstantial evidence because there have been no definitive randomized clinical trials.

FETAL MOVEMENTS

Passive unstimulated fetal activity commences as early as 7 weeks and becomes more sophisticated and coordinated by the end of pregnancy (Vindla and James, 1995). Indeed, beyond 8 menstrual weeks, fetal body movements are never absent for periods exceeding 13 minutes (DeVries and co-workers, 1985). Between 20 and 30 weeks, general body movements become organized, and the fetus starts to show rest-activity cycles (Sorokin and co-workers, 1982). In the third trimester, fetal movement maturation continues until approximately 36 weeks, when behavioral states are established in most normal fetuses. Nijhuis and colleagues (1982) studied fetal heart rate patterns, general body movements, and eye movements and described four fetal behavioral states:

- **State 1F** is a quiescent state—quiet sleep—with a narrow oscillatory bandwidth of the fetal heart rate
- **State 2F** includes frequent gross body movements, continuous eye movements, and wider oscillation of the fetal heart rate. This state is analogous to rapid eye movement (REM) or active sleep in the neonate
- **State 3F** includes continuous eye movements in the absence of body movements and no heart rate accelerations. The existence of this state is disputed (Pillai and James, 1990a)
- **State 4F** is one of vigorous body movement with continuous eye movements and heart rate accelerations. This state corresponds to the awake state in infants.

Fetuses spend most of their time in states 1F and 2F. For example, at 38 weeks, 75 percent of time is spent in these two states (Nijhuis and colleagues, 1982).

These behavioral states—particularly 1F and 2F, which correspond to quiet sleep and active sleep—have been used to develop an increasingly sophisticated understanding of fetal behavior. Oosterhof and co-workers (1993) studied fetal urine

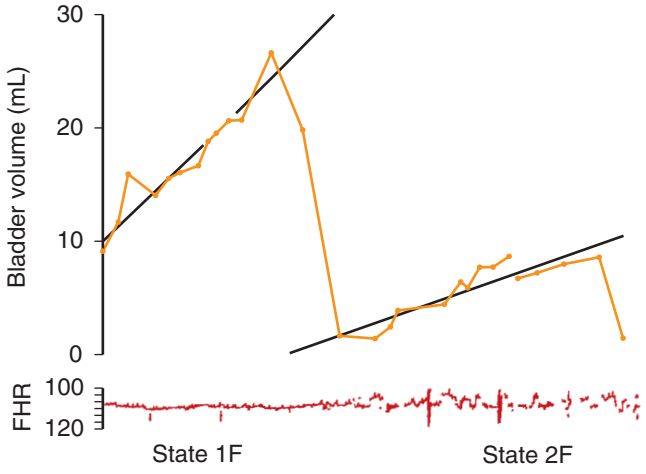

FIGURE 15-1 Fetal bladder volume measurements together with fetal heart rate variation record in relation to 1F or 2F behavior states. State 1F fetal heart rate has a narrow bandwidth consistent with quiet sleep. State 2F heart rate shows wide oscillation of the baseline consistent with active sleep. (Modified from Oosterhof and co-workers, 1993, with permission.)

production in normal pregnancies in states 1F or 2F. As shown in **Figure 15-1**, bladder volumes increased during state 1F quiet sleep. During state 2F, the fetal heart rate baseline bandwidth increased appreciably, and bladder volume was significantly diminished. The latter was due to fetal voiding as well as decreased urine production. These phenomena were interpreted to represent reduced renal blood flow during active sleep.

An important determinant of fetal activity appears to be sleep-awake cycles, which are independent of the maternal sleep-awake state. *Sleep cyclicity* has been described as varying from about 20 minutes to as much as 75 minutes. Timor-Tritsch and associates (1978) reported that the mean length of the quiet or inactive state for term fetuses was 23 minutes. Patrick and associates (1982) measured gross fetal body movements with real-time sonography for 24-hour periods in 31 normal pregnancies and found the longest period of inactivity to be 75 minutes. Amnionic fluid volume is another important determinant of fetal activity. Sherer and colleagues (1996) assessed the number of fetal movements in 465 pregnancies during biophysical profile testing in relation to amnionic fluid volume estimated using sonography. They observed decreased fetal activity with diminished amnionic volumes and suggested that a restricted uterine space might physically limit fetal movements.

Sadovsky and colleagues (1979b) studied fetal movements in 120 normal pregnancies and classified the movements into three categories according to both maternal perceptions and independent recordings using piezoelectric sensors. Weak, strong, and rolling movements were described, and their relative contributions to total weekly movements throughout the last half of pregnancy were quantified. As pregnancy advances, weak movements decrease and are superseded by more vigorous movements, which increase for several weeks and then subside at term. Presumably, declining amnionic fluid and space account for diminishing activity at term. **Figure 15-2** shows fetal movements during the last half of gestation in 127 pregnancies with normal outcomes. The mean number of weekly movements calculated from 12-hour daily recording periods increased from approximately 200 at 20 weeks to a maximum of 575 movements at 32 weeks. Fetal movements then declined to an average of 282 at 40 weeks. Normal weekly maternal counts of fetal movements ranged between 50 and 950, with large daily variations that included counts as low as 4 to 10 per 12-hour period in normal pregnancies.

Clinical Application

In 1973, Sadovsky and Yaffe described seven case reports of pregnancies with decreased fetal activity that preceded fetal death. Since then, various methods have been described to quantify fetal movement as a way of prognosticating well-being. Methods include use of a tocodynamometer, visualization with sonography, and maternal subjective perceptions. Most investigators have reported excellent correlation between maternally perceived fetal motion and movements documented by instrumentation. For example, Rayburn (1980) found that 80 percent of all movements observed during sonographic monitoring were perceived by the mother. In contrast, Johnson and colleagues (1992) reported that beyond 36 weeks, mothers perceived only 16 percent of fetal body movements recorded by a Doppler device. Fetal motions lasting more than 20 seconds were identified more accurately by the mother than shorter episodes.

Although several fetal movement counting protocols have been used, neither the optimal number of movements nor the

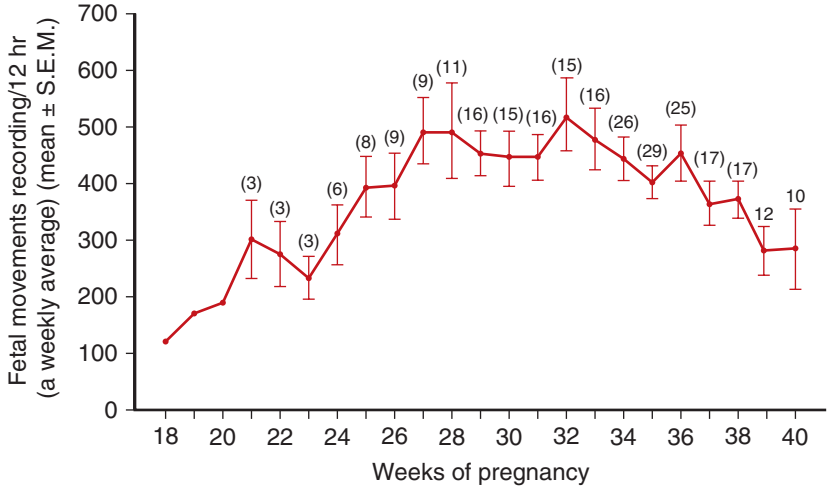

FIGURE 15-2 Graph depicts averages of fetal movements counted during 12-hour periods (mean ± SEM). (From Sadovsky and associates, 1979a, with permission.)

ideal duration for counting them has been defined. For example, in one method, perception of 10 fetal movements in up to 2 hours is considered normal (Moore and Piaquadio, 1989). In another, women are instructed to count fetal movements for 1 hour a day, and the count is accepted as reassuring if it equals or exceeds a previously established baseline count (Neldam, 1983). The American College of Obstetricians and Gynecologists (2002) suggests that one approach to assessing fetal movement is to have the woman count distinct fetal movements on a daily basis after 28 weeks' gestation. The perception of 10 distinct movements in up to 2 hours is considered reassuring. The counting can be discontinued for that day after 10 movements.

Commonly, women may present in the third trimester complaining of subjectively reduced fetal movement. Harrington and colleagues (1998) reported that 7 percent of 6793 women delivered at a London hospital presented with a complaint of decreased fetal movement. Fetal heart rate monitoring tests were employed if sonographic scans for fetal growth or Doppler velocimetry were abnormal. The pregnancy outcomes for women who complained of decreased fetal movement were not significantly different from those for women without this complaint. Nonetheless, the authors recommended evaluation to reassure the mother.

Grant and co-workers (1989) performed an unparalleled investigation of maternally perceived fetal movements and pregnancy outcome. More than 68,000 pregnancies were randomly assigned between 28 and 32 weeks. Women in the fetal movement arm of the study were instructed by specially employed midwives to record the time needed to feel 10 movements each day. This required an average of 2.7 hours each day. Women in the control group were informally asked about movements during prenatal visits. Reports of decreased fetal motion were evaluated with tests of fetal well-being. Antepartum death rates for normally formed singletons were similar in the two study groups regardless of prior risk status. Despite the counting policy, most stillborn fetuses were dead by the time the mothers reported for medical attention. Importantly, these investigators did not conclude that maternal perceptions of fetal activity were meaningless. Conversely, they concluded that informal maternal perceptions were as valuable as formally counted and recorded fetal movement.

FETAL BREATHING

After decades of uncertainty as to whether the fetus normally breathes, Dawes and co-workers (1972) showed small inward and outward flows of tracheal fluid, indicating fetal thoracic movement in sheep. These chest wall movements differed from those following birth in that they were discontinuous. Another interesting feature of fetal respiration was *paradoxical chest wall movement.* As shown in **Figure 15-3**, during inspiration the chest wall paradoxically collapses and the abdomen protrudes (Johnson and co-workers, 1988). In the newborn or adult, the opposite occurs. One interpretation of the paradoxical respiratory motion might be coughing to clear amnionic fluid debris. Although the physiological basis for the breathing reflex is not completely understood, such exchange of amnionic fluid appears to be essential for normal lung development.

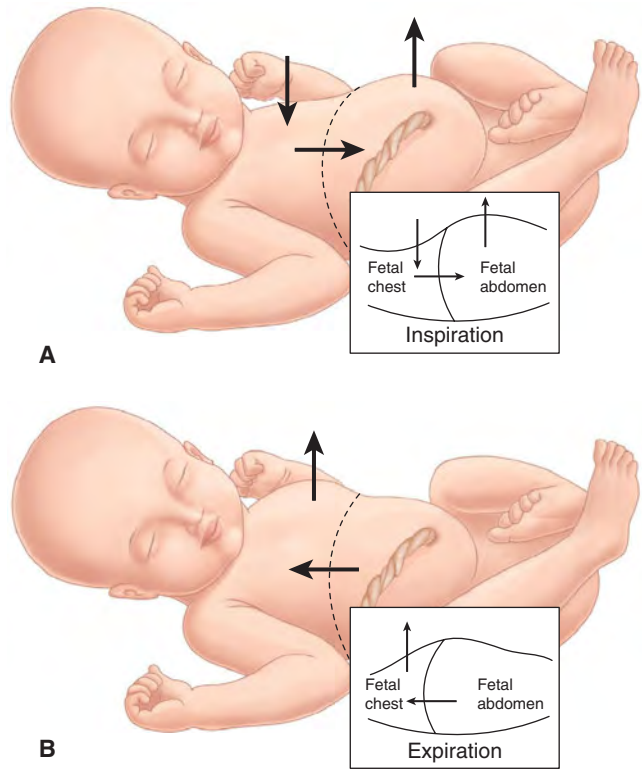

FIGURE 15-3 Paradoxical chest movement with fetal respiration. (Adapted from Johnson and co-workers, 1988.)

Dawes (1974) identified two types of respiratory movements. The first are *gasps or sighs,* which occurred at a frequency of 1 to 4 per minute. The second, *irregular bursts of breathing,* occurred at rates up to 240 cycles per minute. These latter rapid respiratory movements were associated with REM. Badalian and co-workers (1993) studied the maturation of normal fetal breathing using color flow and spectral Doppler analysis of nasal fluid flow as an index of lung function. They suggested that fetal respiratory rate decreased in conjunction with increased respiratory volume at 33 to 36 weeks and coincidental with lung maturation.

Many investigators have examined fetal breathing movements, using sonography to determine whether monitoring chest wall movements might be of benefit to evaluate fetal health. Several variables in addition to hypoxia were found to affect fetal respiratory movements. These included labor—during which it is normal for respiration to cease—hypoglycemia, sound stimuli, cigarette smoking, amniocentesis, impending preterm labor, gestational age, and the fetal heart rate itself.

Because fetal breathing movements are episodic, interpretation of fetal health when respirations are absent may be tenuous. Patrick and associates (1980) performed continuous 24-hour observation periods using sonography in an effort to characterize fetal breathing patterns during the last 10 weeks of pregnancy. A total of 1224 hours of fetal observation was completed in 51 pregnancies. **Figure 15-4** shows the percentage of time spent breathing near term. Clearly, there is diurnal variation, because breathing substantively diminishes during the night. In addition, breathing activity increases somewhat following maternal meals. Total absence of breathing was observed

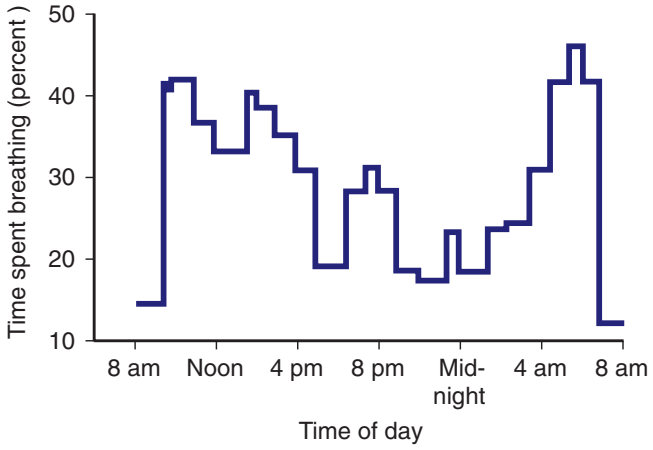

FIGURE 15-4 The percentage of time spent breathing by 11 fetuses at 38 to 39 weeks demonstrated a significant increase in fetal breathing activity after breakfast. Breathing activity diminished during the day and reached its minimum between 8 pm and midnight hours. There was a significant increase in the percentage of time spent breathing between 4 and 7 am, when mothers were asleep. (Adapted from Patrick and co-workers, 1980.)

in some of these normal fetuses for up to 122 minutes, indicating that fetal evaluation to diagnose absent respiratory motion may require long periods of observation.

The potential for breathing activity to be an important marker of fetal health is unfulfilled because of the multiplicity of factors that normally affect breathing. Most clinical applications have included assessment of other fetal biophysical indices, such as heart rate. As will be discussed, fetal breathing has become a component of the *biophysical profile.*

CONTRACTION STRESS TESTING

As amnionic fluid pressure increases with uterine contractions, myometrial pressure exceeds collapsing pressure for vessels coursing through uterine muscle, ultimately decreasing blood flow to the intervillous space. Brief periods of impaired oxygen exchange result, and if uteroplacental pathology is present, these elicit late fetal heart rate decelerations (see Chap. 18, p. 421). Contractions also may produce a pattern of variable decelerations as a result of cord compression, suggesting oligohydramnios, which is often a concomitant of placental insufficiency.

Ray and colleagues (1972) used this concept in 66 complicated pregnancies and developed what they termed the *oxytocin challenge test* and later called the *contraction stress test.* Contractions were induced using intravenous oxytocin, and the fetal heart rate response was recorded using standard monitoring. The criterion for a positive (abnormal) test was uniform repetitive late fetal heart rate decelerations. These reflected the uterine contraction waveform and had an onset at or beyond the acme of a contraction. Such late decelerations could be the result of uteroplacental insufficiency. The tests were generally repeated on a weekly basis, and the investigators concluded that negative (normal) contraction stress tests forecast fetal health. One disadvantage cited was that the average contraction stress test required 90 minutes to complete.

TABLE 15-1. Criteria for Interpretation of the Contraction Stress Test

- Negative: no late or significant variable decelerations
- Positive: late decelerations following 50% or more of contractions (even if the contraction frequency is fewer than three in 10 minutes)
- Equivocal-suspicious: intermittent late decelerations or significant variable decelerations
- Equivocal-hyperstimulatory: fetal heart rate decelerations that occur in the presence of contractions more frequent than every 2 minutes or lasting longer than 90 seconds
- Unsatisfactory: fewer than three contractions in 10 minutes or an uninterpretable tracing

Reprinted, with permission, from the American College of Obstetricians and Gynecologists. Antepartum fetal surveillance. ACOG Practice Bulletin 9. Washington, DC: ACOG; 2007.

Fetal heart rate and uterine contractions are recorded simultaneously with an external monitor. If at least three spontaneous contractions of 40 seconds or longer are present in 10 minutes, no uterine stimulation is necessary (American College of Obstetricians and Gynecologists, 2007). Contractions are induced with either oxytocin or nipple stimulation if there are fewer than three in 10 minutes. If oxytocin is preferred, a dilute intravenous infusion is initiated at a rate of 0.5 mU/min and doubled every 20 minutes until a satisfactory contraction pattern is established (Freeman, 1975). The results of the contraction stress test are interpreted according to the criteria shown in Table 15-1.

Nipple stimulation to induce uterine contractions is usually successful for contraction stress testing (Huddleston and associates, 1984). One method recommended by the American College of Obstetricians and Gynecologists (2007) involves a woman rubbing one nipple through her clothing for 2 minutes or until a contraction begins. She is instructed to restart after 5 minutes if the first nipple stimulation did not induce three contractions in 10 minutes. Advantages include reduced cost and shortened testing times. Although Schellpfeffer and associates (1985) reported unpredictable uterine hyperstimulation and fetal distress, others did not find excessive activity to be harmful (Frager and Miyazaki, 1987).

NONSTRESS TESTS

Freeman (1975) and Lee and colleagues (1975) introduced the *nonstress test* to describe fetal heart rate acceleration in response to fetal movement as a sign of fetal health. This test involved the use of Doppler-detected fetal heart rate acceleration coincident with fetal movements perceived by the mother. By the end of the 1970s, the nonstress test had become the primary method of testing fetal health. The nonstress test was easier to perform,

and normal results were used to further discriminate false-positive contraction stress tests. Simplistically, the nonstress test is primarily a test of *fetal condition,* and it differs from the contraction stress test, which is a test of *uteroplacental function.* Currently, nonstress testing is the most widely used primary testing method for assessment of fetal well-being and has also been incorporated into the biophysical profile testing system subsequently discussed.

Fetal Heart Rate Acceleration

The fetal heart rate normally is increased or decreased by autonomic influences mediated by sympathetic or parasympathetic impulses from brainstem centers. Beat-to-beat variability is also under the control of the autonomic nervous system (Matsuura and colleagues, 1996). Consequently, pathological loss of acceleration may be seen in conjunction with significantly decreased beat-to-beat variability of the fetal heart rate (see Chap. 18, p. 414). Loss of such reactivity, however, is most commonly associated with sleep cycles, discussed earlier. It also may be caused by central depression from medications or maternal cigarette smoking (Jansson and co-workers, 2005; Oncken and colleagues, 2002).

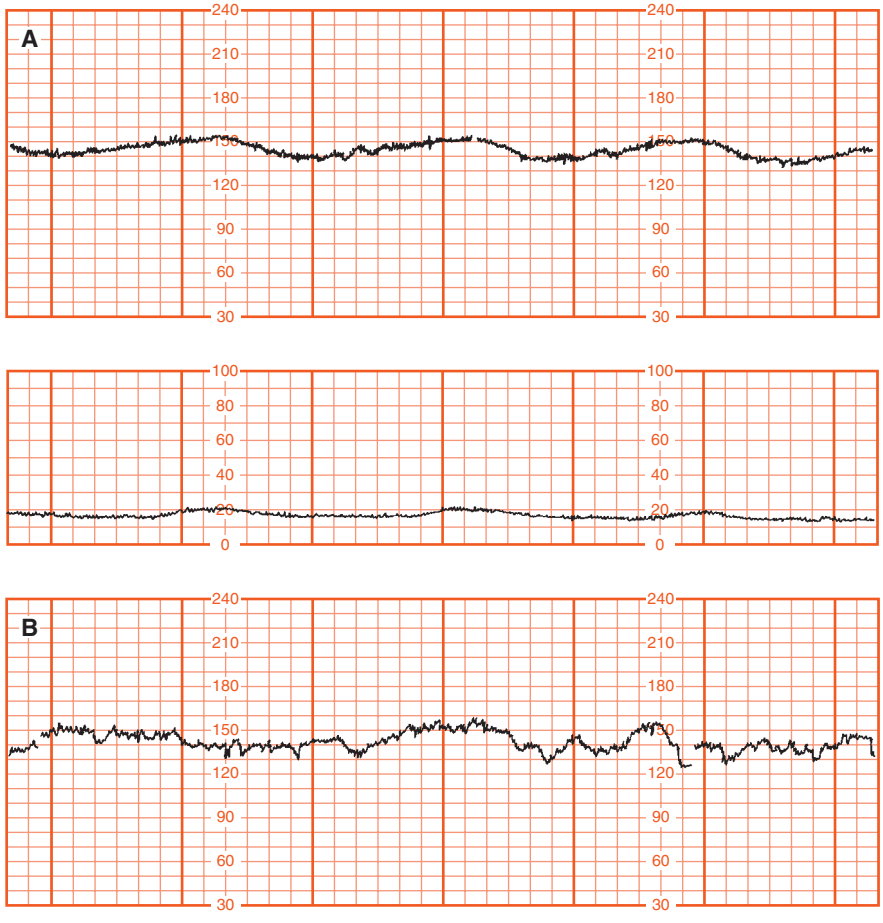

FIGURE 15-5 Two antepartum fetal heart rate (FHR) tracings in a 28-week pregnant woman with diabetic ketoacidosis. **A.** FHR tracing (*upper panel*) and accompanying contraction tracing (*second panel*). Tracing, obtained during maternal and fetal acidemia shows absence of accelerations, diminished variability, and late decelerations with weak spontaneous contractions. **B.** FHR tracing shows return of normal accelerations and variability of the fetal heart rate following correction of maternal acidemia.

The nonstress test is based on the hypothesis that the heart rate of a fetus who is not acidotic as a result of hypoxia or neurological depression will temporarily accelerate in response to fetal movement (Fig. 15-5). Fetal movements during testing are identified by maternal perception and recorded. Similarly, Smith and colleagues (1988) observed a decrease in the number of accelerations in preterm fetuses subsequently found to have lower umbilical artery blood P_{O_2} values.

Gestational age influences acceleration or reactivity of fetal heart rate. Pillai and James (1990b) studied the development of fetal heart rate acceleration patterns during normal pregnancy. The percentage of body movements accompanied by acceleration and the amplitude of these accelerations increased with gestational age (Fig. 15-6). Guinn and colleagues (1998) studied nonstress test results between 25 and 28 weeks in 188 pregnancies that ultimately had normal outcomes. Only 70 percent of these normal fetuses demonstrated the required 15 beats per minute (bpm) or more of heart rate acceleration. Lesser degrees of acceleration, that is, 10 bpm, occurred in 90 percent of the fetuses.

The National Institute of Child Health and Human Development Fetal Monitoring Workshop (1997) has defined normal acceleration based on gestational age. The acme of acceleration is 15 bpm or more above the baseline rate, and the acceleration lasts 15 seconds or longer but less than 2 minutes in fetuses at or beyond 32 weeks. Before 32 weeks, accelerations are defined as having an acme 10 bpm or more above baseline for 10 seconds or longer.

Normal Nonstress Tests

There have been many different definitions of normal nonstress test results. They vary as to the number, amplitude, and duration of acceleration, as well as the test duration. The definition currently recommended by the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics (2007) is two or more accelerations that peak at 15 bpm or more above baseline, each lasting 15 seconds or more, and all occurring within 20 minutes of beginning the test (Fig. 15-7). It was also recommended that accelerations with or without fetal movements be accepted, and that a 40-minute or longer tracing—to account for fetal sleep cycles—should be performed before concluding that there was insufficient fetal reactivity. Miller and colleagues (1996b) reviewed outcomes in fetuses with nonstress tests considered as nonreactive because there was only one acceleration. They concluded that one acceleration was just as reliable as two in predicting healthy fetal status.

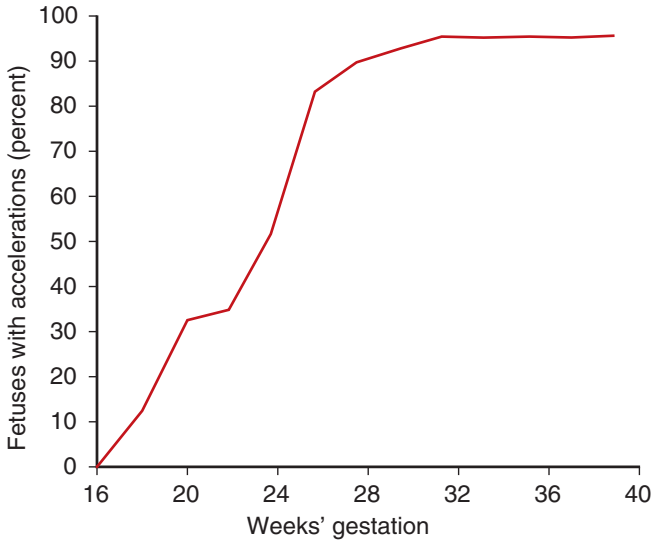

FIGURE 15-6 Percentage of fetuses with at least one acceleration of 15 beats/min sustained for 15 sec concurrent with fetal movement. (Adapted from Pillai and James, 1990b.)

Although a normal number and amplitude of accelerations seems to reflect fetal well-being, "insufficient acceleration" does not invariably predict fetal compromise. Indeed, some investigators have reported 90-percent or higher false-positive rates (Devoe and associates, 1986). Because healthy fetuses may not move for periods of up to 75 minutes, Brown and Patrick (1981) considered that a longer duration of nonstress testing might increase the positive-predictive value of an abnormal, that is, nonreactive, test. They concluded that either the test became reactive during a period up to 80 minutes or the test remained nonreactive for 120 minutes, indicating that the fetus was very ill.

Not only are there many different definitions of normal nonstress test results, but the reproducibility of interpretations is problematic. For example, Hage (1985) mailed five nonstress tests, blinded to specific patient clinical data, to a national sample of obstetricians for their interpretations. He concluded that although nonstress testing is popular, the reliability of test interpretation needs improvement. Such problems with subjective interpretation have prompted efforts to computerize analysis of nonstress tests. Pardey and colleagues (2002) have developed such a system—*Sonicaid Fetal Care.* Turan and colleagues (2007) evaluated the *Oxford Sonicaid 8002 cCTG* system in 58 growth-restricted fetuses and compared findings with those obtained by multiple other tests. They concluded that the computerized system performed best when used with umbilical venous Doppler findings or as a substitute for the traditional nonstress test in the biophysical profile score.

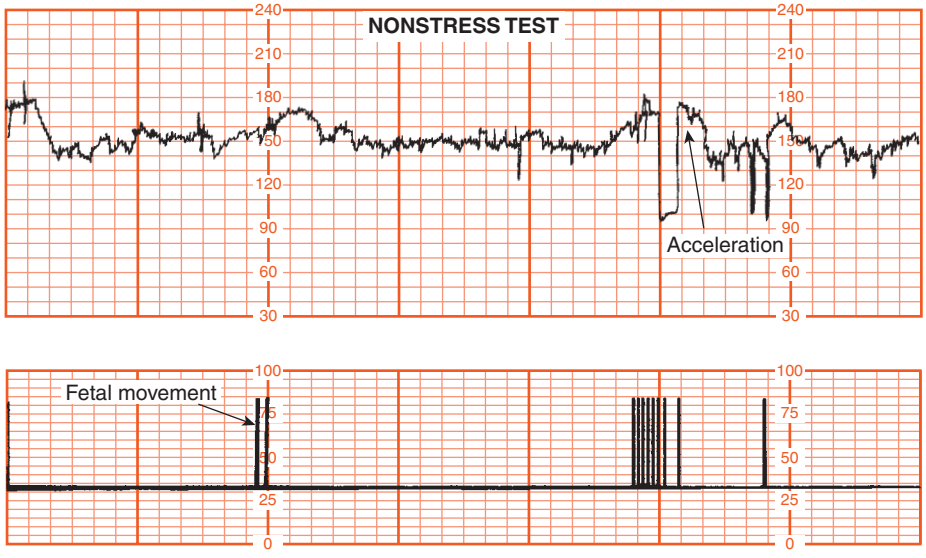

FIGURE 15-7 Reactive nonstress test. In the upper panel, notice increase of fetal heart rate to more than 15 beats/min for longer than 15 sec following fetal movements, indicated by the vertical marks (*lower panel*).

Abnormal Nonstress Tests

There are abnormal nonstress test patterns that reliably forecast severe fetal jeopardy. Hammacher and co-workers (1968) described tracings with what they termed a *silent oscillatory pattern.* This pattern consisted of a fetal heart rate baseline that oscillated less than 5 bpm and presumably indicated absent acceleration and beat-to-beat variability. Hammacher considered this pattern ominous.

Visser and associates (1980) described a "terminal cardiotocogram," which included: (1) baseline oscillation of less than 5 bpm, (2) absent accelerations, and (3) late decelerations with spontaneous uterine contractions. These results were similar to experiences from Parkland Hospital in which absence of accelerations during an 80-minute recording period in 27 fetuses was associated consistently with evidence of uteroplacental pathology (Leveno and associates, 1983). The latter included fetal-growth restriction in 75 percent, oligohydramnios in 80 percent, fetal acidosis in 40 percent, meconium in 30 percent, and placental infarction in 93 percent. Thus, the lack of fetal heart rate acceleration, when not due to maternal sedation, is an ominous finding (Fig. 15-8). Similarly, Devoe and coworkers (1985) concluded that nonstress tests that were nonreactive for 90 minutes were almost invariably—93 percent—associated with significant perinatal pathology.

Interval between Testing

The interval between tests, originally rather arbitrarily set at 7 days, appears to have been shortened as experience evolved with nonstress testing. According to the American College of Obstetricians and Gynecologists (2007), more frequent testing is advocated by some investigators for women with postterm pregnancy, multifetal gestation, type 1 diabetes mellitus, fetal-growth restriction, or gestational hypertension (Devoe, 2008; Freeman, 2008; Graves, 2007; Kennelly and Sturgiss, 2007). In these circumstances, some investigators perform twice-weekly tests, with additional testing performed

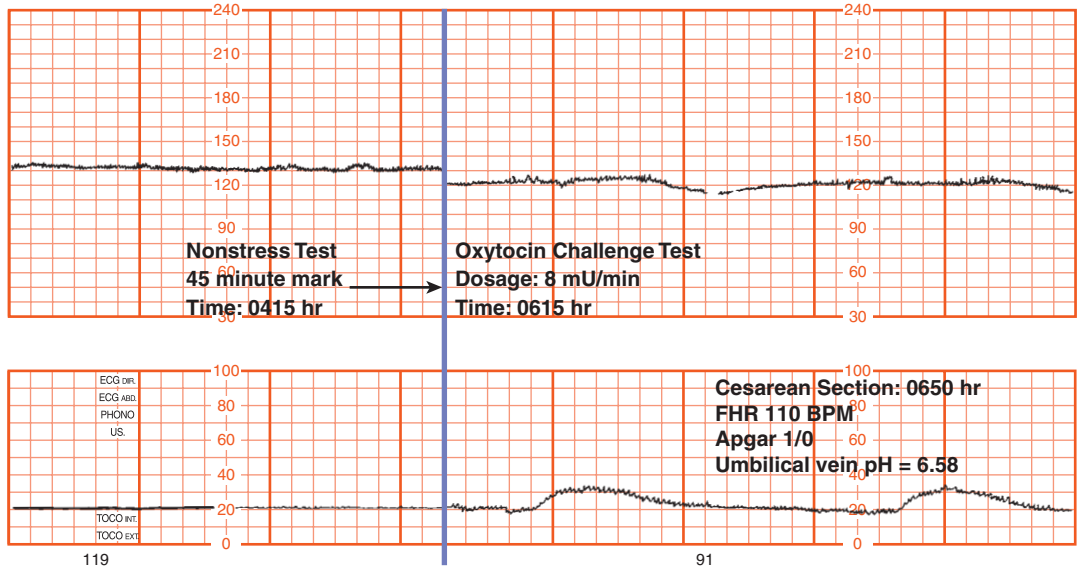

FIGURE 15-8 Nonreactive nonstress test (*left side of tracing*) followed by contraction stress test showing mild, late decelerations (*right side of tracing*). Cesarean delivery was performed, and the severely acidemic fetus could not be resuscitated.

for maternal or fetal deterioration regardless of the time elapsed since the last test. Others perform nonstress tests daily or even more frequently, for example, with severe preeclampsia remote from term (see Chap. 34, p. 728).

Decelerations During Nonstress Testing

Fetal movements commonly produce heart rate decelerations. Timor-Tritsch and associates (1978) reported this during nonstress testing in half to two thirds of tracings, depending on the vigor of the fetal motion. This high incidence of decelerations inevitably makes interpretation of their significance problematic. Indeed, Meis and co-workers (1986) reported that variable fetal heart rate decelerations during nonstress tests were not a sign of fetal compromise. The American College of Obstetricians and Gynecologists (2007) has concluded that variable decelerations, if nonrepetitive and brief—less than 30 seconds—do not indicate fetal compromise or the need for obstetrical intervention. In contrast, repetitive variable decelerations—at least three in 20 minutes—even if mild, have been associated with an increased risk of cesarean delivery for fetal distress. Decelerations lasting 1 minute or longer have been reported to have an even worse prognosis (Bourgeois, 1984; Druzin, 1981; Pazos, 1982, and all their coworkers).

Hoskins and associates (1991) attempted to refine interpretation of testing that shows variable decelerations by adding sonographic estimation of amnionic fluid volume. The incidence of cesarean delivery for intrapartum fetal distress progressively increased concurrently with the severity of variable decelerations and decline of amnionic fluid volume. Severe variable decelerations during a nonstress test plus an amnionic fluid index of $\leq$ 5 cm resulted in a 75-percent cesarean delivery rate. Fetal distress in labor, however, also frequently developed in those pregnancies with variable decelerations but with normal amounts of amnionic fluid. Similar results were reported by Grubb and Paul (1992).

False-Normal Nonstress Tests

Smith and associates (1987) performed a detailed analysis of the causes of fetal death within 7 days of normal nonstress tests. The most common indication for testing was postterm pregnancy. The mean interval between testing and death was 4 days, with a range of 1 to 7 days. The single most common autopsy finding was meconium aspiration, often associated with some type of umbilical cord abnormality. They concluded that an acute asphyxial insult had provoked fetal gasping. They also concluded that nonstress testing was inadequate to preclude such an acute asphyxial event and that other biophysical characteristics might be beneficial. For example, assessment of amnionic fluid volume was considered valuable. Other ascribed frequent causes of fetal death included intrauterine infection, abnormal cord position, malformations, and placental abruption.

ACOUSTIC STIMULATION TESTS

Loud external sounds have been used to startle the fetus and thereby provoke heart rate acceleration—an *acoustic stimulation nonstress test*. A commercially available acoustic stimulator is positioned on the maternal abdomen, and a stimulus of 1 to 2 seconds is applied (Eller and associates, 1995). This may be repeated up to three times for up to 3 seconds (American College of Obstetricians and Gynecologists, 2007). A positive response is defined as the rapid appearance of a qualifying acceleration following stimulation (Devoe, 2008). Perez-Delboy and colleagues (2002) randomized 113 women to nonstress testing with and without vibroacoustic stimulation. Such stimulation shortened the average time for nonstress testing from 24 to 15 minutes.

TABLE 15-2. Components and Their Scores for the Biophysical Profile

Component	Score 2	Score 0
Nonstress test[a]	≥2 accelerations of ≥15 beats/min for ≥15 sec within 20–40 min	0 or 1 acceleration within 20–40 min
Fetal breathing	≥1 episode of rhythmic breathing lasting ≥30 sec within 30 min	<30 sec of breathing within 30 min
Fetal movement	≥3 discrete body or limb movements within 30 min	<3 discrete movements
Fetal tone	≥1 episode of extremity extension and subsequent return to flexion	0 extension/flexion events
Amnionic fluid volume[b]	A pocket of amnionic fluid that measures at least 2 cm in two planes perpendicular to each other (2 × 2 cm pocket)	Largest single vertical pocket ≤2 cm

[a] May be omitted if all four sonographic components are normal.
[b] Further evaluation warranted, regardless of biophysical composite score, if largest vertical amnionic fluid pocket ≤2 cm.

BIOPHYSICAL PROFILE

Manning and colleagues (1980) proposed the combined use of five fetal biophysical variables as a more accurate means of assessing fetal health than a single element. Required equipment includes a sonography machine and Doppler ultrasound to record fetal heart rate. Typically, these tests require 30 to 60 minutes of examiner time. Shown in **Table 15-2** are the five biophysical components assessed, which include: (1) fetal heart rate acceleration, (2) fetal breathing, (3) fetal movements, (4) fetal tone, and (5) amnionic fluid volume. Normal variables were assigned a score of 2 each and abnormal variables, a score of 0. Thus, the highest score possible for a normal fetus is 10. Kopecky and associates (2000) observed that 10 to 15 mg of morphine sulfate administered to a mother caused a significant decrease in the biophysical score by suppressing fetal breathing and heart rate acceleration.

Manning and colleagues (1987) tested more than 19,000 pregnancies using the biophysical profile interpretation and management shown in **Table 15-3**. They reported a false-normal test rate, defined as an antepartum death of a structurally normal fetus, of approximately 1 per 1000. More than 97 percent of the pregnancies tested had normal test results. The most common identifiable causes of fetal death after a normal biophysical profile include fetomaternal hemorrhage, umbilical cord accidents, and placental abruption (Dayal and associates, 1999).

Manning and co-workers (1993) published a remarkable description of 493 fetuses in which biophysical scores were performed immediately before measurement of umbilical venous blood pH values obtained via cordocentesis. Approximately 20 percent of tested fetuses had growth restriction, and the remainder had alloimmune hemolytic anemia. As shown in **Figure 15-9**, a biophysical score of 0 was invariably associated with significant fetal acidemia, whereas normal score of 8 or 10 was associated with normal pH. An equivocal test result—a score of 6—was a poor predictor of abnormal outcome. A decrease from an abnormal result—a score of 2 or 4—to a very abnormal score (0) was a progressively more accurate predictor of abnormal outcome.

Salvesen and colleagues (1993) correlated the biophysical profile with umbilical venous blood pH obtained at cordocentesis in 41 pregnancies complicated by diabetes. They also found that abnormal pH was significantly associated with abnormal biophysical profile scores. They concluded, however, that the biophysical profile was of limited value in the prediction of fetal pH, because nine mildly acidemic fetuses had normal antepartum tests. Weiner and colleagues (1996) assessed the meaning of antepartum fetal tests in 135 overtly growth-restricted fetuses and came to a similar conclusion. They found that morbidity and mortality in severe fetal-growth restriction were determined primarily by gestational age and birthweight and not by abnormal fetal tests. Lalor and associates (2008) recently updated the Cochrane review and concluded that there is insufficient evidence at this time to support the use of the biophysical profile as a test of fetal well-being in high-risk pregnancies. Kaur and associates (2008) performed daily biophysical profiles to ascertain the optimal delivery time in 48 growth-restricted preterm fetuses who weighed < 1000 g. Despite scores of 8 in 27 fetuses and 6 in 13, there were six deaths and 21 acidotic fetuses. They conclude that a high incidence of false-positive and –negative results is seen in very preterm fetuses.

Modified Biophysical Profile

Because the biophysical profile is labor intensive and requires a person trained in sonography, Clark and co-workers (1989) used

TABLE 15-3. Biophysical Profile Score, Interpretation, and Pregnancy Management

Biophysical Profile Score	Interpretation	Recommended Management
10	Normal, nonasphyxiated fetus	No fetal indication for intervention; repeat test weekly except in diabetic patients and postterm pregnancy (twice weekly)
8/10 (Normal AFV) 8/8 (NST not done)	Normal, nonasphyxiated fetus	No fetal indication for intervention; repeat testing per protocol
8/10 (Decreased AFV)	Chronic fetal asphyxia suspected	Deliver
6	Possible fetal asphyxia	If amnionic fluid volume abnormal, deliver If normal fluid at >36 weeks with favorable cervix, deliver If repeat test ≤6, deliver If repeat test >6, observe and repeat per protocol
4	Probable fetal asphyxia	Repeat testing same day; if biophysical profile score ≤6, deliver
0 to 2	Almost certain fetal asphyxia	Deliver

AFV = amnionic fluid volume; NST = nonstress test.

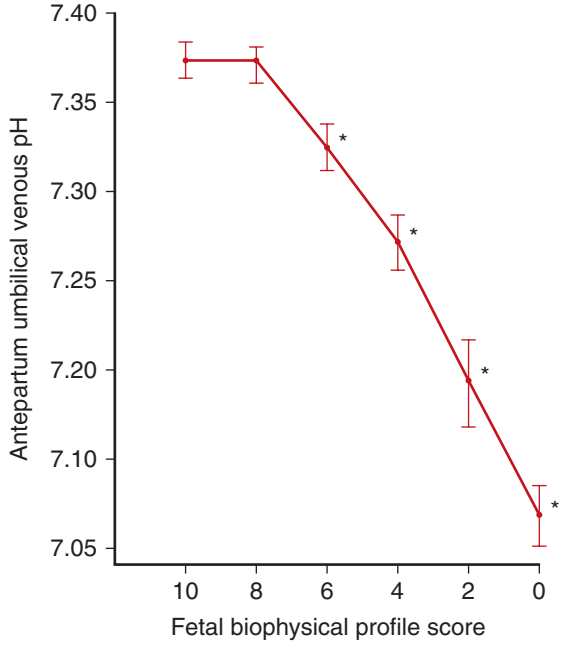

FIGURE 15-9 Mean umbilical vein pH (±2 SD) in relation to fetal biophysical profile score category. (This figure was published in *American Journal of Obstetrics & Gynecology,* Vol. 169, No. 4, FA Manning, R Snijders, CR Harman, et al., Fetal biophysical profile score. VI. Correlation with antepartum umbilical venous fetal pH, pp. 755–763, Copyright Elsevier 1993.)

an abbreviated biophysical profile as their first-line antepartum screening test in 2628 singleton pregnancies. Specifically, a vibroacoustic nonstress test was performed twice weekly and combined with amnionic fluid index determination (see Chap. 21, p. 490). An amnionic fluid index of <5 cm was considered abnormal. This abbreviated biophysical profile required approximately 10 minutes to perform, and they concluded that it was a superb method of antepartum surveillance because there were no unexpected fetal deaths.

Nageotte and colleagues (1994) also combined biweekly nonstress tests with the amnionic fluid index and considered ≤5 cm to be abnormal. They performed 17,429 modified biophysical profiles in 2774 women and concluded that such testing was an excellent method of fetal surveillance. Miller and associates (1996a) reported results with more than 54,000 modified biophysical profiles performed in 15,400 high-risk pregnancies. They described a false-negative rate of 0.8 per 1000 and a false-positive rate of 1.5 percent.

The American College of Obstetricians and Gynecologists and the American Academy of Pediatrics (2007) have concluded that the modified biophysical profile test is as predictive of fetal well-being as other approaches to biophysical fetal surveillance.

AMNIONIC FLUID VOLUME

Amnionic fluid volume is commonly evaluated in women with complaints of decreased fetal movement (Frøen and colleagues, 2008). Moreover, amnionic fluid has become an integral

component in the antepartum assessment of pregnancies at risk for fetal death. This is based on the rationale that decreased uteroplacental perfusion may lead to diminished fetal renal blood flow, decreased urine production, and ultimately, oligohydramnios. As discussed in Chapter 21 (p. 490), the amnionic fluid index, the deepest vertical pocket, and the 2 × 2-cm pocket used in the biophysical profile are some sonographic-techniques used to estimate amnionic fluid volume (Chamberlain, 1984; Manning, 1984; Nabhan, 2008; Rutherford, 1987, and all their colleagues).

In their review of 42 reports on the amnionic fluid index published between 1987 and 1997, Chauhan and co-workers (1999) concluded that an index of ≤ 5.0 cm significantly increased the risk of either cesarean delivery for fetal distress or a low 5-minute Apgar score. Similarly, in a retrospective analysis of 6423 pregnancies managed at Parkland Hospital, Casey and colleagues (2000) found that an amnionic fluid index of ≤ 5 cm was associated with significantly increased perinatal morbidity and mortality rates. Locatelli and associates (2004) reported an increased risk of low-birthweight infants if there was oligohydramnios so defined.

Not all investigators agree with the concept that an index of ≤ 5 cm portends adverse outcomes. Magann and colleagues (1999, 2004) concluded that the index was a poor diagnostic test and that it better predicted normal than abnormal volumes. Driggers and co-workers (2004) and Zhang and associates (2004) did not find a correlation with poor outcomes in pregnancies in which the index was below 5 cm. In the only randomized trial reported to date, Conway and colleagues (2000) concluded that nonintervention to permit spontaneous onset of labor was as effective as induction in term pregnancies with amnionic fluid index values ≤5 cm.

DOPPLER VELOCIMETRY

Doppler ultrasound is a noninvasive technique to assess blood flow by characterizing downstream impedance (see Chap. 16, p. 362). Three fetal vascular circuits, which include the umbilical artery, middle cerebral artery, and ductus venosus, are currently being assessed using Doppler technology to determine fetal health and help time delivery for growth-restricted fetuses. Maternal uterine artery Doppler velocimetry has also been evaluated in efforts to predict placental dysfunction. The goal of such testing is to optimize the time of delivery—late enough to avoid complications of preterm delivery and early enough to avoid stillbirth (Ghidini, 2007).

Doppler Blood Flow Velocity

Wave forms were first studied systematically in the umbilical arteries late in pregnancy, and abnormal wave forms correlated with hypovascularity of the umbilical placental villous structure such as shown in **Figure 15-10** (Trudinger, 2007). It was shown that 60 to 70 percent of the small placental arterial channels would need to be obliterated before the umbilical artery Doppler waveform became abnormal. Such extensive placental vascular pathology has a major effect on the fetal circulation. According to Trudinger (2007), because more than 40 percent of the combined fetal ventricular output is directed to the placenta, obliteration of vascular channels in the placental-umbilical circulation increases afterload and leads to fetal hypoxemia. This in turn leads to dilatation and redistribution of middle cerebral artery blood flow. Ultimately, pressure rises in the ductus venosus due to afterload in the right side of the fetal heart. Thus, it is postulated that such placental vascular dysfunction results in increased umbilical artery blood flow resistance, which progresses to decreased middle cerebral artery impedance followed ultimately by abnormal flow in the ductus venosus (Baschat, 2004). In this scenario, abnormal Doppler waveforms in the ductus venosus are a late finding in the progression of fetal deterioration due to chronic hypoxemia.

Umbilical Artery Velocimetry

The use of Doppler ultrasound to measure blood flow in pregnancy was described at the end of the 1970s (Trudinger, 2007). The umbilical artery systolic-diastolic (S/D) ratio is considered abnormal if it is above the 95th percentile for gestational age or

FIGURE 15-10 Acrylic casts of the umbilical arterial vascular tree within a placental lobule. They were prepared by injection of the umbilical artery at the site of cord insertion and later acid digestion of the tissue. **A.** Normal placenta. **B.** Placenta from a pregnancy with absent end diastolic flow in the umbilical artery recorded before delivery. (From Trudinger, 2007, with permission.)

if diastolic flow is either absent or reversed (see Chap. 16, p. 363). Absent or reversed end-diastolic flow as shown in **Figure 15-11** signifies increased impedance to umbilical artery blood flow (see also Fig. 16-27, p. 364). It is reported to result from poorly vascularized placental villi and is seen in extreme cases of fetal-growth restriction (Todros and co-workers, 1999). Zelop and colleagues (1996) found that the perinatal mortality rate for absent end-diastolic flow was approximately 10 percent, and for reversed end-diastolic flow, it approximated 33 percent. Spinillo and associates (2005) studied neurodevelopmental outcome at 2 years of age in 266 growth-restricted fetuses delivered between 24 and 35 weeks' gestation following umbilical artery Doppler testing. Of infants with absent or reversed flow in the umbilical artery, 8 percent had evidence of cerebral palsy, compared with 1 percent of those in whom Doppler flow was either normal or was above the 95th percentile but without reversed flow.

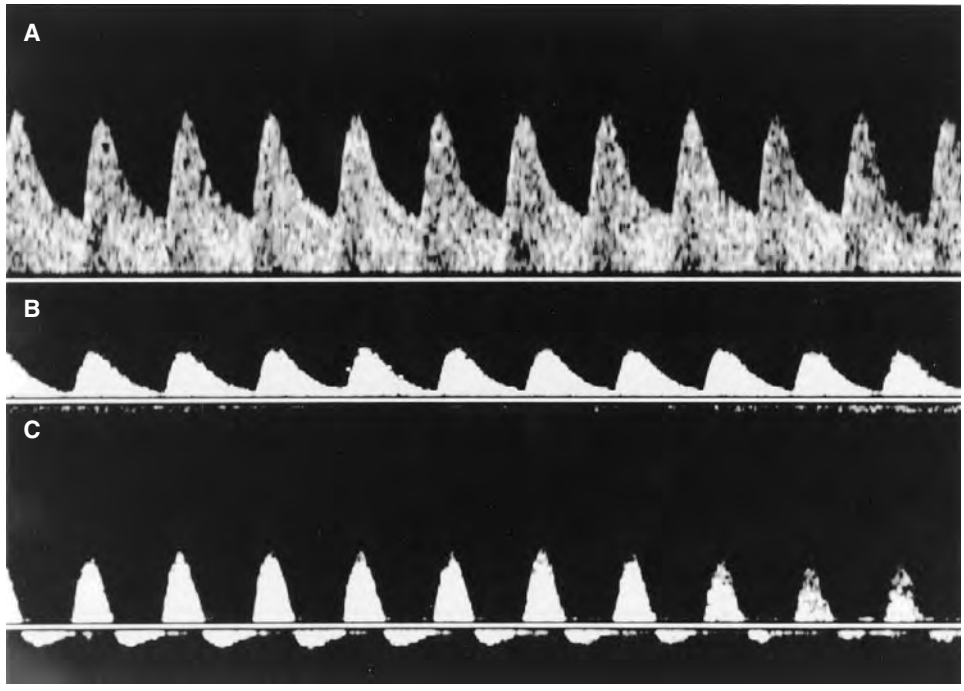

FIGURE 15-11 Three studies of fetal umbilical artery velocimetry. The peaks represent systolic velocity, and the troughs show the diastolic velocity. **A.** Normal velocimetry pattern. **B.** Velocity is zero during diastole (trough reaches the horizontal line). **C.** Arterial velocity is reversed during diastole (trough is below horizontal line).

Doppler ultrasound of the umbilical artery has been subjected to more extensive assessment with randomized controlled trials than has any previous test of fetal health. Williams and colleagues (2003) randomized 1360 high-risk women to either nonstress testing or Doppler velocimetry. They found a significantly increased incidence of cesarean delivery for fetal distress in the nonstress test group compared with that for those tested with Doppler velocimetry—8.7 versus 4.6 percent, respectively. One interpretation of this finding is that the nonstress test more frequently identified fetuses in jeopardy. Conversely, Gonzalez and associates (2007) found that abnormal umbilical artery Doppler findings in a cohort of growth-restricted fetuses were the best predictors of perinatal outcomes.

The utility of umbilical artery Doppler velocimetry was reviewed by the American College of Obstetricians and Gynecologists (2000, 2004). It was concluded that no benefit has been demonstrated other than in pregnancies with suspected fetal-growth restriction. Specifically, no benefits have been demonstrated for velocimetry for other conditions such as postterm pregnancy, diabetes, systemic lupus erythematosus, or antiphospholipid antibody syndrome. Similarly, velocimetry has not proved of value as a screening test for detecting fetal compromise in the general obstetrical population.

Middle Cerebral Artery

Doppler velocimetry interrogation of the middle cerebral artery (MCA) has received particular attention because of observations that the hypoxic fetus attempts *brain sparing* by reducing cerebrovascular impedance and thus increasing blood flow. Such brain sparing in growth-restricted fetuses has been documented by Konje and colleagues (2001) to undergo reversal. They reported that 8 of 17 fetuses with this reversal died. Ott and co-workers (1998) randomized 665 women undergoing modified biophysical profiles to either the profile alone or combined with middle cerebral to umbilical artery velocity flow assessment. There were no significant differences in pregnancy outcomes between these two study groups.

In a different application, Oepkes and colleagues (2006) used MCA Doppler velocimetry to detect severe fetal anemia in 165 fetuses with D alloimmunization. They prospectively compared serial amniocentesis for measurement of bilirubin levels with Doppler measurement of peak systolic velocity in the middle cerebral artery. These investigators concluded that Doppler could safely replace amniocentesis in the management of isoimmunized pregnancies. Indeed, Doppler velocimetry of the MCA is useful for detection and management of fetal anemia of any cause (Moise, 2008). The American College of Obstetricians and Gynecologists (2006) also concluded that such use of Doppler is appropriate in centers with personnel trained in the procedure (see Chap. 16, p. 364).

Ductus Venosus

The use of Doppler ultrasound to assess the fetal venous circulation is the most recent application of this technology. Bilardo and colleagues (2004) prospectively studied umbilical artery

and ductus venosus Doppler results in 70 growth-restricted fetuses at 26 to 33 weeks' gestation. They concluded that ductus venosus Doppler velocimetry was the best predictor of perinatal outcome. Importantly, however, negative or reversed flow in the ductus venous was a late finding because these fetuses had already sustained irreversible multiorgan damage due to hypoxemia. Also, gestational age at delivery was a major determinant of perinatal outcome independent of ductus venous flow. Specifically, 36 percent of growth-restricted fetuses delivered between 26 and 29 weeks succumbed compared with 5 percent delivered from 30 to 33 weeks.

Baschat and co-workers (2007) systemically studied 604 growth-restricted fetuses using umbilical artery, middle cerebral artery, and ductus venosus Doppler velocimetry and reached conclusions similar to those of Bilardo and colleagues (2004). Specifically, absent or reversed flow in the ductus venosus was associated with profound generalized fetal metabolic collapse. They too reported that gestational age was a powerful cofactor in ultimate perinatal outcome for growth-restricted fetuses delivered before 30 weeks. Put another way, by the time severely abnormal flow is seen in the ductus venosus, it is too late because the fetus is already near death. However, earlier delivery puts the fetus at risk for death due to preterm delivery. Ghidini (2007) concluded that these reports do not support routine use of ductus venous Doppler in the monitoring of growth-restricted fetuses and recommended further study.

Uterine Artery

Vascular resistance in the uterine circulation normally decreases in the first half of pregnancy due to invasion of maternal uterine vessels by trophoblastic tissue (see Chap. 3, p. 54). This process can be detected using Doppler flow velocimetry of the uterine arteries. Uterine artery Doppler may be most helpful in assessing pregnancies at high risk of complications related to uteroplacental insufficiency (Abramowicz and Sheiner, 2008). Persistence or development of high-resistance patterns have been linked to a variety of pregnancy complications (Lees and co-workers, 2001; Yu and associates, 2005). In a study of 30,519 unselected British women, Smith and colleagues (2007) assessed uterine artery velocimetry at 22 to 24 weeks. The risk of fetal death before 32 weeks when associated with abruption, preeclampsia, or fetal-growth restriction was significantly linked to high-resistance flow. They and others suggest continued research on the role of uterine artery Doppler velocimetry as a screening tool to detect pregnancies at risk for stillbirth (Reddy and associates, 2008).

CURRENT ANTENATAL TESTING RECOMMENDATIONS

According to the American College of Obstetricians and Gynecologists (2007), there is no "best test" to evaluate fetal well-being. Three testing systems—contraction stress test, nonstress test, and biophysical profile—have different end points to consider depending on the clinical situation. The American College of Obstetricians and Gynecologists (2002) patient education pamphlet describes these tests of fetal well-being and summarizes as follows: "Monitoring helps you and your doctor during your pregnancy by telling more about the well-being of the baby. If a test result suggests that there may be a problem, this does not always mean that the baby is in trouble. It simply may mean that you need special care or more tests. Discuss any questions you have about monitoring with your doctor."

The most important consideration in deciding when to begin antepartum testing is the prognosis for neonatal survival. The severity of maternal disease is another important consideration. In general, with the majority of high-risk pregnancies, most authorities recommend that testing begin by 32 to 34 weeks. Pregnancies with severe complications might require testing as early as 26 to 28 weeks. The frequency for repeating tests has been arbitrarily set at 7 days, but more frequent testing is often done.

Significance of Fetal Testing

Does antenatal fetal testing really improve fetal outcome? Platt and co-workers (1987) reviewed its impact between 1971 and 1985 at Los Angeles County Hospital. During this 15-year period, more than 200,000 pregnancies were managed, and nearly 17,000 of these women underwent antepartum testing of various types. Fetal surveillance increased from less than 1 percent of pregnancies in the early 1970s to 15 percent in the mid-1980s. These authors concluded that such testing was clearly beneficial because the fetal death rate was significantly less in the tested high-risk pregnancies compared with the rate in those not tested.

A contrasting opinion on the benefits of antenatal fetal testing was offered by Thacker and Berkelman (1986). It was their view that efficacy is best evaluated in randomized controlled trials. After reviewing 600 reports, they found only four such trials, all performed with the nonstress test, and none with the contraction stress test. The numbers in these four trials were considered too small to detect important benefits and did not support the use of either test. Enkin and colleagues (2000) reviewed evidence in the Cochrane Library from controlled trials of antepartum fetal surveillance. They concluded that "despite their widespread use, most tests of fetal well-being should be considered of experimental value only rather than validated clinical tools."

Another important and unanswered question is whether antepartum fetal surveillance identifies fetal asphyxia early enough to prevent brain damage. Todd and co-workers (1992) attempted to correlate cognitive development in infants up to age 2 years following either abnormal umbilical artery Doppler velocimetry or nonstress test results. Only abnormal nonstress tests were associated with marginally poorer cognitive outcomes. These investigators concluded that by the time fetal compromise is diagnosed with antenatal testing, fetal damage has already been sustained. Low and colleagues (2003) reached a similar conclusion in their study of 36 preterm infants delivered based on antepartum test results. Manning and co-workers (1998) studied the incidence of cerebral palsy in 26,290 high-risk pregnancies managed with serial biophysical profile testing. They compared these outcomes with those of 58,657 low-risk pregnancies in which antepartum testing was not performed. The rate of cerebral palsy was 1.3 per 1000 in tested pregnancies compared with 4.7 per 1000 in untested women.

Antenatal forecasts of fetal health have clearly been the focus of intense interest for more than two decades. When such testing is reviewed, several themes emerge:

1. Methods of fetal forecasting have evolved continually, a phenomenon that at least suggests dissatisfaction with the precision or efficacy of any given method
2. The fetal biophysical performance is characterized by wide ranges of normal biological variation, resulting in difficulty determining when such performance should be considered abnormal. *How many movements, respirations, or accelerations? In what time period?* Unable to easily quantify normal fetal biophysical performance, most investigators have resorted to somewhat arbitrary answers to such questions
3. Despite the invention of increasingly complex testing methods, abnormal results are seldom reliable, prompting many clinicians to use antenatal testing to forecast fetal *wellness* rather than *illness*.

CHAPTER 16

Fetal Imaging

SONOGRAPHY IN OBSTETRICS 349
NORMAL AND ABNORMAL FETAL ANATOMY 354
3- AND 4-DIMENSIONAL SONOGRAPHY 361
DOPPLER 362
M-MODE ECHOCARDIOGRAPHY 365
MAGNETIC RESONANCE IMAGING (MRI) 365

Recent advances in fetal imaging have been the result of technological achievements in sonography and magnetic resonance imaging, with dramatic improvements in resolution and image display. Both 3- and 4-dimensional ultrasound imagings have continued to evolve, and Doppler applications have expanded. Magnetic resonance imaging has added immensely to the already profound impact of sonography on obstetrics. A sonographic examination performed with the exacting recommended standards of the American Institute of Ultrasound in Medicine (2007) offers vital information about fetal anatomy, physiology, growth, and well-being.

SONOGRAPHY IN OBSTETRICS

Since the first obstetrical application of sonographic imaging by Donald and co-workers (1958), this technique has become indispensable for fetal evaluation.

Technology

The real-time image on the ultrasound screen is produced by sound waves reflected back from organs, fluids, and tissue interfaces of the fetus within the uterus. Transducers made of piezoelectric crystals convert electrical energy into sound waves that are emitted in synchronized pulses, then "listen" for the returning echoes. Because air is a poor transmitter of high-frequency sound waves, soluble gel is applied to the skin to act as a coupling agent. Sound waves pass through layers of tissue, encounter an interface between tissues of different densities, and are reflected back to the transducer. Dense tissue such as bone produces high-velocity reflected waves, which are displayed brightly on the screen. Conversely, fluid generates few reflected waves and appears dark or anechoic on the screen. The electrical pulses created by the echoes are converted into digital representations, the most common of which is the 2-dimensional real-time image. Depending on settings, these digital images can be generated at 50 to greater than 100 frames/second. Post-processing techniques then smooth the combined images and yield the appearance of real-time imaging.

Higher-frequency transducers yield better image resolution, whereas lower frequencies penetrate tissue more effectively. Current transducers offer wide-bandwidth technology, which allows them to perform over a range of frequencies. In the second trimester, a 4- to 6-megahertz-bandwidth transducer is often in close enough proximity to the fetus to provide precise images. However, by the third trimester, a lower frequency 2- to 5-megahertz-bandwidth transducer may be needed for penetration, but can lead to compromised resolution. This explains why resolution is often poor when imaging obese patients and why low-frequency transducers are needed to *reach* the fetus through the maternal tissues (Dashe and colleagues, 2009). In early pregnancy, 4- to 9-megahertz-bandwidth vaginal transducers provide excellent resolution because the small embryo is close to the transducer.

Safety

Sonography should be performed only with a valid medical indication and with the lowest possible exposure setting to gain necessary information—the ALARA principle—*As Low As Reasonably*

Achievable (American Institute of Ultrasound in Medicine, 2007, 2008). As discussed in Chapter 41 (p. 921), recent studies have suggested that prolonged exposure to ultrasound affects the migration of brain cells in fetal mice (Rakic, 2006). These findings have not altered the use of sonography in pregnant women because clinical application is unlikely to harm the human fetus. Duplex Doppler coupled with real-time imaging requires monitoring of the *thermal index*, which is displayed during its use. Microbubble ultrasound contrast agents are not used in pregnancy because they might raise the *mechanical index* (see Chap. 41, p. 921).

The American Institute of Ultrasound in Medicine (2003) recommends that fetal sonography be performed only by professionals who have been trained to recognize medically important conditions such as fetal anomalies, artifacts that may mimic pathology, and techniques to avoid ultrasound exposure beyond what is considered safe for the fetus. Importantly, the use of sonography for "keepsake fetal imaging" is not condoned by either the American Institute of Ultrasound in Medicine (2007) or the Food and Drug Administration (Rados, 2004).

Clinical Applications

Accurate assessment of gestational age, fetal growth, and the detection of fetal and placental abnormalities are major benefits of sonography. The American Institute of Ultrasound in Medicine (2007), in conjunction with the American College of Obstetrics and Gynecology (2009) and the American College of Radiology (2007), has updated guidelines for obstetrical sonographic studies. The sensitivity of sonography for detecting fetal anomalies varies according to factors such as gestational age, maternal habitus, position of the fetus, features of the equipment, skill of the sonographer, and the specific abnormality in question. All women undergoing sonographic examination should be counseled about its limitations. Although it will never be possible to detect all structural abnormalities, significant advances have been made.

TABLE 16-1. Some Indications for First-Trimester Ultrasound Examination

1. Confirm an intrauterine pregnancy
2. Evaluate a suspected ectopic pregnancy
3. Define the cause of vaginal bleeding
4. Evaluate pelvic pain
5. Estimate gestational age
6. Diagnose or evaluate multifetal gestations
7. Confirm cardiac activity
8. Assist chorionic villus sampling, embryo transfer, and localization and removal of an intrauterine device
9. Assess for certain fetal anomalies, such as anencephaly, in high-risk patients
10. Evaluate maternal pelvic masses and/or uterine abnormalities
11. Measure nuchal translucency when part of a screening program for fetal aneuploidy
12. Evaluate suspected gestational trophoblastic disease

From the American Institute of Ultrasound in Medicine (2007), with permission.

First-Trimester Evaluation

Indications for performing sonography in the first 14 weeks are listed in Table 16-1. Early pregnancy can be evaluated using transabdominal or transvaginal sonography, or both. The components listed in Table 16-2 should be assessed. With transvaginal scanning, the gestational sac is reliably seen in the uterus by 5 weeks, and fetal echoes and cardiac activity by 6 weeks. The crown-rump length is the most accurate biometric predictor of gestational age. This image should be obtained in a sagittal plane and include neither the yolk sac nor a limb bud. If carefully performed, it has a variation of only 3 to 5 days.

TABLE 16-2. Components of Standard Ultrasound Examination by Trimester

First Trimester	Second and Third Trimester
1. Gestational sac location	1. Fetal number; multifetal gestations: amnionicity, chorionicity, fetal sizes, amnionic fluid volume, and fetal genitalia, if visualized
2. Embryo and/or yolk sac identification	2. Presentation
3. Crown-rump length	3. Fetal cardiac activity
4. Cardiac activity	4. Placental location and its relationship to the internal cervical os
5. Fetal number, including amnionicity and chorionicity of multiples when possible	5. Amnionic fluid volume
6. Assessment of embryonic/fetal anatomy appropriate for the first trimester	6. Gestational age
7. Evaluation of the uterus, adnexa, and cul-de-sac	7. Fetal weight
8. Assessment of the fetal nuchal region if possible	8. Evaluation of the uterus, adnexa, and cervix
	9. Fetal anatomical survey, including documentation of technical limitations

Modified from the American Institute of Ultrasound in Medicine (2007), with permission.

With first-trimester sonography, anembryonic gestation, embryonic demise, and molar and ectopic pregnancies can all be reliably diagnosed (see Chaps. 9, 10, and 11). Using transvaginal examination, cardiac motion is typically observed when the embryo has reached 5 mm in length. Multifetal gestation can be identified early, and this is the optimal time to determine chorionicity (see Chap. 39, p. 865). The first trimester is the ideal time to evaluate certain maternal pelvic structures, including the uterus, adnexa, and cul-de-sac, however, cervical length is best evaluated in the second trimester.

Fetal Abnormalities

Assessment for certain fetal anomalies, such as *anencephaly* in patients at increased risk, is considered an acceptable indication for first-trimester sonographic examination (Table 16-1). Research has also focused on the potential detection of fetal anomalies and syndromes in the late first trimester (Bahado-Singh and Cheng, 2004). Dane and colleagues (2007) reported that 17 of 24 fetal defects discovered by transvaginal sonography in 1290 women were seen in the first trimester. These included central nervous system, neck, neural tube, and cardiac malformations. Similarly, Souka and associates (2006) reported a detection rate of 50 percent for anomalies with sonography during this time.

Nuchal Translucency. This is the maximum thickness of the subcutaneous translucent area between the skin and soft tissue overlying the fetal spine at the back of the neck (**Fig. 16-1**). It is measured in the sagittal plane between 11 and 14 weeks using precise criteria (**Table 16-3**). When increased, there is a higher risk for fetal aneuploidy and a variety of structural anomalies. As discussed in Chapter 13 (p. 295), nuchal translucency measurement, combined with maternal serum chorionic gonadotropin and pregnancy-associated plasma protein A assessment, has gained widespread use for first-trimester aneuploidy screening.

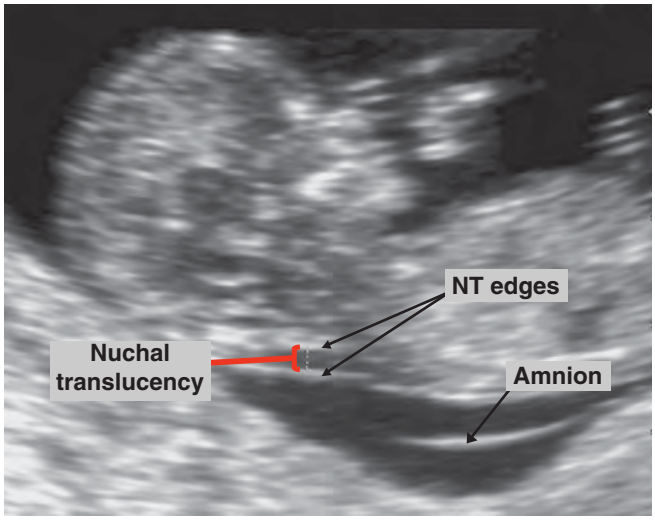

FIGURE 16-1 The nuchal translucency (*NT*) measurement is the maximum thickness of the subcutaneous translucent area between the skin and soft tissue overlying the fetal spine at the back of the neck. Calipers are placed on the inner borders of the nuchal space, at its widest portion, perpendicular to the long axis of the fetus. In this normal fetus at 12 weeks' gestation, the measurement is 2.0 mm. (Used with permission from Dr. Robyn Horsager.)

TABLE 16-3. Guidelines for Nuchal Translucency (NT) Measurement

1. The margins of NT edges must be clear enough for proper caliper placement
2. The fetus must be in the midsagittal plane
3. The image must be magnified so that it is filled by the fetal head, neck, and upper thorax
4. The fetal neck must be in a neutral position, not flexed and not hyperextended
5. The amnion must be seen as separate from the NT line
6. Electronic calipers must be used to perform the measurement
7. Calipers must be placed on the inner borders of the nuchal space with none of the horizontal crossbar itself protruding into the space
8. The calipers must be placed perpendicular to the long axis of the fetus
9. The measurement must be obtained at the widest space of the NT

From the American Institute of Ultrasound in Medicine (2007), with permission.

Second- and Third-Trimester Evaluations

The many indications for second- and third-trimester sonographic examinations are listed in **Table 16-4**. There are three types of sonographic evaluations: *standard, specialized,* and *limited.*

1. The *standard*—also termed *basic*—obstetrical sonographic examination is most commonly performed. Its components are listed in Table 16-2, including a survey of fetal anatomy, which is listed in **Table 16-5**. When multifetal gestations are studied, documentation includes the number(s) of chorions and amnions, comparison of fetal sizes, estimation of amnionic fluid volume in each sac, and description of fetal genitalia if visualized. Fetal anatomy may be adequately assessed after approximately 18 weeks. If a complete survey of fetal anatomy cannot be obtained—for example, due to oligohydramnios, fetal position, or maternal obesity—the limitation should be noted in the report (American College of Obstetricians and Gynecologists, 2009; American Institute of Ultrasound in Medicine, 2007).
2. There are several types of *specialized* examinations. The *targeted* examination is a detailed anatomical survey performed when an anomaly is suspected on the basis of history, maternal serum screening test abnormalities, or abnormal findings from a standard examination. Other *specialized* examinations include fetal echocardiography, Doppler evaluation, biophysical profile, or additional biometric studies. Specialized studies are performed and interpreted by an experienced operator who determines the examination components on a

TABLE 16-4. Some Indications for Second- or Third-Trimester Ultrasound Examination

Estimation of gestational age
Evaluation of fetal growth
Vaginal bleeding
Abdominal/pelvic pain
Cervical insufficiency
Determination of fetal presentation
Suspected multifetal gestation
Adjunct to amniocentesis or other procedure
Significant uterine size/clinical date discrepancy
Pelvic mass
Suspected molar pregnancy
Adjunct to cervical cerclage
Suspected ectopic pregnancy
Suspected fetal death
Suspected uterine abnormality
Evaluation of fetal well-being
Suspected hydramnios or oligohydramnios
Suspected placental abruption
Adjunct to external cephalic version
Preterm prematurely ruptured membranes and/or preterm labor
Abnormal biochemical markers
Follow-up evaluation of a fetal anomaly
Follow-up evaluation of placental location for suspected placenta previa
History of congenital anomaly in prior pregnancy
Evaluation of fetal condition in late registrants for prenatal care
Findings that may increase the risk for aneuploidy
Screening for fetal anomalies

case-by-case basis (American College of Obstetricians and Gynecologists, 2009).

3. The *limited* examination is performed when a specific question requires investigation. Examples include amnionic fluid assessment, placental location, or evaluation of fetal presentation or viability. In most cases, limited examinations are appropriate only when a prior complete examination is on record (American Institute of Ultrasound in Medicine, 2007).

Fetal Biometry

Various formulas and nomograms allow accurate assessment of gestational age and describe normal growth of fetal structures. Equipment software computes the estimated gestational age from the crown-rump length. It also estimates gestational age and fetal weight using measurements of the biparietal diameter, head and abdominal circumference, and femur length. Estimates are typically most accurate when multiple parameters are used with nomograms derived from fetuses of similar ethnic or racial background living at similar altitude. Even the best models may over- or underestimate fetal weight by as much as 15 percent (American Institute of Ultrasound in Medicine, 2007). Nomograms for individual structures such as the fetal cerebellum, ears, interocular and binocular orbital distances, thoracic circumference, kidneys, long bones, and feet may be used to address specific questions about organ system abnormalities or syndromes.

Gestational Age

Crown-rump length is most accurate in the first trimester. Biparietal diameter (BPD) is most accurate from 14 to 26 weeks, with a variation of 7 to 10 days. The BPD is measured from the outer edge of the proximal skull to the inner edge of the distal skull, at the level of the thalami and cavum septum pellucidum (Fig. 16-2). The head circumference (HC) also is measured. If the head shape is flattened—*dolichocephaly*, or rounded—*brachycephaly*, the HC is more reliable than the BPD. The femur length (FL) correlates well with both BPD and gestational age. It is measured with the beam perpendicular to the long axis of the shaft, excluding the epiphysis, and has a variation of 7 to 11 days in the second trimester (Fig. 16-3). The abdominal circumference (AC) has the widest variation, up to 2 to 3 weeks, because it involves soft tissue. This circumference is most affected by fetal

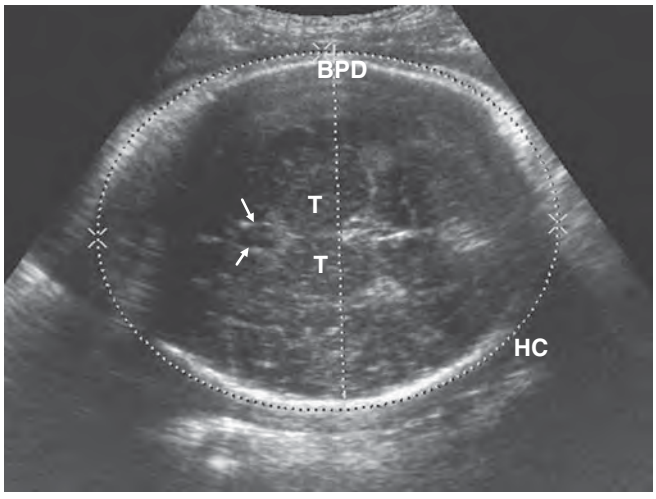

FIGURE 16-2 The transthalamic view is a transverse (axial) image obtained at the level of the thalami (*T*) and cavum septum pellucidum (*bounded by arrows*). The biparietal diameter (*BPD*) and head circumference (*HC*) are measured in this view.

growth. The AC is measured at the skin line in a transverse view of the fetus at the level of the fetal stomach and umbilical vein (Fig. 16-4).

The variability of gestational age estimation increases with advancing pregnancy. Individual measurements are least accurate in the third trimester, and estimates are improved by averaging the four parameters. If one parameter differs significantly from the others, it may be excluded from the calculation. The outlier could result from poor visibility, but it could also indicate a fetal abnormality or growth problem. Sonography performed to evaluate fetal growth should typically be performed at least 2 to 4 weeks apart (American College of Obstetricians and Gynecologists, 2009; American Institute of Ultrasound in Medicine, 2007).

Amnionic Fluid

Determination of amnionic fluid volume is an important method of fetal assessment and is discussed in Chapter 21 (p. 490). Subjectively, oligohydramnios is obvious crowding of the fetus and absence of significant fluid pockets. Conversely, hydramnios is apparent fluid excess.

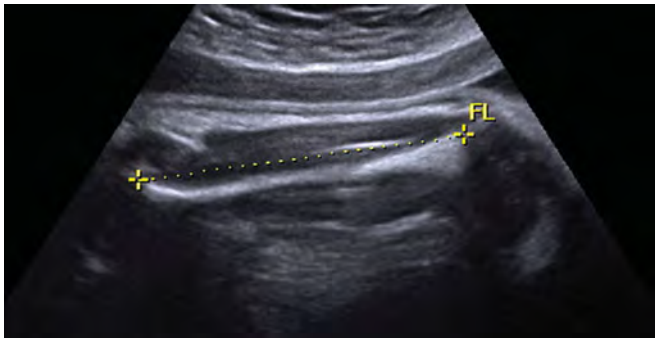

FIGURE 16-3 Example of the femur length (*FL*), obtained perpendicular to the femoral shaft.

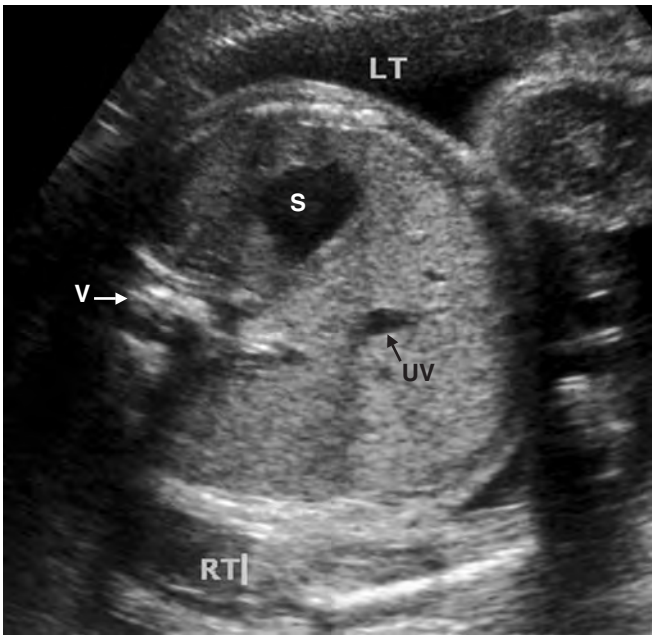

FIGURE 16-4 The abdominal circumference is measured in the transverse plane, at the level of the stomach (*S*) and the confluence of the umbilical vein (*UV*) with the portal sinus. The fetal vertebral body (*V*) aids in orienting anteroposterior anatomy of the image slice.

Several objective measurements have been used to evaluate amnionic fluid volume. The most widely used is the *amnionic fluid index (AFI),* which is calculated by adding the depth in centimeters of the largest vertical pocket in each of four equal uterine quadrants (Phelan and colleagues, 1987). Reference ranges have been established from 16 weeks onward, and in most normal pregnancies, the AFI ranges between 8 and 24 cm (see Fig. 21-1, p. 491). Another method measures the largest vertical pocket of amnionic fluid. The normal range is 2 to 8 cm. Values < 2 cm signify oligohydramnios, whereas those > 8 cm define hydramnios. This latter method is commonly used for twin pregnancies (Fig. 16-5).

FIGURE 16-5 The largest vertical pocket of amnionic fluid is increased (11 cm) in this twin pregnancy complicated by twin-twin transfusion syndrome.

NORMAL AND ABNORMAL FETAL ANATOMY

An important goal of sonographic evaluation is to categorize fetal components as anatomically normal or abnormal. Deviations from normal typically prompt specialized examination. In the discussion that follows, only a few of literally hundreds of fetal anomalies are described.

Central Nervous System

Anomalies of the fetal brain are among the most common, and sonography is extremely useful to detect and characterize them. Three transverse (axial) views are imaged: (1) the *transthalamic view* is used to measure BPD and HC and includes the thalami and cavum septum pellucidum (see Fig. 16-2); (2) the *transventricular view* includes the atria of the lateral ventricles, which contain the echogenic choroid plexus (**Fig. 16-6**); (3) the *transcerebellar view* is obtained by angling the view back through the posterior fossa (**Fig. 16-7**). Here, the cerebellum and cisterna magna are typically measured. Between 15 and 22 weeks, the cerebellar diameter in millimeters is roughly equivalent to the gestational age in weeks (Goldstein and associates, 1987).

Abnormalities detected in any of these three views suggest a possible fetal brain anomaly. Specialized evaluation may permit accurate diagnosis of abnormalities such as neural-tube defects, ventriculomegaly, holoprosencephaly, hydranencephaly, Dandy-Walker malformation, agenesis of the corpus callosum, porencephaly, or intracranial tumor.

Neural-Tube Defects

These malformations are the second most common class of congenital anomalies—cardiac anomalies are the most common. Neural-tube defects are found in approximately 1.6 per 1000 live births in the United States, and their incidence is as high as 8 per 1000 in the United Kingdom. Defects result from incomplete closure of the neural tube by the embryonic age of 26 to 28 days. Prenatal diagnosis with maternal serum alpha-fetoprotein screening and sonography are discussed in detail in Chapter 13 (p. 287).

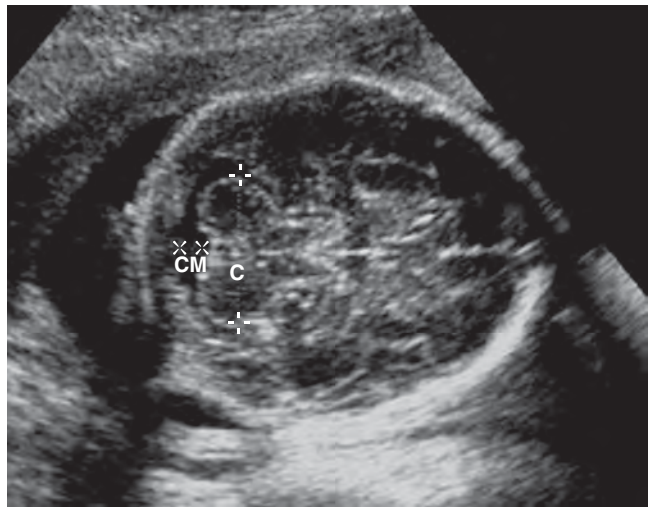

FIGURE 16-7 Transcerebellar view of the posterior fossa, demonstrating measurement of the cerebellum (*C*) and cisterna magna (*CM*).

Anencephaly is a lethal defect characterized by absence of the brain and cranium above the base of the skull and orbits (**Fig. 16-8**). It can be diagnosed in the late first trimester, and with adequate visualization, virtually all cases may be diagnosed in the second trimester. Inability to obtain a view of the biparietal diameter should raise suspicion. Hydramnios from impaired fetal swallowing is common in the third trimester.

Cephalocele—also termed encephalocele—is a herniation of meninges and brain tissue through a cranial defect, typically an occipital midline defect. Associated hydrocephalus and microcephaly are common, and there is a high incidence of mental impairment among surviving infants. Cephalocele is an important

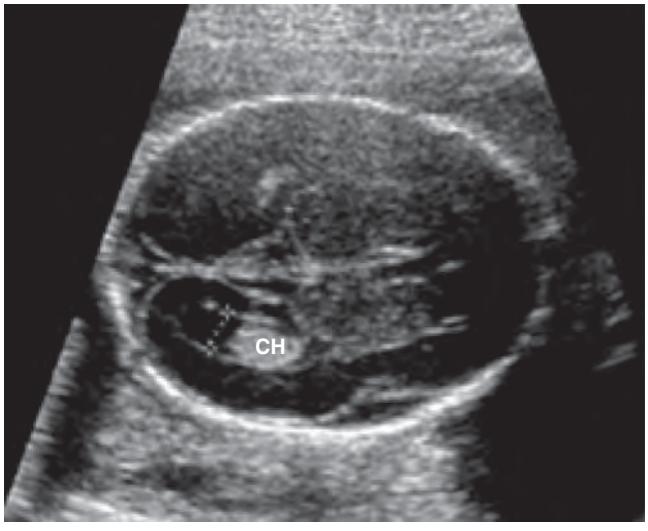

FIGURE 16-6 Transventricular view of the atrium of the lateral ventricle, which is marked by calipers and contains the echogenic choroid plexus (*CH*).

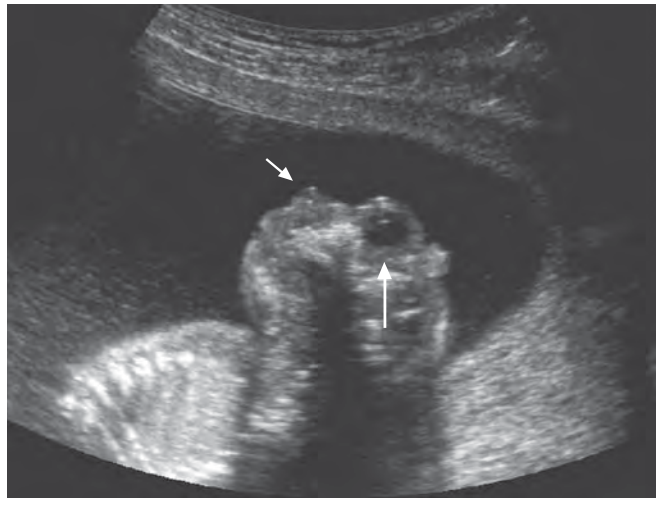

FIGURE 16-8 Anencephaly. This sagittal image shows the absence of forebrain and cranium above the skull base and orbit. The long white arrow points to the fetal orbit, and the short white arrow indicates the nose.

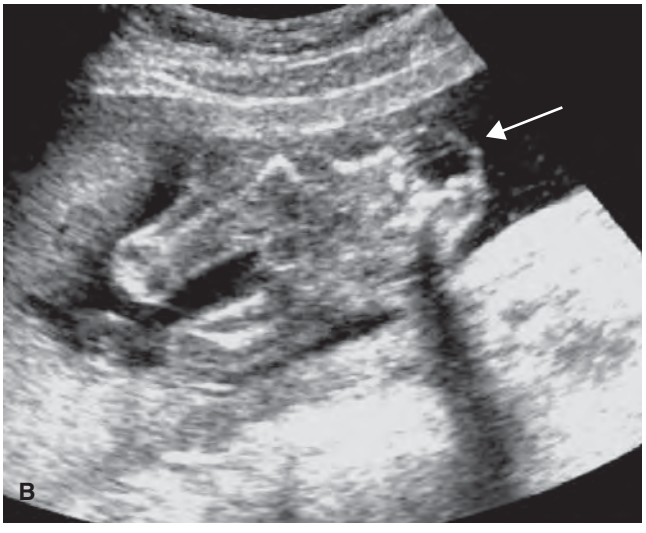

FIGURE 16-9 Sagittal (**A**) and transverse (**B**) views of the spine in a fetus with a large lumbosacral meningomyelocele (*arrow*).

feature of the autosomal recessive *Meckel-Gruber syndrome.* A cephalocele that is not in the occipital midline may be caused by the *amnionic band sequence.*

Spina bifida is an opening in the vertebrae through which a meningeal sac may protrude. In 90 percent of cases, the sac contains neural elements, and the anomaly is termed a *meningomyelocele.* When a meningeal sac alone protrudes through the defect, it is a *meningocele.* Spinal defects usually can be imaged in multiple planes (**Fig. 16-9**). Transverse images provide the best visualization of the extent of the defect and overlying soft tissue. Movement of the lower extremities does not predict normal function after birth. The *Arnold-Chiari II* malformation associated with spina bifida occurs when downward displacement of the spinal cord pulls a portion of the cerebellum through the foramen magnum into the upper cervical canal. Classically, fetuses with spina bifida have one or more of the following sonographic cranial findings: scalloping of the frontal bones—the so-called "lemon sign" (see Fig. 13-4, p. 291), bowing of the cerebellum with effacement of the cisterna magna—the "banana sign" (see Fig. 13-5), small biparietal diameter, and ventriculomegaly (Campbell and colleagues, 1987).

Ventriculomegaly

Enlargement of the cerebral ventricles is a nonspecific marker of abnormal brain development (Pilu, 2008; Wyldes and Watkinson, 2004). The lateral ventricle is commonly measured at its *atrium,* which is the confluence of the temporal and occipital horns (see Fig. 16-6). The atrial measurement is normally between 5 and 10 mm from 15 weeks until term. Mild ventriculomegaly is diagnosed when the atrial width measures 10 to 15 mm, and overt or severe ventriculomegaly when it exceeds 15 mm (**Fig. 16-10**). A *dangling choroid plexus* characteristically is found in severe cases (Cardoza and associates, 1988a, 1988b; Mahony and colleagues, 1988).

Ventriculomegaly may be caused by a wide variety of genetic and environmental insults, and prognosis is determined by both etiology and rate of progression. Generally, the larger the atrium, the greater the likelihood of abnormal outcome (Gaglioti and co-workers, 2009; Joó and associates, 2008). Initial evaluation of ventricular enlargement includes a thorough examination of fetal anatomy, fetal karyotyping, and testing for congenital infections such as cytomegalovirus and toxoplasmosis (Chap. 58, p. 1210). That said, even when ventriculomegaly is mild and appears isolated, counseling may be a challenge, because the prognosis is variable. Bloom and colleagues (1997) found that a third of infants prenatally diagnosed with isolated and mild ventriculomegaly were developmentally delayed.

Holoprosencephaly

With this abnormality, the prosencephalon fails to divide completely into two separate cerebral hemispheres and underlying diencephalic structures. As a result, in the most severe form—*alobar holoprosencephaly*—a single monoventricle, with or without a covering mantle of cortex, surrounds the fused central thalami (**Fig. 16-11**). Differentiation into two cerebral hemispheres is induced by prechordal mesenchyme, which is also responsible for differentiation of the midline face. Thus, there may be associated anomalies of the eyes or orbits—hypotelorism or cyclopia;

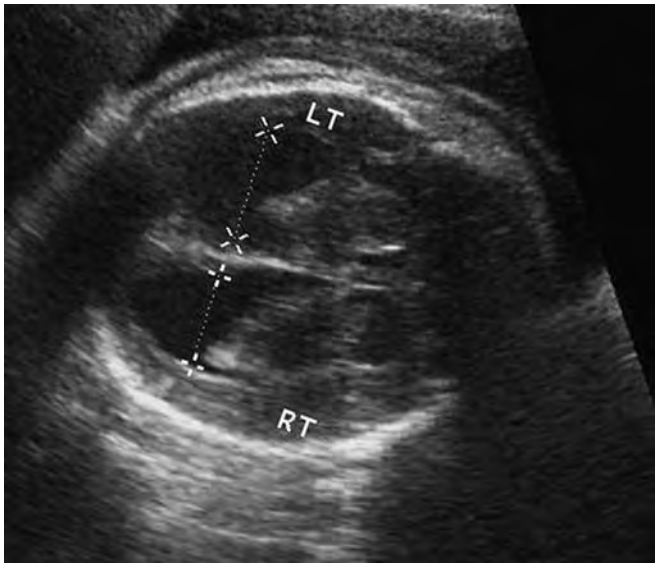

FIGURE 16-10 The atria appear unusually prominent in this fetus with ventriculomegaly (caliper measurements 20 mm).

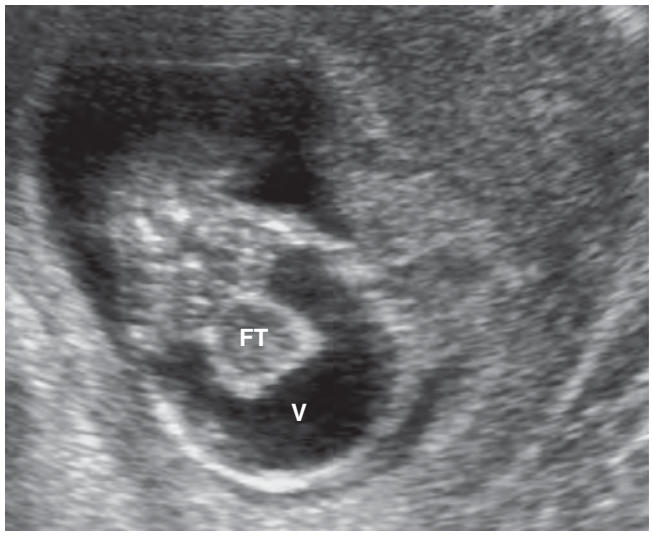

FIGURE 16-11 In this 14-week fetus with a lobar holoprosencephaly, the thalami are fused (*FT*) and surrounded by a monoventricle (*V*).

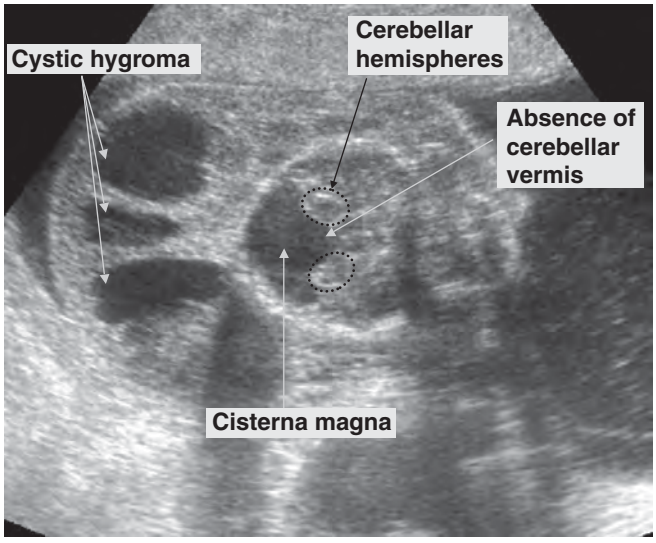

FIGURE 16-12 This 17-week fetus has a Dandy-Walker malformation of the posterior fossa, as well as large, septated cystic hygromas. The cerebellar hemispheres are visibly separated, with absence of the cerebellar vermis, such that the fourth ventricle communicates with the cisterna magna. The cystic hygromas are the fluid-filled sacs that extend from the posterior aspect of the neck.

nose—arhinia or proboscis; and lips—median cleft. The birth prevalence is 1 in 10,000 to 15,000, although it is much more common in abortuses. Approximately half of all cases have a chromosomal abnormality, particularly trisomy 13, although other aneuploidies and at least nine separate gene mutations have also been reported (Shiota and colleagues, 2007). Fetal karyotyping should be offered when this anomaly is identified.

Dandy-Walker Malformation

Originally described by Dandy and Blackfan (1914), this abnormality of the posterior fossa is characterized by agenesis of the cerebellar vermis, enlargement of the posterior fossa, and elevation of the tentorium. The birth prevalence is approximately 1 per 12,000 (Long and colleagues, 2006). Sonographically, fluid in the enlarged cisterna magna visibly communicates with the fourth ventricle through the defect in the cerebellar vermis, with visible separation of the cerebellar hemispheres (Fig. 16-12). Ventriculomegaly is common.

The Dandy-Walker malformation is associated with a large number of genetic and sporadic syndromes, aneuploidies, congenital viral infections, and some teratogens, all of which greatly affect the prognosis. Thus, the initial evaluation mirrors that for ventriculomegaly (p. 355). Even when vermian agenesis appears to be partial and relatively subtle, there is a high incidence of associated anomalies, and the prognosis is typically poor (Ecker and colleagues, 2000; Long and associates, 2006). Figure 16-2 depicts a fetus with Dandy-Walker malformation and septated cystic hygromas in the setting of aneuploidy.

Cystic Hygroma

This is a malformation of the lymphatic system in which fluid-filled sacs extend from the posterior neck (Fig. 16–12). Cystic hygromas are often large and multiseptated. They typically develop as part of a lymphatic obstruction sequence, in which lymph from the head fails to drain into the jugular vein and accumulates instead in jugular lymphatic sacs. The enlarged thoracic duct can impinge on the developing heart. Cystic hygromas are associated with an increased risk for cardiac malformations. In some cases, these are flow-related anomalies such as a hypoplastic left heart or coarctation of the aorta.

Approximately 60 to 70 percent of cystic hygromas cases are associated with aneuploidy. Of fetuses with cystic hygromas diagnosed in the second trimester, approximately 75 percent of aneuploid cases are 45,X—*Turner syndrome* (Johnson and colleagues, 1993; Shulman and associates, 1992). When cystic hygromas are diagnosed in the first trimester, the most common aneuploidy is *trisomy 21*, as reported in Malone and co-workers (2005). In this prospective series, first-trimester fetuses with cystic hygromas were five times more likely to be aneuploid than the fetuses with an increased nuchal translucency. Cystic hygromas also may be an isolated finding or part of a genetic syndrome such as *Noonan syndrome* (Lee and associates, 2009).

Large cystic hygromas are usually found in the setting of hydrops fetalis, rarely resolve, and carry a poor prognosis. Small hygromas may undergo spontaneous resolution, and provided that the fetal karyotype and echocardiography are normal, the prognosis *may* be good (Shulman and co-workers, 1992; Trauffer and associates, 1994).

Thorax

The lungs are best visualized after 20 to 25 weeks and appear as homogeneous structures surrounding the heart. In the four-chamber view of the chest, they comprise approximately two thirds of the area. A variety of thoracic malformations including cystic adenomatoid malformation, extralobar pulmonary sequestration, and bronchogenic cysts may be seen sonographically as cystic or solid space-occupying lesions. Fetal therapy for such lesions is discussed in Chapter 13 (p. 305).

(L = left; LA = left atrium; LV = left ventricle; R = right; RA = right atrium; RV = right ventricle.) (Redrawn from Comstock CH: Normal fetal heart axis and position, *Obstetrics & Gynecology*, 1987, vol. 70, no. 2, pp. 255–259, with permission.)

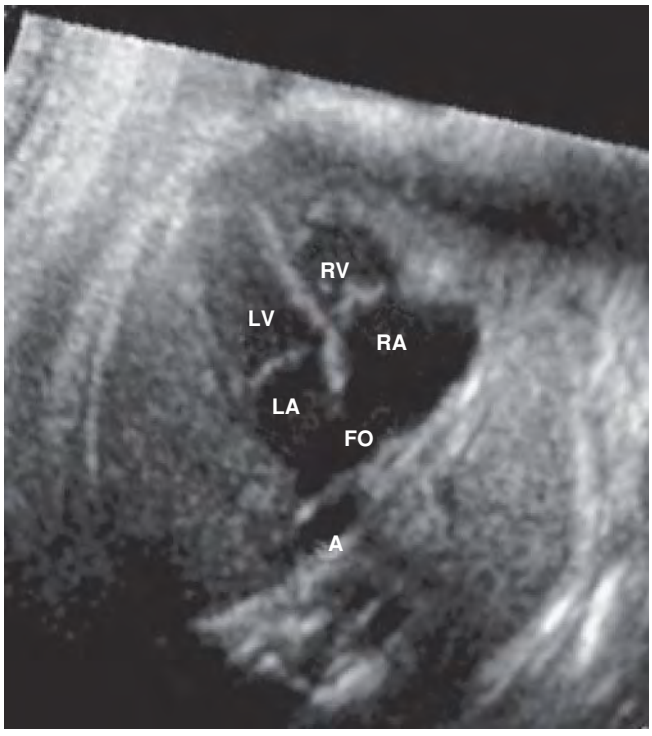

FIGURE 16-14 Four-chamber view of the fetal heart, showing the location of the left and right atria (*LA, RA*), left and right ventricles (*LV, RV*), foramen ovale (*FO*), and descending thoracic aorta (*A*).

Diaphragmatic Hernia

The incidence of congenital diaphragmatic hernia is approximately 1 per 3700 births (Wenstrom and colleagues, 1991). They are left-sided and posterior in 90 percent, and the most common sonographic finding is repositioning of the heart to the middle or right side of the thorax by the stomach and bowel. With improved technology, visualization of the liver within the thorax is increasingly common. Associated findings include absence of the stomach bubble within the abdomen, small abdominal circumference, and bowel peristalsis seen in the fetal chest. Almost half of cases are associated with other major anomalies or aneuploidy. Thus, a thorough evaluation of all fetal structures should be performed, and amniocentesis for fetal karyotyping should be offered. Fetal therapy for diaphragmatic hernia is discussed in Chapter 13 (p. 307).

Heart

As a group, cardiac malformations are the most common congenital anomalies with an incidence of approximately 8 per 1000 live births (see Chap. 12, p. 281). Almost 90 percent of cardiac defects are multifactorial or polygenic, another 1 to 2 percent are the result of a single-gene disorder or a gene-deletion syndrome, and 1 to 2 percent result from exposure to a teratogen such as isotretinoin, hydantoin, or diabetic hyperglycemia. *Up to 30 to 40 percent of cardiac defects diagnosed prenatally are associated with chromosomal abnormalities* (Moore and co-workers, 2004; Paladini and colleagues, 2002). Thus, their recognition should prompt fetal karyotyping. Fortunately, up to 50 to 70 percent of aneuploid fetuses have extracardiac anomalies that are identifiable sonographically. The most frequently encountered aneuploidies are Down syndrome, trisomies 18 and 13, and Turner syndrome (45,X).

Components of the Examination

The standard cardiac assessment includes a four-chamber view, evaluation of rate and rhythm, and, if possible, evaluation of the cardiac outflow tracts.

The four-chamber view is a transverse plane through the fetal thorax at a level immediately above the diaphragm (**Figs. 16-13** and **16-14**). It allows evaluation of heart size, its position in the chest, cardiac axis, atria and ventricles, foramen ovale, atrial septum primum, interventricular septum, and atrioventricular valves. The two atria and ventricles should be similar in size, respectively, and the apex of the heart should form a 45-degree angle with the left anterior chest wall (Fig. 16–13). Abnormalities of cardiac axis are frequently encountered in the setting of structural cardiac anomalies. Smith and colleagues (1995) found that 75 percent of fetuses with congenital heart anomalies had an axis angle that exceeded 75 degrees. Similarly, Shipp and co-workers (1995) found that 45 percent of those with abnormal hearts had left axis deviation.

The American Institute of Ultrasound in Medicine (2007) recommends that if technically feasible, each standard examination should attempt to evaluate both left and right ventricular outflow tracts (**Fig. 16-15**). Evaluation of the cardiac outflow tracts may aid detection of abnormalities not initially appreciated in the four-chamber view, such as transposition of the great vessels, Fallot tetralogy, or truncus arteriosus.

A specialized examination with fetal echocardiography is typically performed if there are any of the following: abnormality noted in the four-chamber or outflow tract views, arrhythmia, presence of extracardiac anomaly that confers increased risk, known genetic syndrome that may include a cardiac defect,

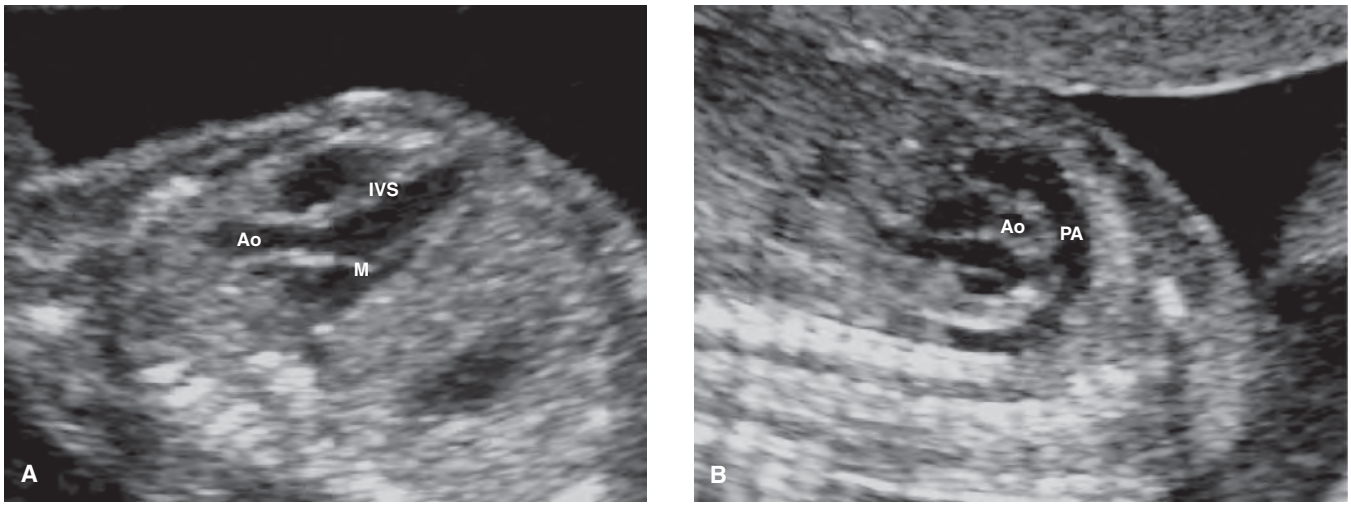

FIGURE 16-15 Views of the left and right ventricular outflow tracts. **A.** The left ventricular outflow tract demonstrates the continuity of the interventricular septum (*IVS*) and mitral valve (*M*) with the walls of the aorta (*Ao*). **B.** The right ventricular outflow tract shows the normal orientation of the aorta (*Ao*) and pulmonary artery (*PA*).

increased nuchal translucency in the first trimester in a fetus with a normal karyotype, insulin-treated diabetes prior to pregnancy, family history of congenital heart defect (see Chap. 12, p. 281), or exposure to a medication associated with increased risk for cardiac malformations.

Abdominal Wall

The integrity of the abdominal wall at the level of the cord insertion is assessed during the standard examination (Fig. 16-16). *Gastroschisis* and *omphalocele*, collectively termed *ventral wall defects,* are relatively common fetal anomalies. As discussed in Chapter 13 (p. 290), they are often detected because of elevated maternal serum alpha-fetoprotein screening.

Gastroschisis

This is a full-thickness abdominal wall defect typically located to the right of the umbilical cord insertion, and bowel herniates through the defect into the amnionic cavity (Fig. 16-17). Its incidence is 1 per 2000 to 5000 pregnancies, and it is the one major anomaly more common in infants of younger mothers. Santiago-Munoz and colleagues (2007) reported an average maternal age of approximately 20 years in 60 pregnancies complicated by gastroschisis. Associated bowel abnormalities such as *jejunal atresia* are found in 15 to 30 percent of cases and are believed to be a result of vascular damage or mechanical trauma. The anomaly is not associated with an increased risk for aneuploidy and usually has a survival rate of approximately 90 percent (Kitchanan, 2000; Nembhard, 2001; Santiago-Munoz, 2007, and all their colleagues).

Fetuses with gastroschisis are at increased risk for growth restriction, affecting 15 to nearly 40 percent (Puligandla and associates, 2004; Santiago-Munoz and co-workers, 2007). Infants with growth restriction, however, did not have increased mortality rates or longer hospitalization compared with affected infants who were normally grown. Ergün and colleagues (2005) reported that in 75 infants with gastroschisis, the only risk factor associated with longer hospitalization was delivery before 36 weeks.

FIGURE 16-16 Transverse sonogram of a second-trimester fetus with an intact anterior abdominal wall and normal cord insertion.

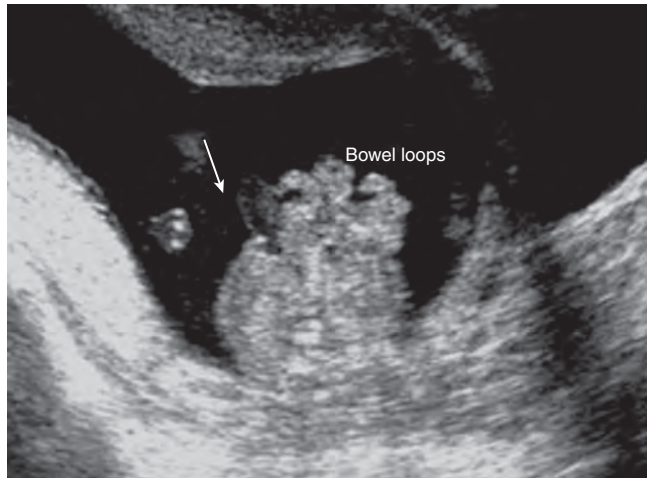

FIGURE 16-17 Transverse view of fetal abdomen. In this fetus with gastroschisis, extruded bowel loops are floating in the amnionic fluid to the right of the normal umbilical cord insertion site (*arrow*).

Omphalocele

This anomaly complicates approximately 1 per 5000 pregnancies. It forms when the lateral ectomesodermal folds fail to meet in the midline, leaving the abdominal contents covered only by a two-layered sac of amnion and peritoneum. The umbilical cord inserts into the apex of the sac (Fig. 16-18). In over half of cases, an omphalocele is associated with other major anomalies or aneuploidy. It also is a component of syndromes such as *Beckwith–Wiedemann, cloacal exstrophy,* and *pentalogy of Cantrell.* The smaller the defect, the greater the risk for aneuploidy (De Veciana and associates, 1994). The prognosis is determined by the size of the omphalocele and also by accompanying genetic or structural abnormalities (Heider and co-workers, 2004). Like other major anomalies, identification of an omphalocele mandates a complete fetal evaluation, and karyotyping is recommended.

Gastrointestinal Tract

The stomach is visible in nearly all fetuses after 14 weeks, and the liver, spleen, gallbladder, and bowel can be identified in many second- and third-trimester fetuses. Nonvisualization of the stomach within the abdomen is associated with a number of abnormalities. These include esophageal atresia, diaphragmatic hernia, abdominal wall defects, and neurological abnormalities that inhibit fetal swallowing. If the stomach is not seen on initial examination, the examination should be repeated. Millener and co-workers (1993), however, found that even with subsequent visualization of the stomach, a third of fetuses had an abnormal outcome.

The appearance of the bowel changes with fetal maturation. Occasionally it may appear bright, or echogenic, particularly if a higher frequency transducer is used (Vincoff and associates, 1999). Echogenic bowel is most commonly a normal variant or indicative of swallowed intra-amnionic blood. However, when the bowel appears as bright as fetal bone, there is a slightly increased risk for underlying gastrointestinal malformation, congenital infection such as cytomegalovirus, cystic fibrosis, and trisomy 21 (see Chap. 13, p. 296).

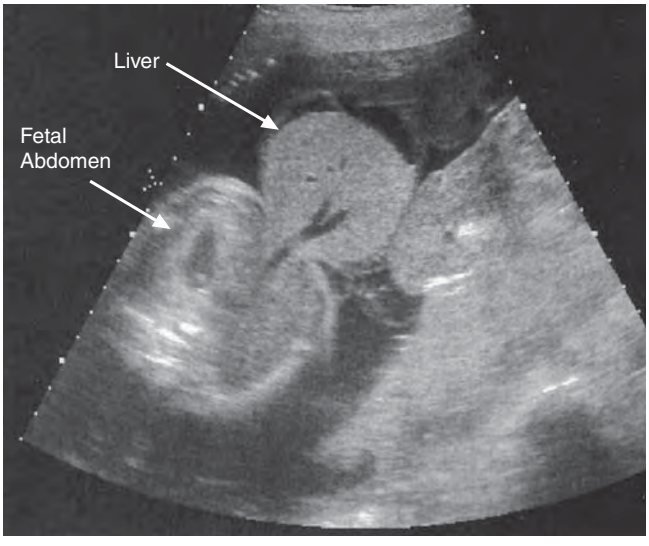

FIGURE 16-18 Transverse view of the abdomen showing an omphalocele as a large abdominal wall defect with exteriorized liver covered by a thin membrane.

FIGURE 16-19 Double-bubble sign of duodenal atresia is seen on this axial abdominal image of the fetus.

Gastrointestinal Atresia

Most atresias are characterized by obstruction with proximal bowel dilatation. In general, the more proximal the obstruction, the more likely it is to be associated with hydramnios.

Esophageal atresia may be suspected when the stomach cannot be visualized and hydramnios is present. That said, in up to 90 percent of cases, a concomitant *tracheoesophageal fistula* allows fluid to enter the stomach, and thus prenatal detection is problematic (Pretorius and colleagues, 1987a). Approximately half of fetuses with esophageal atresia have associated anomalies, including aneuploidy in 20 percent and growth restriction in 40 percent. Cardiac malformations are especially common.

Duodenal atresia occurs in approximately 1 in 10,000 live births (Robertson and colleagues, 1994). It is associated with the sonographic *double-bubble sign,* which represents distension of the stomach and the first part of the duodenum (Fig. 16-19). This finding is usually not present prior to 24 weeks. Demonstrating continuity between the stomach and proximal duodenum will differentiate duodenal atresia from other causes of abdominal cystic structures. Approximately 30 percent of fetuses with duodenal atresia diagnosed antenatally have trisomy 21, and more than half have other anomalies. Obstructions in the more distal small bowel usually result in multiple dilated loops that may have increased peristaltic activity.

Large bowel obstructions and *anal atresia* are less readily diagnosed by sonography because hydramnios is not a typical feature, and the bowel may not be significantly dilated. The transverse view through the pelvis may reveal the enlarged rectum as a fluid-filled structure between the bladder and the sacrum.

Kidneys and Urinary Tract

Fetal kidneys are easily visible adjacent to the fetal spine, frequently as early as 14 weeks, and routinely by 18 weeks. Reference tables are available to provide normal kidney dimensions throughout pregnancy. The placenta and membranes are the major source of amnionic fluid early in pregnancy, but after 18

weeks, most of the fluid is produced by the kidneys. Fetal urine production increases from 5 mL/hr at 20 weeks to approximately 50 mL/hr at term (Rabinowitz and co-workers, 1989). Unexplained oligohydramnios suggests a urinary tract abnormality, whereas normal amnionic fluid volume in the second half of pregnancy suggests urinary tract patency with at least one functioning kidney.

Renal Agenesis

One or both kidneys are congenitally absent in 1 in 4000 births. The kidney is not visible, and the adrenal gland typically enlarges to fill the renal fossa. Hoffman and colleagues (1992) have aptly termed this the *lying down adrenal sign.* If renal agenesis is bilateral, no urine is produced, and the resulting anhydramnios leads to pulmonary hypoplasia, limb contractures, a distinctive compressed face, and death from cord compression or pulmonary hypoplasia. When this combination of abnormalities results from renal agenesis, it is called *Potter syndrome,* after Dr. Edith Potter, who described it in 1946. When these abnormalities result from scant amnionic fluid of some other etiology, it is called *Potter sequence.*

Polycystic Kidney Disease

Of the hereditary polycystic diseases, only the infantile form of autosomal recessive polycystic kidney disease may be reliably diagnosed antenatally. As discussed in Chapter 48 (p. 1042), the autosomal dominant condition usually does not manifest until adulthood, although prenatal diagnosis has been described (Pretorius and associates, 1987b). Infantile polycystic kidney disease is characterized by abnormally large kidneys that fill the fetal abdomen and appear to have a solid, ground-glass texture (**Fig. 16-20**). The abdominal circumference is enlarged, and there is severe oligohydramnios. The cystic changes can only be identified microscopically.

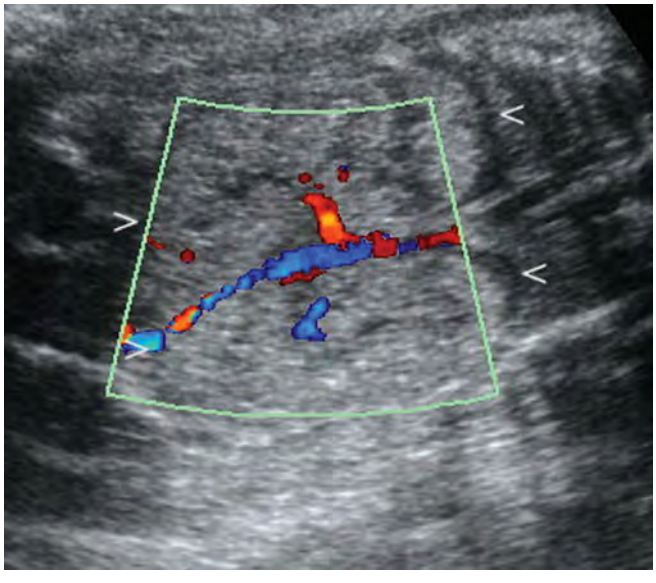

FIGURE 16-20 Coronal view of fetal abdomen and lower thorax displays the classic appearance of bilaterally enlarged echogenic kidneys in this fetus with autosomal recessive infantile polycystic kidneys. Arrows mark the upper and lower poles of each kidney. The renal arteries and aorta are seen with color Doppler mapping.

FIGURE 16-21 Coronal view of the fetal abdomen and lower thorax displays multiple cysts of varying sizes, which do not communicate in the retroperitoneal region of this fetus with multicystic dysplastic kidneys.

Multicystic Dysplastic Kidney Disease

These renal changes arise from complete obstruction or atresia at the level of the renal pelvis or proximal ureter prior to 10 weeks**.** The diagnosis usually can be made antenatally by identifying abnormally dense renal parenchyma with multiple peripheral cysts of varying size that do not communicate with each other or with the renal pelvis (**Fig. 16-21**). This finding should be distinguished from obstructive pyelectasis, in which the fluid-filled areas can be seen to connect. The prognosis for fetuses with multicystic dysplastic kidney disease is generally good if findings are unilateral and amnionic fluid volume is normal. If bilateral, as in Figure 16-21, the prognosis is poor.

Ureteropelvic Junction Obstruction

This condition is the most common cause of neonatal hydronephrosis and affects males at least twice as often as females. The actual obstruction is generally functional rather than anatomical, and it is bilateral in a third of cases (**Fig. 16-22**). It is characterized by dilatation of the renal pelvis—*pyelectasis.* Various measurements taken at all gestational ages are used to predict fetuses that will require postnatal evaluation (Corteville, 1991; Mandell, 1991; Wilson, 1997, and all their colleagues). A commonly used upper limit for the normal renal pelvis diameter is 4 mm before 20 weeks. If this limit is exceeded, sonography is performed again at 34 weeks. If the pelvis is then greater than 7 mm, evaluation in the neonatal period should be considered.

Adra and co-workers (1995) found that two thirds of fetuses with pyelectasis > 8 mm had an abnormality at birth. Similarly, Ismaili and associates (2003) reported that a diameter of at least 7 mm in a third-trimester fetus had a 70-percent positive-predictive value for a renal abnormality. Yamamura and colleagues

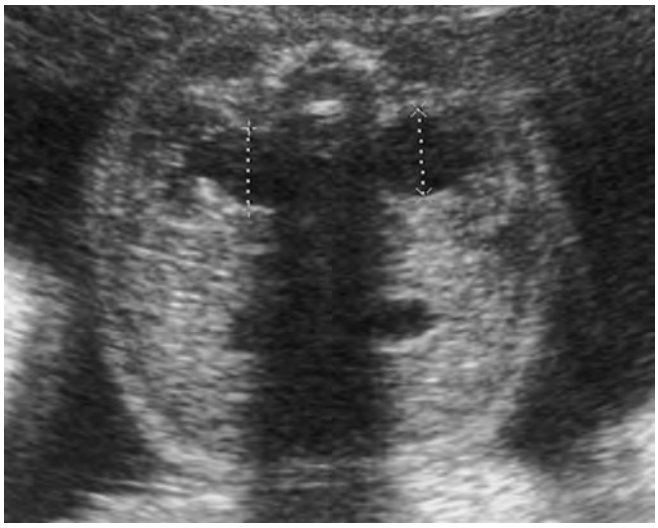

FIGURE 16-22 Transverse view of the kidneys demonstrating hydronephrosis (*calipers*) in a fetus with ureteropelvic junction obstruction.

(2007) recently evaluated mild fetal pyelectasis and found that a single third-trimester follow-up evaluation was a safe and cost-effective management. Specifically, none of the 244 fetuses in their series required antenatal interventions or progressed to severe pyelectasis to justify more intensive follow-up evaluations.

Collecting System Duplication

This is the most common genitourinary anomaly and is found in up to 4 percent of the population. The characteristic obstruction of the upper pole is evident as pyelectasis, often associated with a dilated ureter that may be mistaken for a loop of bowel, as well as with an ectopic ureterocele within the bladder. Reflux of the lower pole moiety is common. In the neonatal period, additional testing such as voiding cystourethrography will determine whether antimicrobial treatment is needed to minimize urinary infections and will assist with planning follow-up or surgical intervention.

Bladder Outlet Obstruction

This distal obstruction of the urinary tract is more common in male fetuses, and the most common etiology is *posterior urethral valves*. Characteristically, there is dilatation of the bladder and proximal urethra. As a result, the urethra resembles a keyhole, and the bladder wall is thickened. Oligohydramnios portends a poor prognosis because of pulmonary hypoplasia. Unfortunately, the outcome is not uniformly good even with a normal amount of fluid. As with other obstructive uropathies, prenatal diagnosis allows some affected fetuses to benefit from early intervention postnatally or even consideration of in utero therapy (see Chap. 13, p. 307).

3- AND 4-DIMENSIONAL SONOGRAPHY

The goal of 3-D imaging is to obtain a volume and then to render that volume to enhance real-time 2-dimensional findings. Special transducers are used to obtain volumes as still images—3D—and as a function of time—4D. By sophisticated postprocessing, a variety of different displays can be produced. Because of the obvious appeal of a 3-D portrait of the fetal face, surface rendering is the most popular technique and is well known to the lay public (**Fig. 16-23**). And for selected anomalies, such as those of the face and skeleton, 3-D may provide additional useful information (Goncalves and associates, 2005). However, comparisons of 3-D with conventional 2-D sonography for the diagnosis of most congenital anomalies have *not* demonstrated an improvement in overall detection (Goncalves and co-workers, 2006; Reddy and colleagues, 2008). The American College of Obstetricians and Gynecologists (2009) recently affirmed that proof of a clinical advantage of 3D sonography in general is lacking. Thus, the precise utility of this exciting technology has yet to be fully determined.

One potential advantage of 3-D volume acquisition is the ability to reformat images in any plane. For example, if the image is obtained in the typical axial plane, volume acquisition can allow the image can be reformatted in sagittal, coronal, or even oblique planes. Sequential "slices" can be generated, similar to computed tomographic (CT) or magnetic resonance (MR) imaging. Applications of this technique include evaluation of intracranial anatomy in the sagittal plane—for example, the corpus callosum, and evaluation of the palate and skeletal system (Benacerraf, 2006; Pilu, 2008; Timor-Tritsch, 2000, and all their colleagues).

Recently, 4-D imaging has also been used to improve visualization of cardiac anatomy. Postprocessing algorithms and techniques have taken advantage of real-time image volumes—with and without color Doppler mapping. An example is *spatiotemporal image correlation—STIC*. They are used to evaluate the

FIGURE 16-23 Surface rendered 3-dimensional image of the fetal face at 33 weeks' gestation.

complex cardiac anatomy and function (DeVore and associates, 2003; Espinoza and colleagues, 2008). Addition of an inversion-mode algorithm may aid imaging of blood flow within the heart and great vessels and may even allow measurement of ventricular blood volume (Goncalves and co-workers, 2004). Systematic approaches or protocols for using these new techniques to evaluate cardiac anatomy and physiology are under development (Espinoza and associates, 2007).

Limitations

There are several limitations to 3-D sonography. To adequately image a fetal surface structure in 3-D, it must be surrounded by amnionic fluid, because crowding by adjacent structures obscures the captured image. Image processing with 3-D sonography lengthens time to completion of the study, although Benacerraf and colleagues (2006) have demonstrated that this can be shortened with experience. Further, there are limitations on image resolution, data storage, and manipulation (Michailidis and co-workers, 2001; Pretorius and colleagues, 2001). The American Institute of Ultrasound in Medicine (2005) and the American College of Obstetricians and Gynecologists (2009) currently recommend that 3-D ultrasound be used only as an adjunct to conventional sonography.

DOPPLER

The use of Doppler in obstetrics has been primarily in the areas of duplex velocimetry and color mapping. The Doppler shift is a phenomenon that occurs when a source of light or sound waves is moving relative to an observer and is detected by the observer as a shift in the wave frequency. When sound waves strike a moving target, the frequency of the sound waves reflected back is shifted proportionate to the velocity and direction of the moving target. Because the magnitude and direction of the frequency shift depend on the relative motion of the moving target, the velocity and direction of the target can be determined.

Important to obstetrics, Doppler may be used to determine the volume and rate of blood flow through maternal and fetal vessels. In this situation, the sound source is the ultrasound transducer, the moving target is the column of red blood cells flowing through the circulation, and the reflected sound waves are observed by the ultrasound transducer. Two types of Doppler are used in medicine:

1. *Continuous wave Doppler* equipment has two separate types of crystals—one transmits high-frequency sound waves, and another continuously receives signals. It cannot be used for imaging of the blood vessel(s). In M-mode echocardiography, continuous wave Doppler is used to evaluate motion through time.
2. *Pulse wave Doppler* uses only one crystal, which transmits the signal and then waits until the returning signal is received before transmitting another one. It allows precise targeting and visualization of the vessel of interest. Pulse wave Doppler also can be configured to allow color-flow mapping with software that displays blood flowing away from the transducer as blue and blood flowing toward the transducer as red. Various combinations of pulse wave Doppler, color-flow Doppler, and real-time sonography are commercially available and are loosely referred to as *duplex Doppler*.

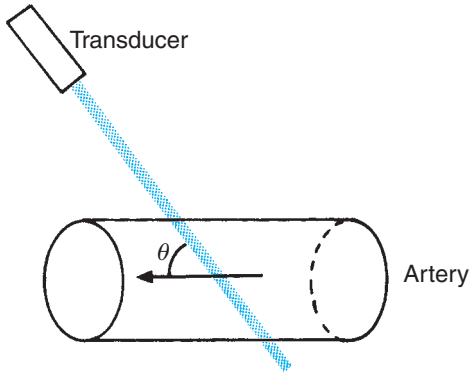

FIGURE 16-24 Doppler equation: Ultrasound emanating from the transducer with initial frequency f_0 strikes blood moving at velocity v. Reflected frequency f_d is dependent on angle τ; between beam of sound and vessel. (From Copel and associates, 1988.)

Clinical Applications

The Doppler equation shown in **Figure 16-24** contains the variables that affect the Doppler shift. An important source of error when calculating flow or velocity is the angle between sound waves from the transducer and flow within the vessel—termed the *angle of insonation* and abbreviated as theta—θ. Because cosine θ is a component of the equation, measurement error becomes large when the angle of insonation is not close to zero, in other words, when blood flow is not coming *directly* toward or away from the transducer. Thus, ratios are used to compare different waveform components, allowing cosine θ to cancel out of the equation. **Figure 16-25** is a schematic of the Doppler waveform and describes the three ratios commonly

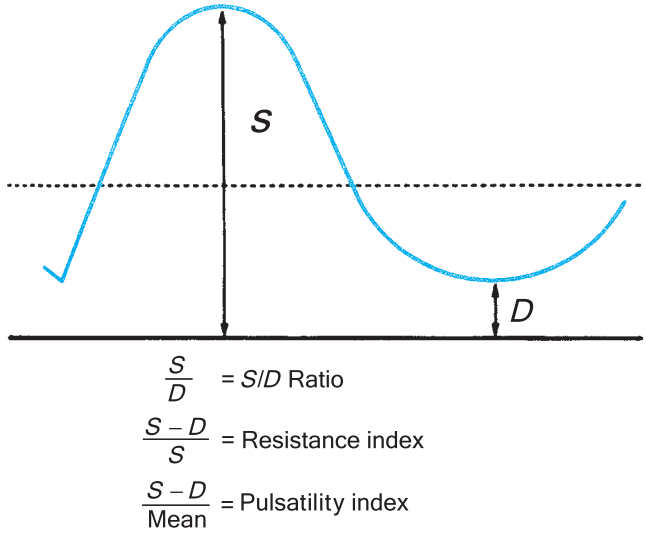

FIGURE 16-25 Doppler systolic–diastolic waveform indices of blood flow velocity. The mean is calculated from computer-digitized waveforms. (D = diastole; S = systole.) (This figure was published in *American Journal of Obstetrics & Gynecology*, Vol. 164, No. 4, JA Low, The current status of maternal and fetal blood flow velocimetry, pp. 1049–1063, Copyright Elsevier 1991.)

used. The simplest is the *systolic-diastolic ratio (S/D ratio),* which compares maximum (peak) systolic flow with end-diastolic flow, thereby evaluating downstream impedance to flow.

Flow in numerous maternal and fetal vessels have been studied to better understand antenatal pathophysiology. **Figure 16-26** illustrates several vessels and their corresponding waveforms. The following discussion is limited to selected obstetrical applications.

Umbilical Artery

This vessel normally has forward flow throughout the cardiac cycle, and the amount of flow during diastole increases as gestation advances. Thus, the *S/D* ratio *decreases,* from about 4.0 at 20 weeks to 2.0 at term. The *S/D* ratio is generally less than 3.0 after 30 weeks. As discussed in Chapter 15 (p. 343), umbilical artery Doppler has been subjected to more rigorous assessment than has any previous test of fetal health (Alfirevic and Neilson, 1995). This measurement is considered to be a useful adjunct in the management of pregnancies complicated by fetal-growth restriction (American College of Obstetricians and Gynecologists, 2008). It is not recommended for screening of low-risk pregnancies or for complications other than growth restriction.

Umbilical artery Doppler is considered abnormal if the *S/D* ratio is above the 95th percentile for gestational age. In extreme cases of growth restriction, end-diastolic flow may become absent or even reversed (**Fig. 16-27**). These should prompt a complete fetal evaluation—almost half of cases are associated with fetal aneuploidy or a major anomaly (Wenstrom and associates, 1991). In the absence of a reversible maternal complication or a fetal anomaly, *reversed* end-diastolic flow suggests severe fetal circulatory compromise and usually prompts immediate delivery. Sezik and colleagues (2004) reported that fetuses of preeclamptic women who had absent or reversed end-diastolic flow were more likely to have hypoglycemia and polycythemia.

Ductus Arteriosus

Doppler evaluation of the ductus arteriosus has been used primarily to monitor fetuses exposed to indomethacin and other nonsteroidal anti-inflammatory agents—NSAIDs. Indomethacin, which is used for tocolysis, may cause ductal constriction or closure (Huhta and colleagues, 1987). The resulting increased

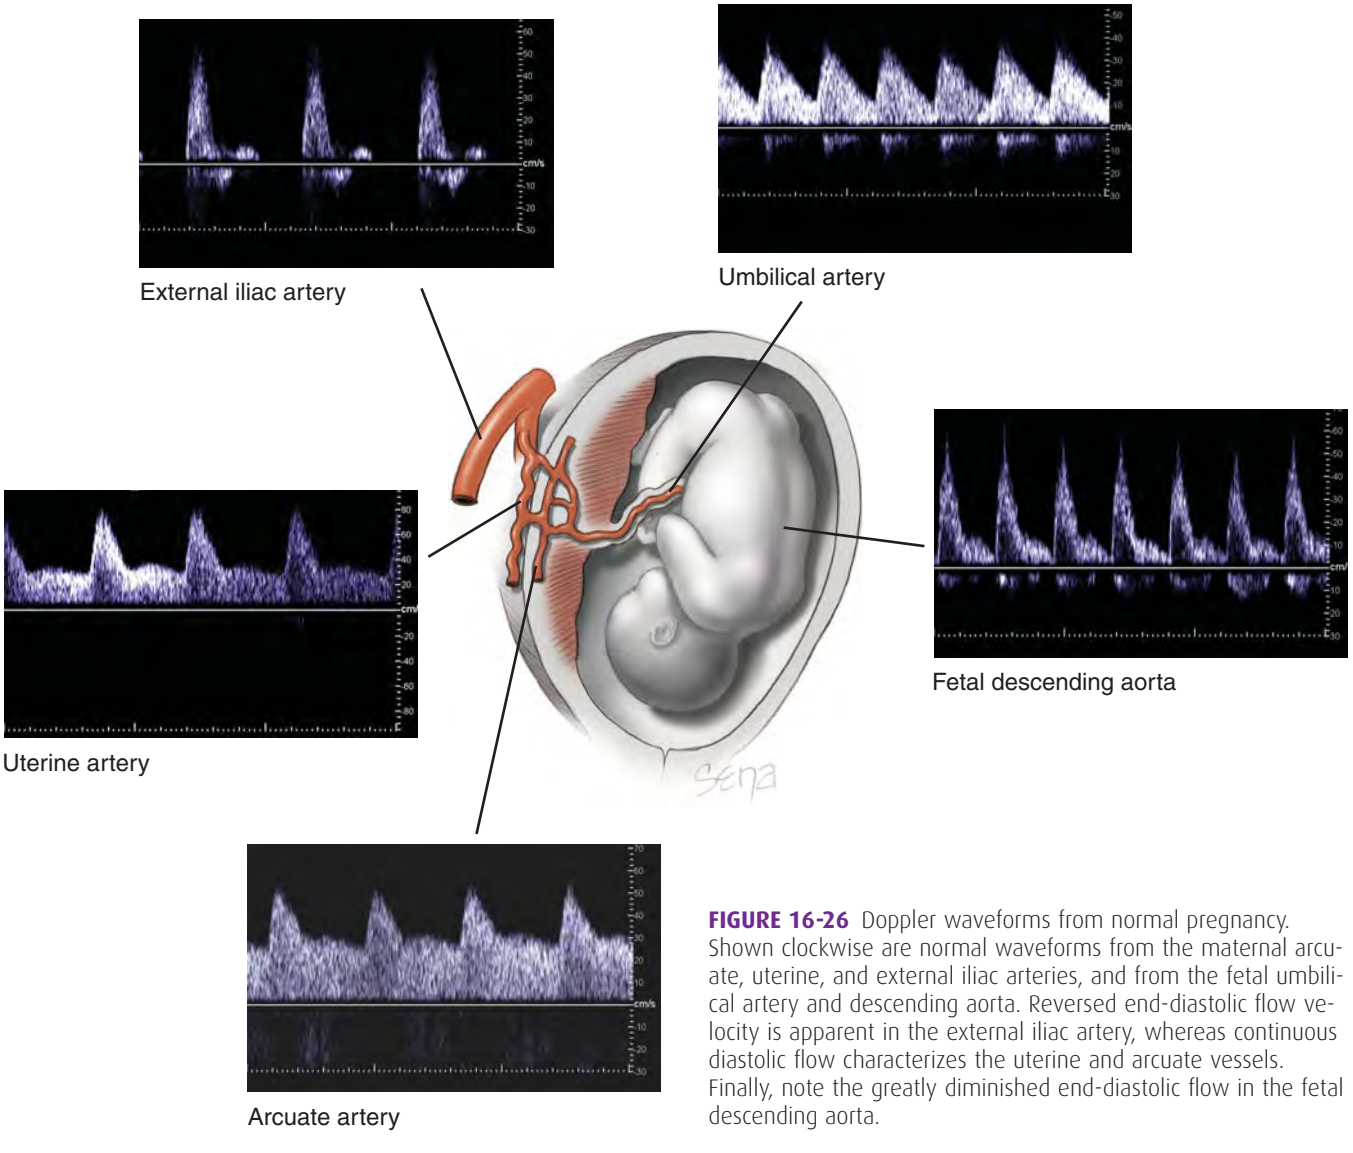

FIGURE 16-26 Doppler waveforms from normal pregnancy. Shown clockwise are normal waveforms from the maternal arcuate, uterine, and external iliac arteries, and from the fetal umbilical artery and descending aorta. Reversed end-diastolic flow velocity is apparent in the external iliac artery, whereas continuous diastolic flow characterizes the uterine and arcuate vessels. Finally, note the greatly diminished end-diastolic flow in the fetal descending aorta.

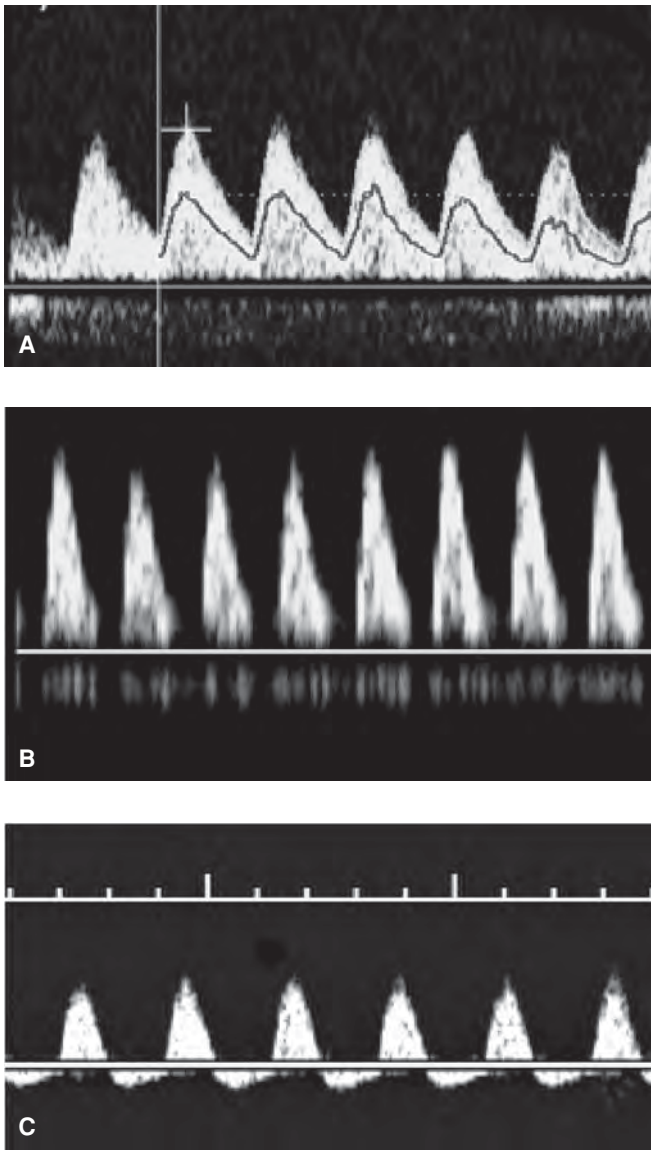

FIGURE 16-27 Umbilical artery Doppler waveforms. **A.** Normal diastolic flow. **B.** Absence of end-diastolic flow. **C.** Reversed end-diastolic flow.

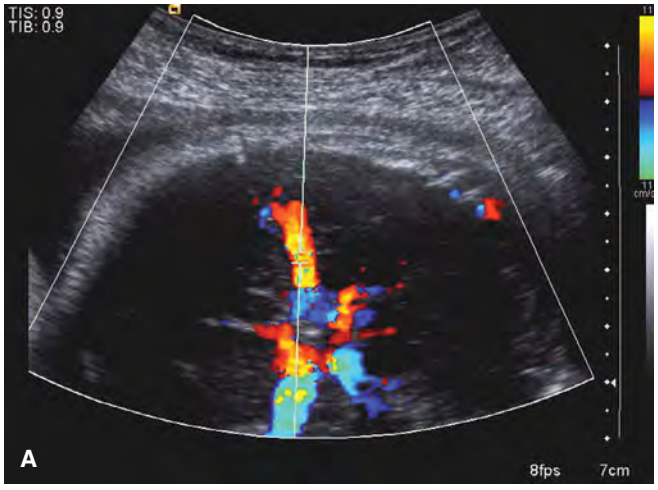
pulmonary flow may cause reactive hypertrophy of the pulmonary arterioles and eventual development of pulmonary hypertension (see Chap. 36, p. 825). Ductal constriction can be reversed, and its persistence may be directly related to increasing dosage and duration of NSAID administration. In a review of 12 randomized controlled trials involving more than 200 exposed pregnancies, Koren and colleagues (2006) reported that NSAIDs increased the odds of ductal constriction by 15-fold. They also concluded that this was a low estimate because most of the pregnancies were exposed for 72 hours or less. In general, ductal constriction is a potentially serious complication that should be avoided. Thus, drug administration duration is typically limited to < 72 hours, and those on NSAIDs are closely monitored so that these can be discontinued if constriction is identified.

Uterine Artery



Uterine blood flow is estimated to increase from 50 mL/min early in gestation to 500 to 750 mL/min by term (see Chap. 5, p. 108). The uterine artery Doppler waveform is unique and characterized by high diastolic flow velocities similar to those in systole (Fig. 16-26). There is also highly turbulent flow, which displays a spectrum of many different velocities. Increased resistance to flow and development of a diastolic notch have been associated with pregnancy-induced hypertension (Arduini, 1987; Fleischer, 1986; Harrington, 1996; North, 1994, and all their colleagues). More recently, Zeeman and co-workers (2003) confirmed that increased impedance of uterine artery velocimetry at 16 to 20 weeks was predictive of superimposed preeclampsia developing in women with chronic hypertension. In a report from the recent workshop on prenatal imaging held by the National Institute of Child Health and Human Development, Reddy and associates (2008) concluded that perinatal benefits of uterine artery Doppler screening have not yet been demonstrated.

Middle Cerebral Artery (MCA)

Doppler measurement of middle cerebral artery velocimetry has been studied and employed clinically for detection of fetal anemia and in the assessment of growth restriction. Although accurate measurement of velocity in other vessels may be limited by high insonating angles, MCA measurements are an exception. Anatomically, the path of this artery is such that flow velocity approaches the transducer "head-on," and the fontanel allows easy insonation (**Fig. 16-28**).

With fetal anemia, the peak systolic velocity is increased due to increased cardiac output and decreased blood viscosity (Segata and Mari, 2004). This has permitted the reliable, noninvasive detection of fetal anemia in cases of blood-group alloimmunization. More than a decade ago, Mari and colleagues (1995) performed MCA velocity studies in 135 normal fetuses and 39 with alloimmunization. They showed that anemic fetuses had a peak systolic velocity above the normal mean. In a subsequent collaborative study of 376 pregnancies, Mari and colleagues (2000) used a threshold of 1.50 multiple of the median (MoM) for peak systolic velocity to correctly identify all fetuses with moderate or severe anemia. The false-positive rate was 12 percent. Others have since reported similar findings (Bahado-Singh and colleagues, 2000; Cosmi and associates, 2002). In many centers, MCA peak systolic velocity has replaced invasive testing with amniocentesis for the detection of fetal anemia (see Chap. 29, p. 622).

MCA Doppler has also been studied as an adjunct to the evaluation of fetal-growth restriction. It is believed that there is a progression of Doppler findings in severely affected fetuses such that increased impedance of flow in the umbilical artery may be detected first. This is followed by redistribution of flow to the brain, with decreasing resistance that has been termed *brain sparing*, and eventually by abnormalities in venous flow (Mari, 2007; Reddy, 2008; Turan, 2008, and all their colleagues). Unfortunately, this brain-sparing effect has not been shown to be protective for the fetus—in fact, it is more likely the opposite. At this time, MCA Doppler has *not* been adopted as standard practice in the management of growth restriction, and its utility in the timing of delivery of such fetuses is uncertain.

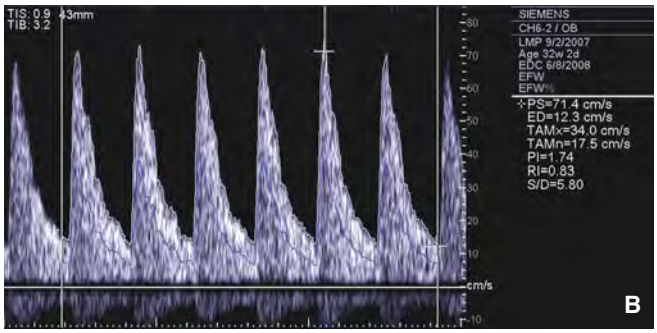


FIGURE 16-28 Middle cerebral artery color Doppler (**A**) and waveform (**B**) in a 32-week fetus with elevated peak systolic velocity secondary to fetal anemia from Rh alloimmunization.

Ductus Venosus

In the setting of severe fetal-growth restriction, cardiac dysfunction may lead to venous flow abnormalities, including pulsatile flow in the umbilical vein and abnormal ductus venosus waveforms (Reddy and associates, 2008). Ductus venosus abnormalities may identify preterm growth-restricted fetuses that are at greatest risk for adverse outcomes (Baschat, 2003, 2004; Bilardo and co-workers, 2004; Figueras and associates, 2009). Trudinger (2007) has proposed that understanding and treatment of the underlying placental vasculopathy are likely to be more important for improving outcomes than for focusing on early delivery. In the workshop on prenatal imaging held by the National Institute of Child Health and Human Development, Reddy and colleagues (2008) concluded that use of venous Doppler for the management of fetal-growth restriction requires demonstration of perinatal benefit before adoption.

M-MODE ECHOCARDIOGRAPHY

Motion-mode, or M-mode sonography is a linear display of the events of the cardiac cycle, with time on the x-axis and motion on the y-axis. It is used commonly to measure the fetal heart rate, and deviations from the normal rate and rhythm are readily apparent. If there is an abnormality, an evaluation of cardiac anatomy is performed. M-mode echocardiography may allow precise characterization of an arrhythmia, including separate evaluation of atrial and ventricular waveforms. It can be used to assess ventricular function and atrial and ventricular outputs, as well as the timing of these events.

Newer applications of color mapping onto the M-mode tracing permit exquisite evaluation of wall motion and blood velocity and categorization of complex arrhythmias (**Fig. 16-29**). Importantly, some of these, for example, supraventricular tachycardias, can be treated to prevent or reverse heart failure. Others, such as premature atrial contractions, resolve spontaneously without intervention. Antenatal treatment is discussed in Chapter 13 (p. 303).

MAGNETIC RESONANCE (MR) IMAGING

The fetus was first studied with MR imagining in the mid-1980s when image acquisition was slow and motion artifact was problematic. Since then, technological advances allowing fast-acquisition MR protocols have been developed. These include SSFSE—Single Shot Fast Spin Echo sequence; HASTE—Half-

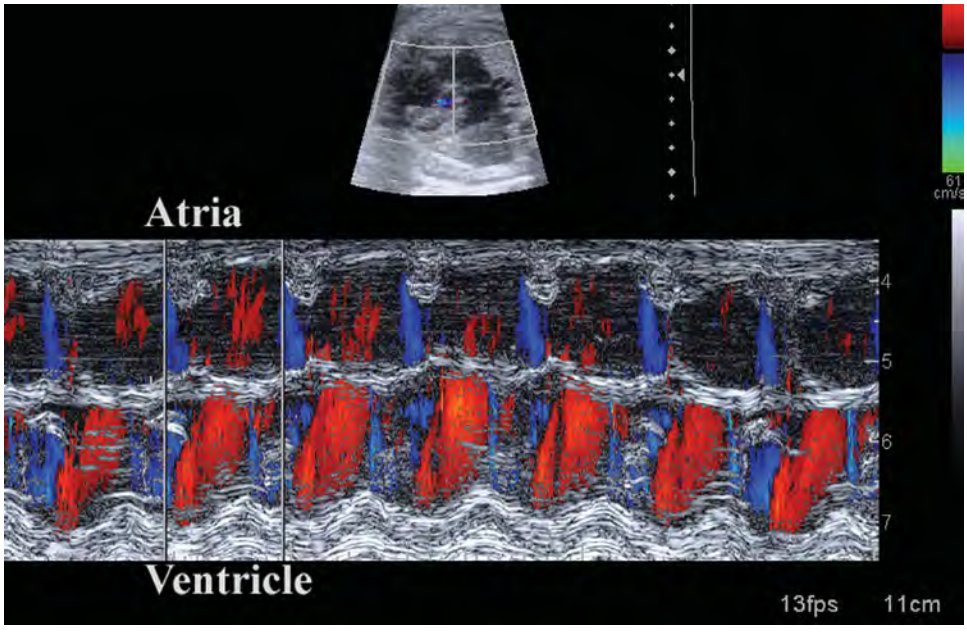

FIGURE 16-29 M-mode with superimposed color Doppler demonstrates the normal concordance between the atrial and ventricular contractions.

Fourier Acquisition Single shot Turbo spin Echo sequence; RARE—Rapid Acquisition with Relaxation Enhancement sequence; and echo-planar imaging. Images are acquired within 1 second or less, eliminating the need for sedation because motion artifact is significantly reduced.

Technologically speaking, MR imaging is superior to sonography because it is hindered only minimally by bony interfaces, maternal obesity, oligohydramnios, or an engaged fetal head. Pragmatically, however, MR imaging is not portable, and it can be time-consuming. Thus, it currently is used as an adjunct to fetal sonography, especially for complex abnormalities of the central nervous system, thorax, and gastrointestinal and genitourinary systems (Farhataziz, 2005; Hawkins, 2008; Matsuoka, 2003; Twickler, 2003, and all their associates).

Safety

MR imaging uses no ionizing radiation however, theoretical concerns include the effects of fluctuating electromagnetic fields and high sound-intensity levels. The strength of the magnetic field is measured in *tesla (T)*. A number of animal and tissue studies have been conducted that address the biological effects of electromagnetic fields. In one, Wiskirchen and colleagues (1999) studied long-term effects of repetitive exposure of human lung fibroblasts to a static 1.5 T magnetic field. They found that exposed and control cells had similar proliferation.

Human studies, although relatively few in number, support the safety of fetal MR imaging. Kanal (1994) reported a large epidemiological retrospective study of nurses and technologists working with MR imaging in which rates of pregnancy loss, infertility, low birth weight, and preterm birth were compared before and after employment. There was no increased incidence of adverse outcome in the MR-exposed group. Two follow-up studies from Nottingham, England, described children exposed to echo-planar MR in utero. In one, Baker and colleagues (1994b) did a three-year follow-up of 20 children and found no increased incidence of disease or disability. In the second, Clements and associates (2000) prospectively followed 20 infants exposed in utero to echo-planar MR imaging and found that pediatric assessments at age 9 months were normal.

Glover and colleagues (1995) attempted to mimic the sound level experienced by the fetal ear during an MR procedure. An adult volunteer swallowed a microphone connected to a thin lead, and the stomach was filled with a liter of fluid to represent the amnionic sac. There was at least a 30-dB attenuation in intensity from the body surface to the fluid-filled stomach. This reduced the acoustic sound pressure down from the dangerous threshold of 120 dB to an acceptable level < 90 dB. This is considerably less than the 135 dB experienced when vibroacoustic stimulation is used (see Chap. 18, p. 427). Arulkuman and associates (1991) reported no evidence of hearing loss in 450 babies exposed to vibroacoustic stimulation. Finally, fetal heart rate patterns and movements during MR procedures demonstrated no change (Vadeyar, 2000).

Studies in pregnancy reported to date have been performed with a magnet strength of 1.5 T or less. It is recommended that informed consent be obtained when fetal MR is performed. In more than 1600 MR procedures performed during pregnancy at the University of Texas Southwestern Medical Center over the past 8 years, there have been no patient safety issues. Maternal anxiety from claustrophobia or fear of the equipment was encountered in less than 1 percent. To reduce maternal anxiety in this small group, a one-time oral dose of diazepam, 5 to 10 mg, or lorazepam, 1 to 2 mg, is given. For some equipment, the maternal weight limit is 350 pounds—thus some obese women will not be candidates (Zaretsky and Twickler, 2003d).

Fetal Anatomic Survey

Although there is experience with normal fetal anatomy imaged with MR imaging, there have been no comparisons with contemporaneous sonography. Zaretsky and colleagues (2003b) applied the American College of Obstetrics and Gynecology ultrasound criteria to an axial sequence and reported that 85 percent of the anatomical targets were adequately visualized. Using axial, coronal, and sagittal MR acquisitions, this same group found that 99 percent of targeted anatomy—excluding the heart—was visualized (Zaretsky and associates, 2003a). In both studies, nonfetal components that included the placenta, amnionic fluid, and maternal pelvis were visualized adequately. These studies and others indicate that MR imaging is more informative beyond 20 weeks.

Central Nervous System

Although sonography is the preferred method of imaging fetal intracranial abnormalities, MR images are superior in many ways because of the improved resolution. Thus, MR imaging is a valuable adjunct in the antenatal diagnosis of some suspected cranial anomalies. Very fast T2 weighted images produce excellent tissue contrast, and cerebrospinal-fluid-containing structures are hyperintense or bright. This allows exquisite detail of the posterior fossa, midline structures, and cerebral cortex. Near-field attenuation caused by the fetal skull on sonography is not a problem with MR imaging, and this feature allows accurate determination of lesion bilaterality. Another major advantage is acquisition of images in the axial, coronal, and sagittal planes in reference to the fetus or the maternal pelvis. Sagittal fetal images are very helpful, for example, in evaluating the corpus callosum when there is mild ventriculomegaly. T1-weighted images are occasionally used to differentiate between fat and hemorrhage.

Routine MR biometry includes BPD, occipitofrontal diameter (OFD), cerebellar width, and cisterna magna and bilateral atrial measurements. Twickler and associates (2002) measured ventricle and cisterna magna values in 60 fetuses from 14 weeks to term. They reported that although atrial measurements are slightly smaller with MR compared with sonography, cisterna magna measurements were similar. Tables have been established for measurements of multiple components of normal brain biometry, including corpus callosum length and cerebellar vermis (Garel, 2004; Tilea and colleagues, 2009).

Fetal Brain Development

Levine and Barnes (1999a) reported that cortical maturation evaluated with MR imaging accurately portrayed cerebral gyra-

tion and sulcation patterns of embryological development. This is important because fetuses with a cerebral abnormality may have a significant lag time in cortical development. And although sonography is limited to evaluate subtle early migrational abnormalities, MR imaging is more accurate, and even more so later in gestation.

Second Opinion MR Imaging Evaluation

At least three large studies have assessed second-opinion MR examination for a cerebral abnormality detected by sonography and its ability to confirm or change a diagnosis and possibly alter clinical management. Levine and co-workers (1999b) evaluated 66 fetuses with such abnormalities and found that MR imaging provided additional information in nearly 60 percent and changed the diagnosis in 40 percent. Importantly, management was clearly changed in 15 percent. Simon and colleagues (2000) studied 73 fetuses with brain anomalies and reported that MR imaging findings changed management in almost half. Twickler and co-workers (2003) reported that MR imaging provided valuable additional information in 65 percent of 72 fetuses. Moreover, in half of these 46 cases, the diagnosis was changed, and this altered clinical management in a third. Evaluation with MR imaging was more likely to confirm sonographic findings prior to 24 weeks, but beyond that 24 weeks, a change of diagnosis or additional information was more frequently found.

The most common reason for fetal MR evaluation is isolated ventriculomegaly. Commonly associated abnormalities may not be well visualized with sonography. For example, in the study by Twickler and associates (2003), the diagnosis of marked ventriculomegaly was narrowed to a more precise diagnosis such as aqueductal stenosis or hydranencephaly (Fig. 16-30). Another was from mild ventriculomegaly to more specific diagnoses such as corpus callosum agenesis and migrational abnormalities. These findings were recently confirmed by Benacerraf and colleagues (2007). These more precise diagnoses impact patient counseling and, to a lesser degree, clinical management.

Cerebral Lesions with Multifetal Gestation

Hu and Twickler (2006) recently reviewed MR findings with complicated multifetal gestations. MR imaging has been used to evaluate monochorionic twin gestations for the possibility of hemorrhage or periventricular leukomalacia in the setting of twin-twin transfusion syndrome or with demise of one twin. Documentation of these problems is particularly important when placental ablation of the vascular anastomoses is considered (see Chap. 13, p. 306, and Chap. 39, p. 874).

Thorax

MR imaging is used to further evaluate thoracic masses and abnormalities to delineate their location and size and to quantify the volume of remaining lung tissue. The tissue contrast between normal lung tissue and thoracic lesions is excellent in most cases. Thoracic abnormalities that are studied further with MR imaging include congenital cystic adenomatoid malformations (CCAM), bronchopulmonary sequestrations (BPS), congenital diaphragmatic hernias (CDH), and chylothoraces (Fig. 16-31). It is also helpful with abnormalities that cause pulmonary hypoplasia such as renal and skeletal dysplasias.

MR imaging is an excellent adjunct to sonography to evaluate fetuses with a congenital diaphragmatic hernia. It aids determination of liver position and identification of abdominal

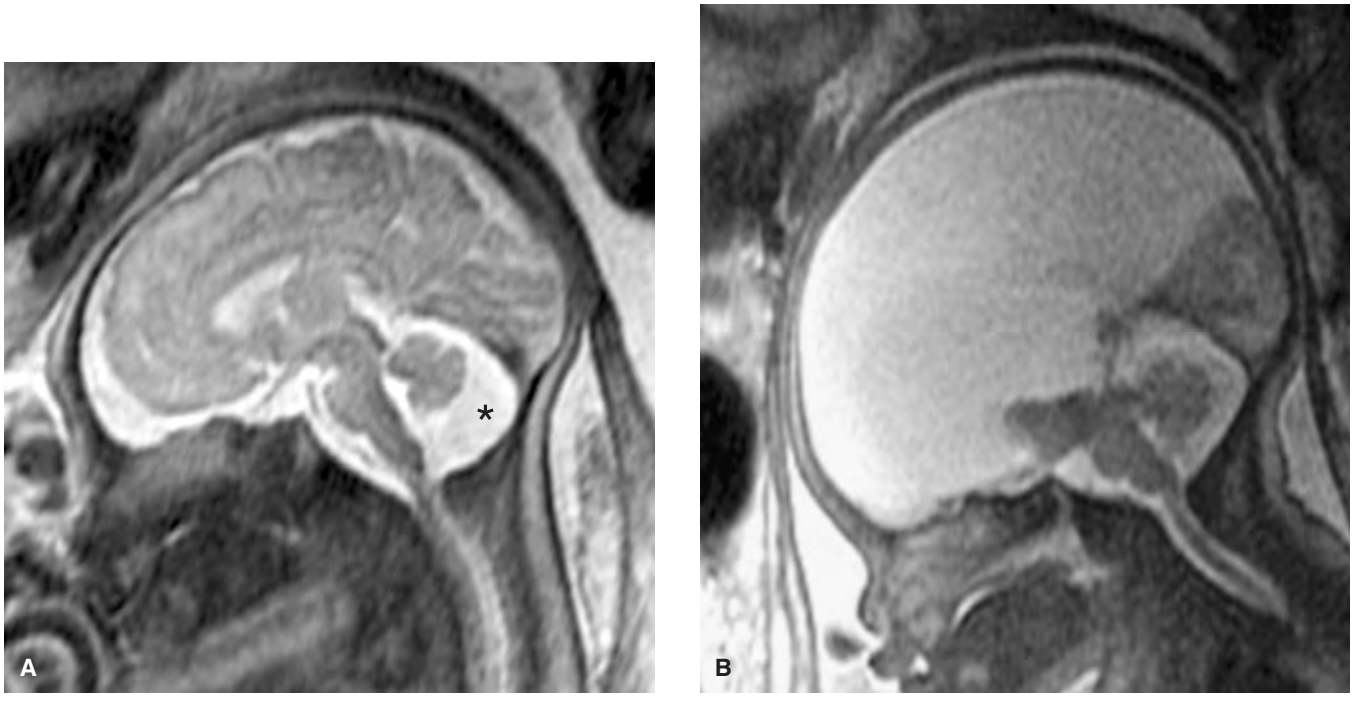

FIGURE 16-30 Magnetic resonance imaging of the fetal brain. **A.** Midline sagittal image of a 37-week fetal brain with a prominent cisterna magna (*asterisk*) and normal vermis. **B.** Midline sagittal image of a 35-week fetal brain with hydranencephaly.

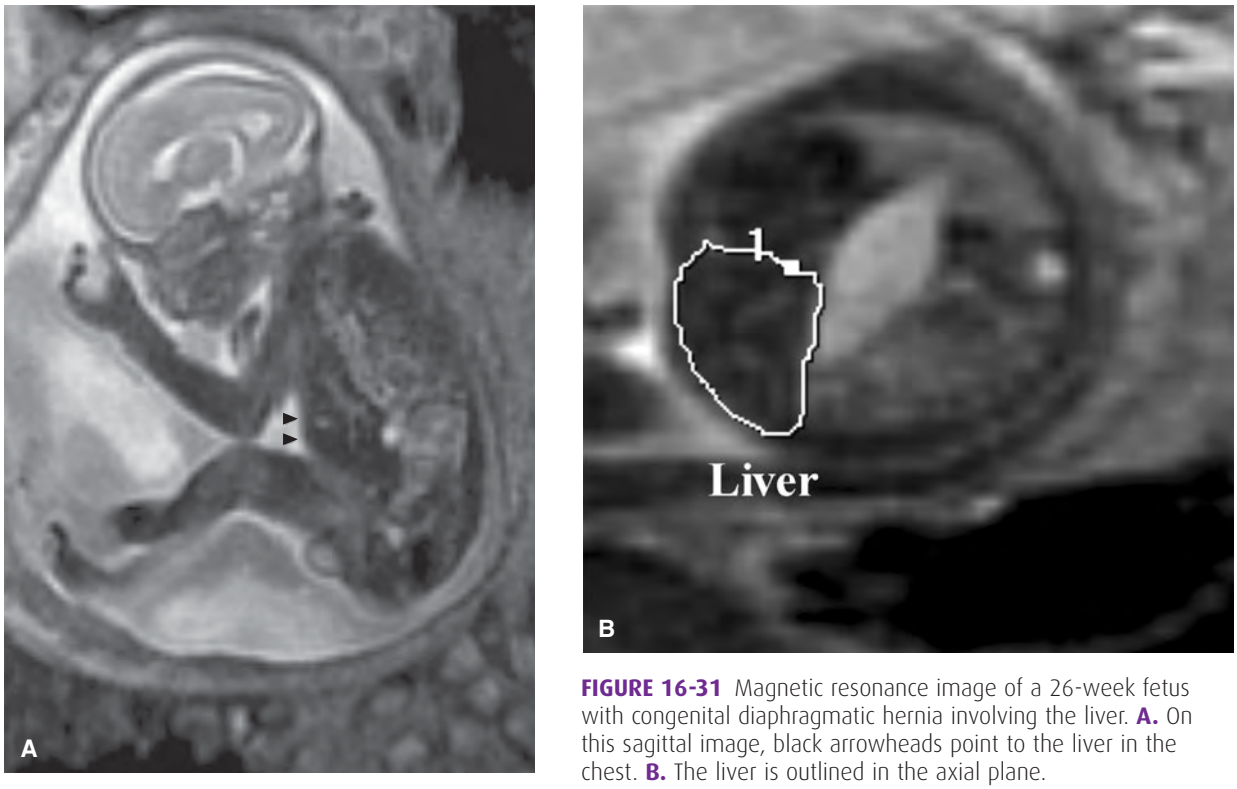

FIGURE 16-31 Magnetic resonance image of a 26-week fetus with congenital diaphragmatic hernia involving the liver. **A.** On this sagittal image, black arrowheads point to the liver in the chest. **B.** The liver is outlined in the axial plane.

contents within the chest (Fig. 16-31) (Hedrick, 2007; Walsh, 2000; Worley, 2009, and all their associates). Findings have been especially helpful in right-sided diaphragmatic hernias.

In some of these cases, prognosis can be estimated by the amount of normal lung tissue that remains or by the percentage of thorax occupied by the fetal liver (Kilian and co-workers, 2009; Worley and colleagues, 2009). However, the lung volume/gestational age ratio as a predictor of lethality with diaphragmatic hernia has shown little utility. In contrast, with renal disorders, this ratio was significantly different between groups with lethal and nonlethal malformations (Zaretsky and colleagues, 2005a).

Abdomen

In many cases, sonography accurately diagnoses genitourinary abnormalities and is the preferred modality. With oligohydramnios or maternal obesity, however, MR imaging is useful to evaluate complex anomalies. Poutamo and co-workers (2000) evaluated 24 fetuses with either oligohydramnios or a suspected urinary tract abnormality. MR evaluation alone led to the diagnosis in eight cases. It added information in 5 of 12 cases complicated by oligohydramnios and in three of 10 cases with normal amnionic fluid volumes. Caire and colleagues (2003) also found MR imaging to be an excellent technique for studying complex anatomical genitourinary malformations.

Determining the origin of a fetal cystic abdominal mass is difficult, especially in the third trimester. In some cases, MR imaging can help differentiate between genitourinary and gastrointestinal abnormalities. The signal intensity of meconium in the colon and urine in the bladder were evaluated in 80 fetuses by Farhataziz and colleagues (2005). They reported that characteristic MR signals of each were most helpful after 24 weeks. In over half of suspected gastrointestinal or genitourinary abnormalities, T1-weighted images added additional information.

Placenta

The clinical importance of identifying women with placenta accreta is discussed in Chapter 35 (p. 776). These women are at risk for severe hemorrhage and hysterectomy, and MR imaging findings may help in surgical planning and patient counseling. Sonography is used to identify myometrial invasion, and MR evaluation can be used as an adjunct in indeterminate cases.

Levine and co-workers (1997) compared the accuracy of MR imaging with that of transabdominal and transvaginal gray-scale sonography with color and power Doppler. Transvaginal sonography was adequate to diagnose six of seven cases of accreta. The remaining case was a posterior placenta accreta that was diagnosed accurately using MR imaging. These investigators reported MR imaging to be helpful only in cases in which the placenta lay outside the range for both transabdominal and transvaginal sonography. Conversely, Warshak and associates (2006) compared MR imaging with sonography and found MR imaging to be superior to evaluate myometrial invasion. Our experience is that sonography is excellent to determine myometrial involvement (**Fig. 16-32**). If sonography with Doppler color flow mapping demonstrates large intraplacental lakes and myometrial thickness < 1 mm, the sensitivity for myometrial invasion is 100 percent (Twickler and colleagues,

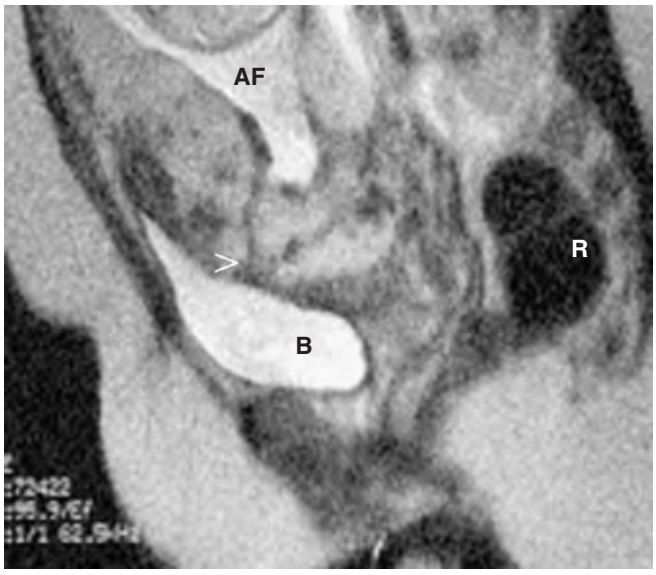

FIGURE 16-32 Magnetic resonance image of placenta increta at 35 weeks. A bridging vessel (*arrowhead*) between the retroplacental vessels and bladder serosal interface. AF = amnionic fluid; B = bladder; R = rectum.

2000). Identification of placenta percreta with bladder wall invasion is less accurate even when both sonography and MR imaging are used.

Fetal and Uterine Volumetry

MR imaging has been used to determine specific organ volumes, and it is potentially useful to reconstruct a 3-D image. Garden and co-workers (1996) used serial MR imaging and reported volume determinations of the fetus and the fetal liver, lungs, and brain. Baker and associates (1994a) calculated fetal weight determined by volume and reported that it compared favorably with sonographic estimated weight. Zaretsky and colleagues (2003c) studied the accuracy of MR imaging versus sonography for fetal weight estimation in 80 women and found good correlations using the Baker equation.

Pelvimetry

A number of studies have used MR pelvimetry to assess pelvic capacity and predict vaginal delivery (see Chap. 20, p. 472). None has been found clinically valuable (Zaretsky and colleagues, 2005b).

SECTION 4

LABOR AND DELIVERY

CHAPTER 17

Normal Labor and Delivery

MECHANISMS OF LABOR 374
CHARACTERISTICS OF NORMAL LABOR 382
MANAGEMENT OF NORMAL LABOR AND DELIVERY . . . 390
LABOR MANAGEMENT PROTOCOLS 405

Childbirth is the period from the onset of regular uterine contractions until expulsion of the placenta. The process by which this normally occurs is called *labor*—a term that in the obstetrical context takes on several connotations from the English language. According to the *New Shorter Oxford English Dictionary* (1993), toil, trouble, suffering, bodily exertion, especially when painful, and an outcome of work are all characteristics of *labor* and thus implicated in the process of childbirth. Such connotations all seem appropriate to us and emphasize the need for all attendants to be supportive of the laboring woman's needs, particularly in regard to effective pain relief.

At Parkland Hospital in 2007, only 50 percent of 13,991 women with singleton cephalic presentations at term had a spontaneous labor and delivery. The remainder had ineffective labor requiring augmentation, had other medical and obstetrical complications requiring induction of labor, or underwent cesarean delivery. It seems excessive to consider 50 percent of parturients as "abnormal" because they did not spontaneously labor and deliver. Hence, the distinction between normal and abnormal is often subjective. This high prevalence of labor abnormalities, however, can be used to underscore the importance of labor events in the successful outcome of pregnancy.

MECHANISMS OF LABOR

At the onset of labor, the position of the fetus with respect to the birth canal is critical to the route of delivery. Thus, fetal position within the uterine cavity should be determined at the onset of labor.

Fetal Lie, Presentation, Attitude, and Position

Fetal orientation relative to the maternal pelvis is described in terms of fetal lie, presentation, attitude, and position.

Fetal Lie

The relation of the fetal long axis to that of the mother is termed *fetal lie* and is either *longitudinal* or *transverse.* Occasionally, the fetal and the maternal axes may cross at a 45-degree angle, forming an *oblique lie*, which is unstable and always becomes longitudinal or transverse during labor. A longitudinal lie is present in greater than 99 percent of labors at term. Predisposing factors for transverse lies include multiparity, placenta previa, hydramnios, and uterine anomalies (see Chap. 20, p. 476).

Fetal Presentation

The *presenting part* is that portion of the fetal body that is either foremost within the birth canal or in closest proximity to it. It can be felt through the cervix on vaginal examination. Accordingly, in longitudinal lies, the presenting part is either the fetal head or breech, creating *cephalic* and *breech presentations*, respectively. When the fetus lies with the long axis transversely, the *shoulder* is the presenting part and is felt through the cervix on vaginal examination. Table 17-1 describes the incidences of the various fetal presentations.

Cephalic Presentation. Such presentations are classified according to the relationship between the head and body of the fetus (Fig. 17-1). Ordinarily, the head is flexed sharply so that the chin is in contact with the thorax. The occipital fontanel is the presenting part, and this presentation is referred to as a *vertex* or *occiput presentation.* Much less commonly, the fetal neck may be sharply extended so that the occiput and back come in contact,

TABLE 17-1. Fetal Presentation in 68,097 Singleton Pregnancies at Parkland Hospital

Presentation	Percent	Incidence
Cephalic	96.8	—
Breech	2.7	1:36
Transverse lie	0.3	1:335
Compound	0.1	1:1000
Face	0.5	1:2000
Brow	0.01	1:10,000

and the face is foremost in the birth canal—*face presentation* (see Fig. 20-6, p. 474). The fetal head may assume a position between these extremes, partially flexed in some cases, with the anterior (large) fontanel, or bregma, presenting—*sinciput presentation*—or partially extended in other cases, to have a *brow presentation* (see Fig. 20-8, p. 476). These latter two presentations are usually transient. As labor progresses, sinciput and brow presentations almost always convert into vertex or face presentations by neck flexion or extension, respectively. Failure to do so can lead to dystocia, as discussed in Chapter 20 (p. 476).

The term fetus usually presents with the vertex, most logically because the uterus is piriform or pear shaped. Although the fetal head at term is slightly larger than the breech, the entire *podalic pole* of the fetus—that is, the breech and its flexed extremities—is bulkier and more mobile than the cephalic pole. The *cephalic pole* is composed of the fetal head only. Until approximately 32 weeks, the amnionic cavity is large compared with the fetal mass, and there is no crowding of the fetus by the uterine walls. Subsequently, however, the ratio of amnionic fluid volume decreases relative to the increasing fetal mass. As a result, the uterine walls are apposed more closely to the fetal parts.

If presenting by the breech, the fetus often changes polarity to make use of the roomier fundus for its bulkier and more mobile podalic pole. As discussed in Chapter 24 (p. 527 and Fig. 24-1), the incidence of breech presentation decreases with gestational age. It is approximately 25 percent at 28 weeks, 17 percent at 30 weeks, 11 percent at 32 weeks, and then decreases to approximately 3 percent at term. The high incidence of breech presentation in hydrocephalic fetuses is in accord with this theory, because in this circumstance, the fetal cephalic pole is larger than its podalic pole.

Breech Presentation. When the fetus presents as a breech, the three general configurations are *frank, complete,* and *footling presentations* and are described in Chapter 24 (p. 527). Breech presentation may result from circumstances that prevent normal version from taking place, for example, a septum that protrudes into the uterine cavity (see Chap. 40, p. 897). A peculiarity of fetal attitude, particularly extension of the vertebral column as seen in frank breeches, also may prevent the fetus from turning. If the placenta is implanted in the lower uterine segment, it may distort normal intrauterine anatomy and result in a breech presentation.

Fetal Attitude or Posture

In the later months of pregnancy the fetus assumes a characteristic posture described as attitude or habitus (see Fig. 17-1). As a rule, the fetus forms an ovoid mass that corresponds roughly to the shape of the uterine cavity. The fetus becomes folded or bent upon itself in such a manner that the back becomes markedly convex; the head is sharply flexed so that the chin is almost in contact with the chest; the thighs are flexed over the abdomen; and the legs are bent at the knees. In all cephalic presentations, the arms are usually crossed over the thorax or become parallel to the sides. The umbilical cord lies in the space between them and the lower extremities. This characteristic posture results from the mode of fetal growth and its accommodation to the uterine cavity.

Abnormal exceptions to this attitude occur as the fetal head becomes progressively more extended from the vertex to the face presentation (see Fig. 17-1). This results in a progressive change in fetal attitude from a convex (flexed) to a concave (extended) contour of the vertebral column.

Fetal Position

Position refers to the relationship of an arbitrarily chosen portion of the fetal presenting part to the right or left side of the birth canal. Accordingly, with each presentation there may be two positions—right or left. The fetal occiput, chin (mentum), and sacrum are the determining points in vertex, face, and breech presentations, respectively (**Figs. 17-2** to **17-6**). Because the presenting part may be in either the left or right position, there are left and right occipital, left and right mental, and left and right sacral presentations, abbreviated as LO and RO, LM and RM, and LS and RS, respectively.

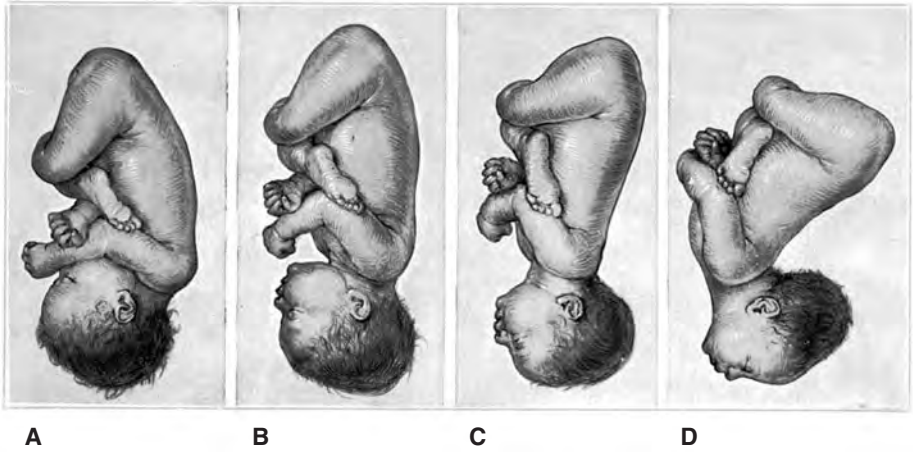

FIGURE 17-1 Longitudinal lie. Cephalic presentation. Differences in attitude of the fetal body in **(A)** vertex, **(B)** sinciput, **(C)** brow, and **(D)** face presentations. Note changes in fetal attitude in relation to fetal vertex as the fetal head becomes less flexed.

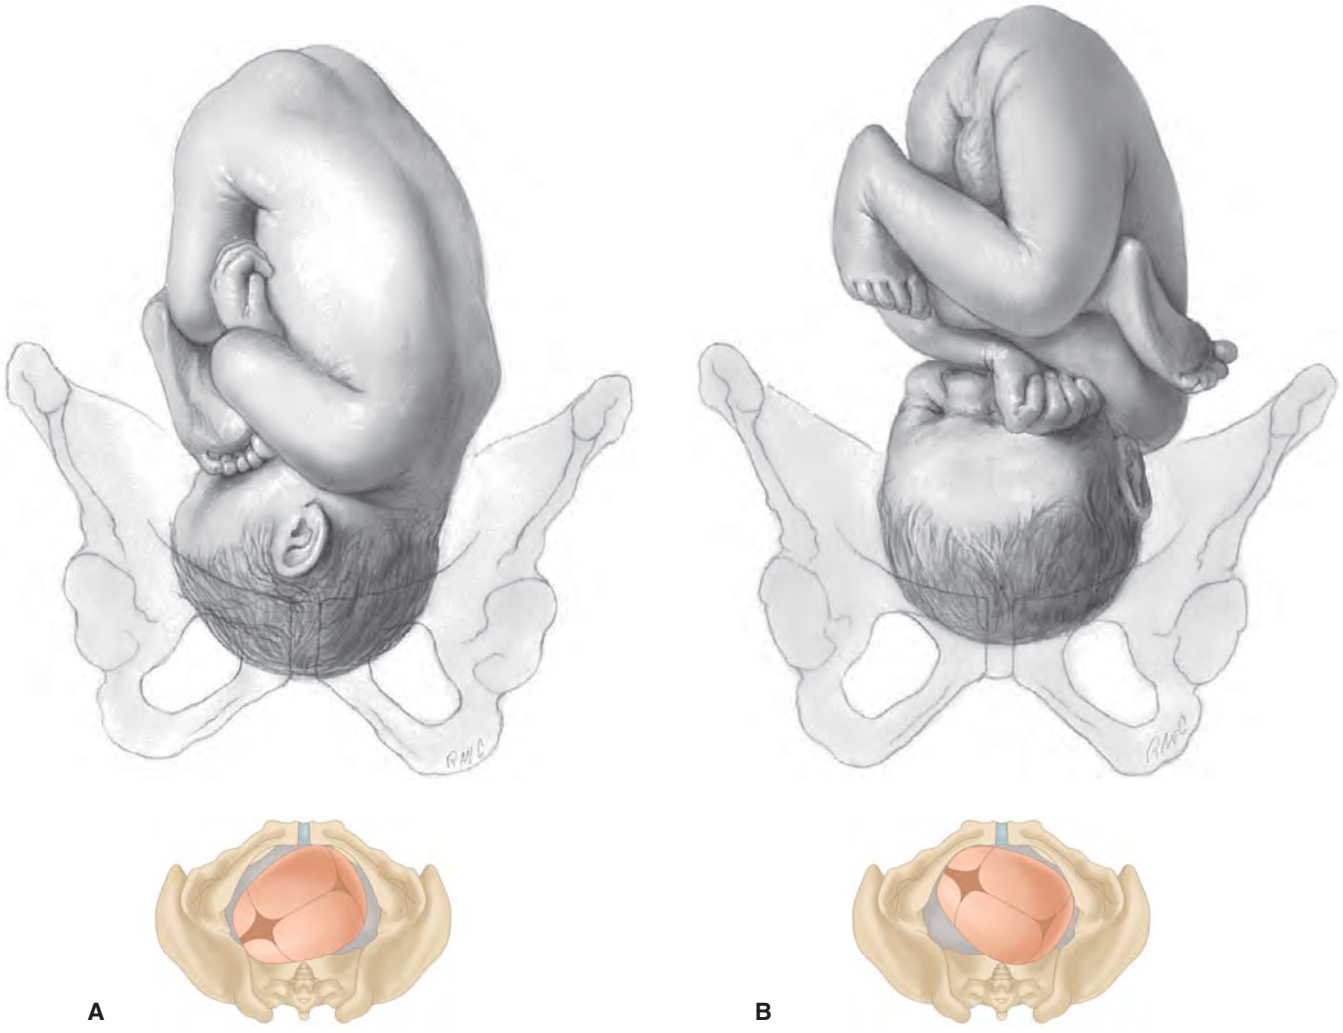

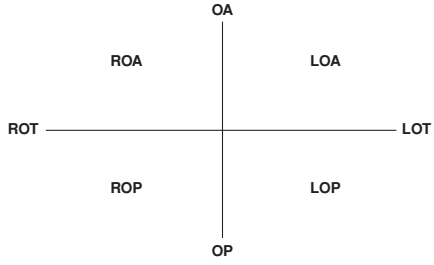

FIGURE 17-2 Longitudinal lie. Vertex presentation. **A.** Left occiput anterior (LOA). **B.** Left occiput posterior (LOP).

Varieties of Presentations and Positions

For still more accurate orientation, the relationship of a given portion of the presenting part to the anterior, transverse, or posterior portion of the maternal pelvis is considered. Because the presenting part in right or left positions may be directed anteriorly (A), transversely (T), or posteriorly (P), there are six varieties of each of the three presentations (see Figs. 17-2 to 17-6). Thus, in an occiput presentation, the presentation, position, and variety may be abbreviated in clockwise fashion as:

Approximately two thirds of all vertex presentations are in the left occiput position, and one third in the right.

In shoulder presentations, the acromion (scapula) is the portion of the fetus arbitrarily chosen for orientation with the maternal pelvis. One example of the terminology sometimes employed for this purpose is illustrated in **Figure 17-7**. The acromion or back of the fetus may be directed either posteriorly or anteriorly and superiorly or inferiorly (see Chap. 20, p. 476). Because it is impossible to differentiate exactly the several varieties of shoulder presentation by clinical examination and because such differentiation serves no practical purpose, it is customary to refer to all transverse lies simply as *shoulder presentations.* Another term used is *transverse lie,* with *back up* or *back down.*

Diagnosis of Fetal Presentation and Position

Several methods can be used to diagnose fetal presentation and position. These include abdominal palpation, vaginal examination, auscultation, and, in certain doubtful cases, sonography. Occasionally plain radiographs, computed tomography, or magnetic resonance imaging may be used.

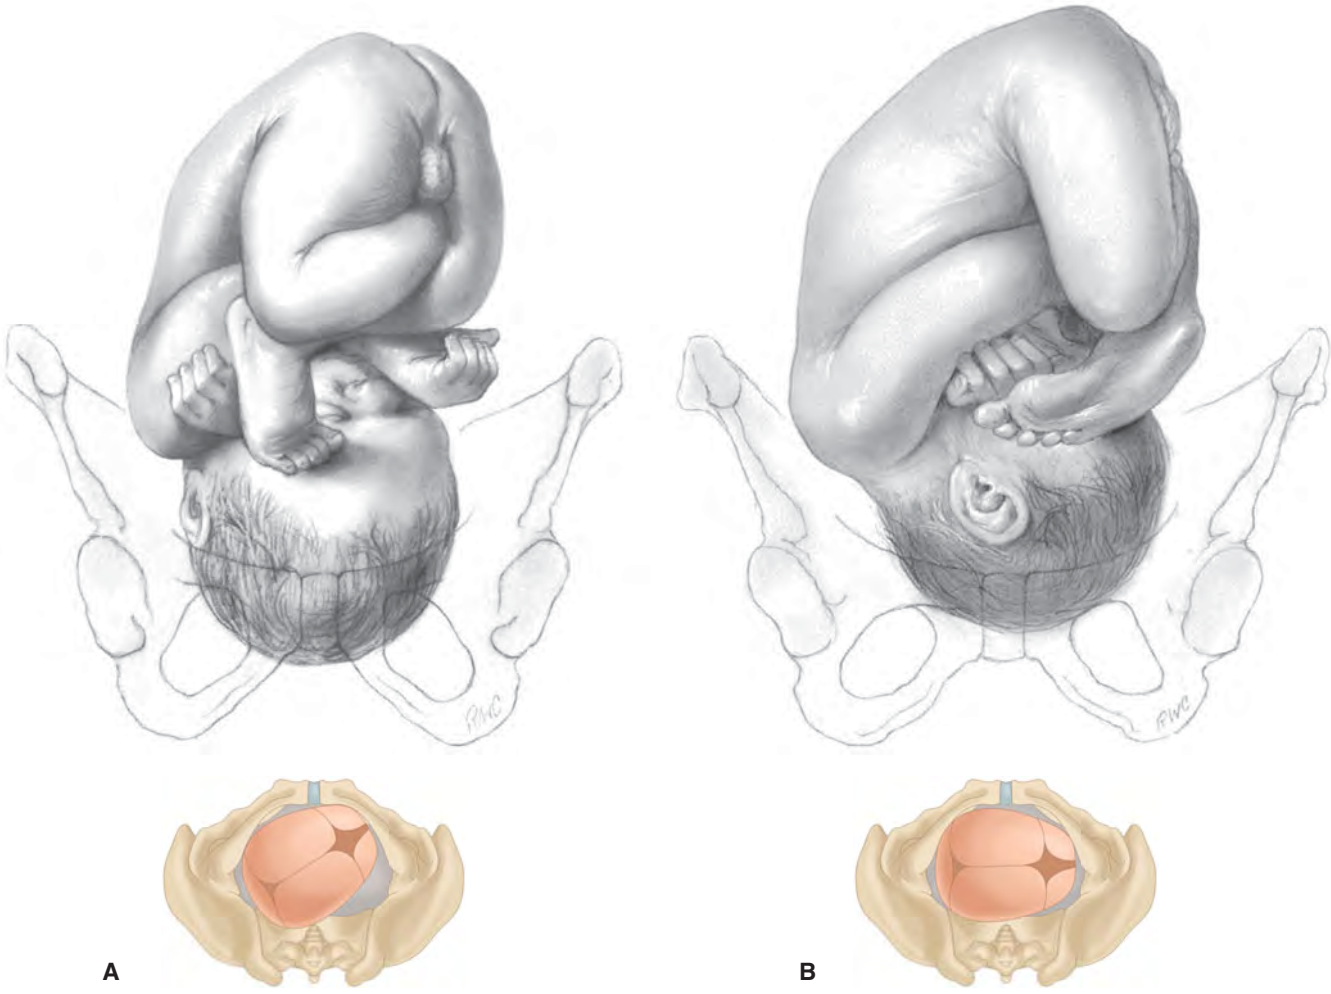

FIGURE 17-3 Longitudinal lie. Vertex presentation. **A**. Right occiput posterior (ROP). **B**. Right occiput transverse (ROT).

Abdominal Palpation—Leopold Maneuvers

Abdominal examination can be conducted systematically employing the four maneuvers described by Leopold in 1894 and shown in **Figure 17-8**. The mother lies supine and comfortably positioned with her abdomen bared. These maneuvers may be difficult if not impossible to perform and interpret if the patient is obese, if there is excessive amnionic fluid, or if the placenta is anteriorly implanted.

1. The first maneuver permits identification of which fetal pole—that is, cephalic or podalic—occupies the uterine fundus. The breech gives the sensation of a large, nodular mass, whereas the head feels hard and round and is more mobile and ballottable
2. Performed after determination of fetal lie, the second maneuver is accomplished as the palms are placed on either side of the maternal abdomen, and gentle but deep pressure is exerted. On one side, a hard, resistant structure is felt—the back. On the other, numerous small, irregular, mobile parts are felt—the fetal extremities. By noting whether the back is directed anteriorly, transversely, or posteriorly, the orientation of the fetus can be determined
3. The third maneuver is performed by grasping with the thumb and fingers of one hand the lower portion of the maternal abdomen just above the symphysis pubis. If the presenting part is not engaged, a movable mass will be felt, usually the head. The differentiation between head and breech is made as in the first maneuver. If the presenting part is deeply engaged, however, the findings from this maneuver are simply indicative that the lower fetal pole is in the pelvis, and details are then defined by the fourth maneuver
4. To perform the fourth maneuver, the examiner faces the mother's feet and, with the tips of the first three fingers of each hand, exerts deep pressure in the direction of the axis of the pelvic inlet. In many instances, when the head has descended into the pelvis, the anterior shoulder may be differentiated readily by the third maneuver.

Abdominal palpation can be performed throughout the latter months of pregnancy and during and between the contractions of labor. With experience, it is possible to estimate the size of the fetus. According to Lydon-Rochelle and colleagues (1993), experienced clinicians accurately identify fetal malpresentation using Leopold maneuvers with a high sensitivity—88

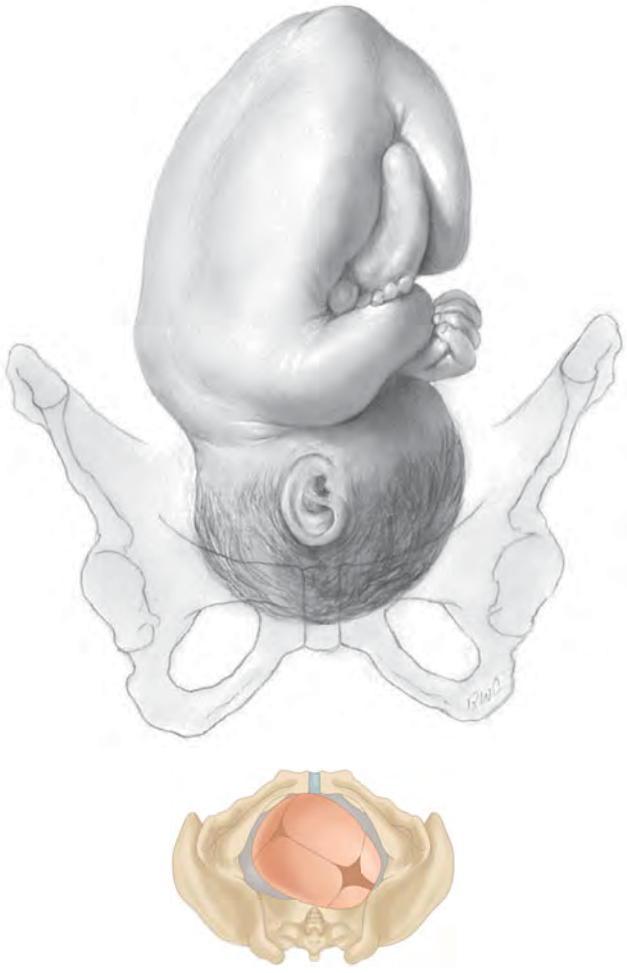

FIGURE 17-4 Longitudinal lie. Vertex presentation. Right occiput anterior (ROA).

percent, specificity—94 percent, positive-predictive value—74 percent, and negative-predictive value—97 percent.

Vaginal Examination

Before labor, the diagnosis of fetal presentation and position by vaginal examination is often inconclusive because the presenting part must be palpated through a closed cervix and lower uterine segment. With the onset of labor and after cervical dilatation, vertex presentations and their positions are recognized by palpation of the various fetal sutures and fontanels. Face and breech presentations are identified by palpation of the facial features and the fetal sacrum, respectively.

In attempting to determine presentation and position by vaginal examination, it is advisable to pursue a definite routine, comprising four movements:

1. The examiner inserts two fingers into the vagina and the presenting part is found. Differentiation of vertex, face, and breech is then accomplished readily
2. If the vertex is presenting, the fingers are directed posteriorly and then swept forward over the fetal head toward the maternal symphysis (**Fig. 17-9**). During this movement, the fingers necessarily cross the sagittal suture and its course is delineated
3. The positions of the two fontanels then are ascertained. The fingers are passed to the most anterior extension of the sagittal suture, and the fontanel encountered there is examined and identified. Then, with a sweeping motion, the fingers pass along the suture to the other end of the head until the other fontanel is felt and differentiated (**Fig. 17-10**)
4. The station, or extent to which the presenting part has descended into the pelvis, can also be established at this time (see p. 392). Using these maneuvers, the various sutures and fontanels are located readily (see Fig. 4-9, p. 84).

Sonography and Radiography

Sonographic techniques can aid identification of fetal position, especially in obese women or in women with rigid abdominal walls. In some clinical situations, information obtained radiographically justifies the minimal risk from a single x-ray exposure (see Chap. 41, p. 915). Zahalka and colleagues (2005) compared digital examinations with transvaginal and transabdominal sonography for determination of fetal head position during second-stage labor and reported that transvaginal sonography was superior.

Mechanisms of Labor with Occiput Anterior Presentation

In most cases, the vertex enters the pelvis with the sagittal suture lying in the transverse pelvic diameter. The fetus enters the pelvis in the *left occiput transverse (LOT)* position in 40 percent of labors and in the *right occiput transverse (ROT)* position in 20 percent (Caldwell and associates, 1934). In *occiput anterior positions—LOA* or *ROA*—the head either enters the pelvis with the occiput rotated 45 degrees anteriorly from the transverse position, or subsequently does so. The mechanism of labor in all these presentations is usually similar.

The positional changes in the presenting part required to navigate the pelvic canal constitute the *mechanisms of labor.* The *cardinal movements of labor* are engagement, descent, flexion, internal rotation, extension, external rotation, and expulsion (**Fig. 17-11**). During labor, these movements not only are sequential but also show great temporal overlap. For example, as part of engagement, there is both flexion and descent of the head. It is impossible for the movements to be completed unless the presenting part descends simultaneously. Concomitantly, uterine contractions effect important modifications in fetal attitude, or habitus, especially after the head has descended into the pelvis. These changes consist principally of fetal straightening, with loss of dorsal convexity and closer application of the extremities to the body. As a result, the fetal ovoid is transformed into a cylinder, with the smallest possible cross section typically passing through the birth canal.

Engagement

The mechanism by which the biparietal diameter—the greatest transverse diameter in an occiput presentation—passes through the pelvic inlet is designated *engagement.* The fetal head may

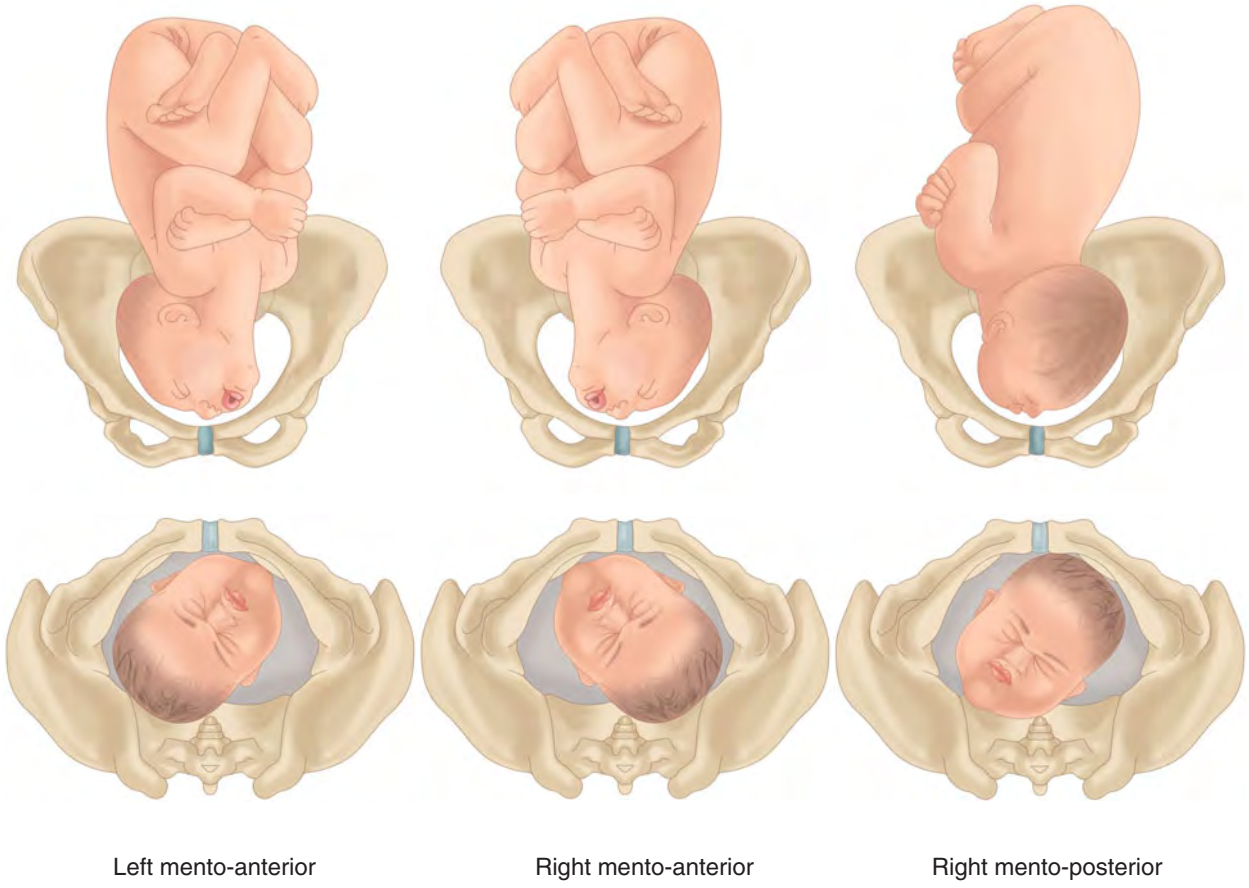

FIGURE 17-5 Longitudinal lie. Face presentation. Left and right mentum anterior and right mentum posterior positions.

FIGURE 17-6 Longitudinal lie. Breech presentation. Left sacrum posterior (LSP).

engage during the last few weeks of pregnancy or not until after labor commencement. In many multiparous and some nulliparous women, the fetal head is freely movable above the pelvic inlet at labor onset. In this circumstance, the head is sometimes referred to as "floating." A normal-sized head usually does not engage with its sagittal suture directed anteroposteriorly. Instead, the fetal head usually enters the pelvic inlet either transversely or obliquely.

Asynclitism. Although the fetal head tends to accommodate to the transverse axis of the pelvic inlet, the sagittal suture, while remaining parallel to that axis, may not lie exactly midway between the symphysis and the sacral promontory. The sagittal suture frequently is deflected either posteriorly toward the promontory or anteriorly toward the symphysis (**Fig. 17-12**). Such lateral deflection to a more anterior or posterior position in the pelvis is called *asynclitism.* If the sagittal suture approaches the sacral promontory, more of the anterior parietal bone presents itself to the examining fingers, and the condition is called *anterior asynclitism.* If, however, the sagittal suture lies close to the symphysis, more of the posterior parietal bone will present, and the condition is called *posterior asynclitism.* With extreme posterior asynclitism, the posterior ear may be easily palpated.

Moderate degrees of asynclitism are the rule in normal labor. However, if severe, the condition is a common reason for cephalopelvic disproportion even with an otherwise normal-sized

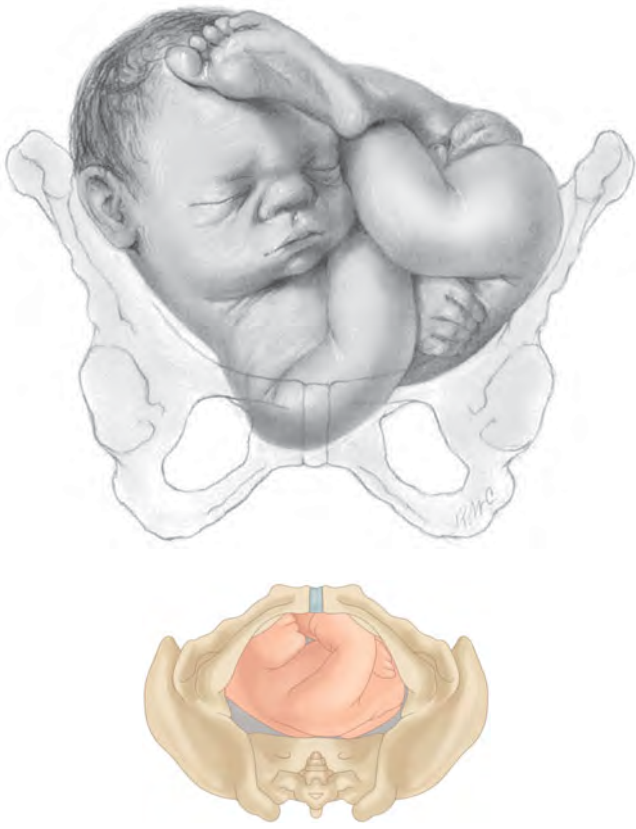

FIGURE 17-7 Transverse lie. Right acromiodorsoposterior (RADP). The shoulder of the fetus is to the mother's right, and the back is posterior.

pelvis. Successive shifting from posterior to anterior asynclitism aids descent.

Descent

This movement is the first requisite for birth of the newborn. In nulliparas, engagement may take place before the onset of labor, and further descent may not follow until the onset of the second stage. In multiparous women, descent usually begins with engagement. Descent is brought about by one or more of four forces: (1) pressure of the amnionic fluid, (2) direct pressure of the fundus upon the breech with contractions, (3) bearing-down efforts of maternal abdominal muscles, and (4) extension and straightening of the fetal body.

Flexion

As soon as the descending head meets resistance, whether from the cervix, walls of the pelvis, or pelvic floor, then flexion of the head normally results. In this movement, the chin is brought into more intimate contact with the fetal thorax, and the appreciably shorter suboccipitobregmatic diameter is substituted for the longer occipitofrontal diameter (**Figs. 17-13** and **17-14**).

Internal Rotation

This movement consists of a turning of the head in such a manner that the occiput gradually moves toward the symphysis pubis anteriorly from its original position or less commonly, posteriorly toward the hollow of the sacrum (**Figs. 17-15**, **17-16**, and **17-17**). Internal rotation is essential for the completion of labor, except when the fetus is unusually small.

Calkins (1939) studied more than 5000 women in labor to the time of internal rotation. He concluded that in approximately two thirds, internal rotation is completed by the time the head reaches the pelvic floor; in about another fourth, internal rotation is completed very shortly after the head reaches the pelvic floor; and in the remaining 5 percent, anterior rotation does not take place. When the head fails to turn until reaching the pelvic floor, it typically rotates during the next one or two contractions in multiparas. In nulliparas, rotation usually occurs during the next three to five contractions.

Extension

After internal rotation, the sharply flexed head reaches the vulva and undergoes extension. If the sharply flexed head, on reaching the pelvic floor, did not extend but was driven farther downward, it would impinge on the posterior portion of the perineum and would eventually be forced through the tissues of the perineum. When the head presses upon the pelvic floor, however, two forces come into play. The first force, exerted by the uterus, acts more posteriorly, and the second, supplied by the resistant pelvic floor and the symphysis, acts more anteriorly. The resultant vector is in the direction of the vulvar opening, thereby causing head extension. This brings the base of the occiput into direct contact with the inferior margin of the symphysis pubis (see Fig. 17-16).

With progressive distension of the perineum and vaginal opening, an increasingly larger portion of the occiput gradually appears. The head is born as the occiput, bregma, forehead, nose, mouth, and finally the chin pass successively over the anterior margin of the perineum (see Fig. 17-17). Immediately after its delivery, the head drops downward so that the chin lies over the maternal anus.

External Rotation

The delivered head next undergoes *restitution* (see Fig. 17-11). If the occiput was originally directed toward the left, it rotates toward the left ischial tuberosity. If it was originally directed toward the right, the occiput rotates to the right. Restitution of the head to the oblique position is followed by completion of external rotation to the transverse position. This movement corresponds to rotation of the fetal body and serves to bring its bisacromial diameter into relation with the anteroposterior diameter of the pelvic outlet. Thus, one shoulder is anterior behind the symphysis and the other is posterior. This movement apparently is brought about by the same pelvic factors that produced internal rotation of the head.

Expulsion

Almost immediately after external rotation, the anterior shoulder appears under the symphysis pubis, and the perineum soon becomes distended by the posterior shoulder. After delivery of the shoulders, the rest of the body quickly passes.

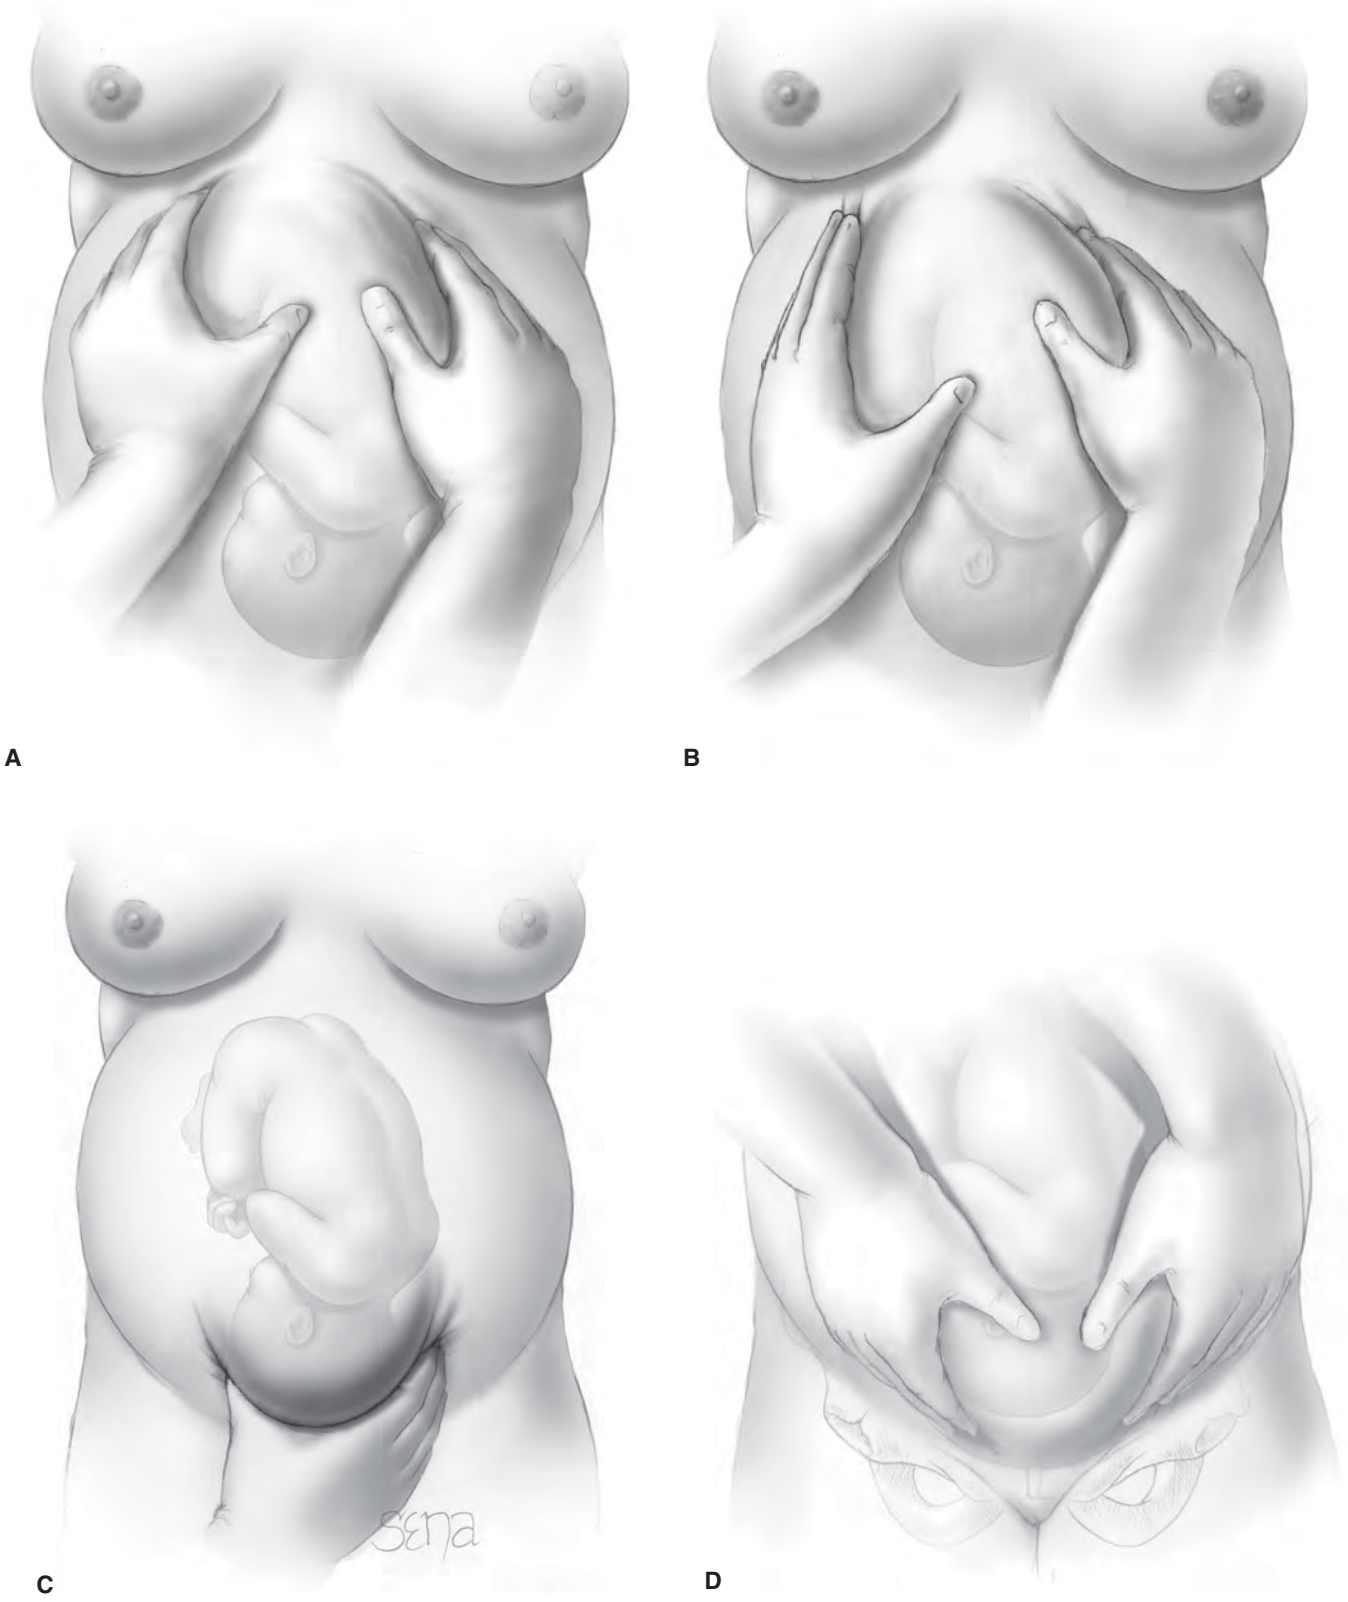

FIGURE 17-8 Leopold maneuvers (**A-D**) performed in fetus with a longitudinal lie in the left occiput anterior position (LOA).

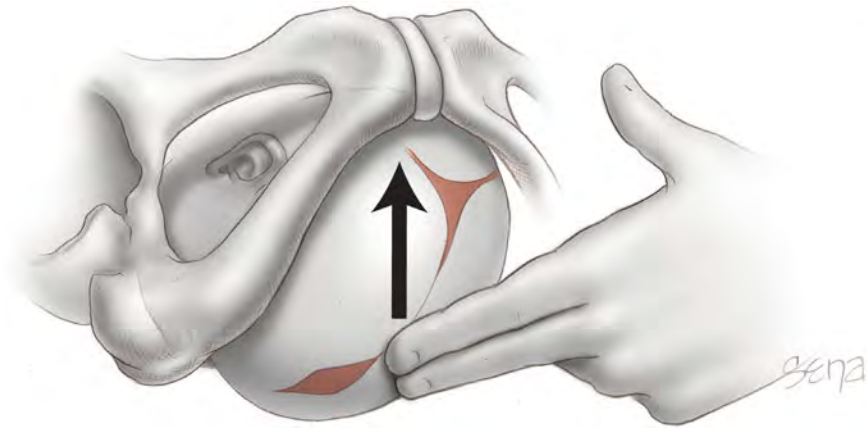

FIGURE 17-9 Locating the sagittal suture by vaginal examination.

Mechanisms of Labor with Occiput Posterior Presentation

In approximately 20 percent of labors, the fetus enters the pelvis in an *occiput posterior (OP)* position. The right occiput posterior (ROP) is slightly more common than the left (LOP) (Caldwell and associates, 1934). It appears likely from radiographic evidence that posterior positions are more often associated with a narrow forepelvis. They also are more commonly seen in association with anterior placentation (Gardberg and Tuppurainen, 1994a).

In most occiput posterior presentations, the mechanism of labor is identical to that observed in the transverse and anterior varieties, except that the occiput has to internally rotate to the symphysis pubis through 135 degrees, instead of 90 and 45 degrees, respectively (see Fig. 17-17).

With effective contractions, adequate flexion of the head, and a fetus of average size, most posteriorly positioned occiputs rotate promptly as soon as they reach the pelvic floor, and labor is not lengthened appreciably. In perhaps 5 to 10 percent of cases, however, rotation may be incomplete or may not take place at all, especially if the fetus is large (Gardberg and Tuppurainen, 1994b). Poor contractions, faulty flexion of the head, or epidural analgesia, which diminishes abdominal muscular pushing and relaxes the muscles of the pelvic floor, may predispose to incomplete rotation. If rotation is incomplete, transverse arrest may result. If no rotation toward the symphysis takes place, the occiput may remain in the direct occiput posterior position, a condition known as *persistent occiput posterior.* Both persistent occiput posterior and transverse arrest represent deviations from the normal mechanisms of labor and are considered further in Chapter 20.

Changes in Shape of the Fetal Head

Caput Succedaneum

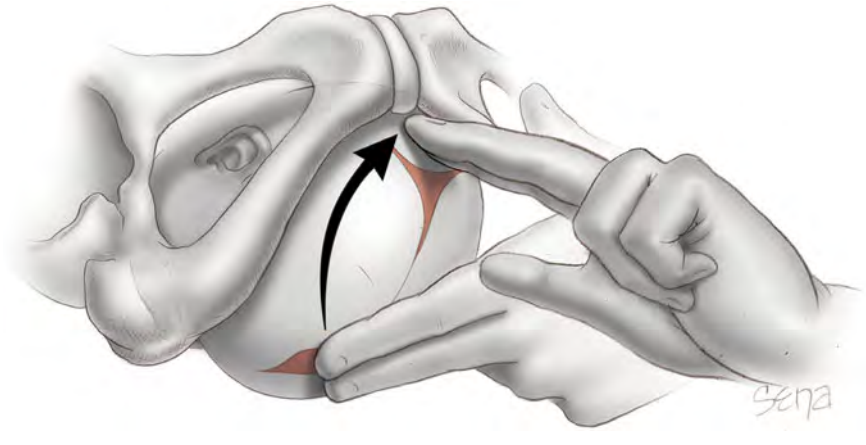
In vertex presentations, the fetal head changes shape as the result of labor forces. In prolonged labors before complete cervical dilatation, the portion of the fetal scalp immediately over the cervical os becomes edematous (see Fig. 29-12, p. 635). This swelling known as the *caput succedaneum* (**Figs. 17-18** and **17-19**). It usually attains a thickness of only a few millimeters, but in prolonged labors it may be sufficiently extensive to prevent the differentiation of the various sutures and fontanels. More commonly, the caput is formed when the head is in the lower portion of the birth canal and frequently only after the resistance of a rigid vaginal outlet is encountered. Because it develops over the most dependent area of the head, one may deduce the original fetal head position by noting the location of the caput succedaneum.

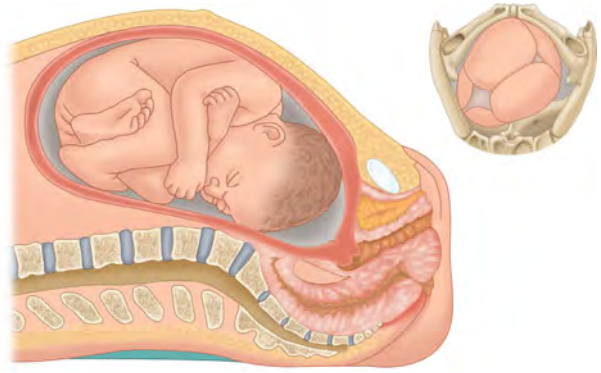
Molding

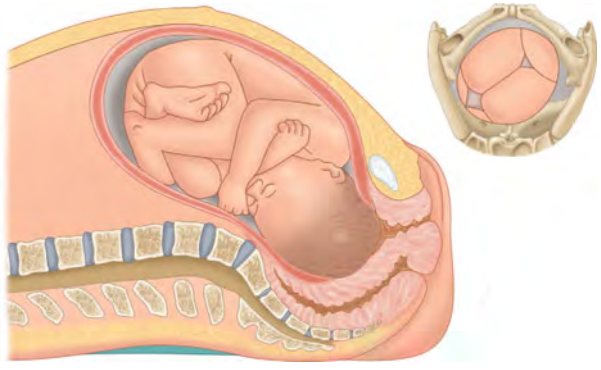
The change in fetal head shape from external compressive forces is referred to as *molding.* Possibly related to Braxton Hicks contractions, some molding develops before labor. Most studies indicate that there is seldom overlapping of the parietal bones. A "locking" mechanism at the coronal and lambdoidal connections actually prevents such overlapping (Carlan and colleagues, 1991). Molding results in a shortened suboccipitobregmatic diameter and a lengthened mentovertical diameter. These changes are of greatest importance in women with contracted pelves or asynclitic presentations. In these circumstances, the degree to which the head is capable of molding may make the difference between spontaneous vaginal delivery and an operative delivery. Some older literature cited severe head molding as a cause for possible cerebral trauma. Because of the multitude of associated factors, for example, prolonged labor with fetal sepsis and acidosis, it is impossible to link molding to any alleged fetal or neonatal neurological sequelae. Most cases of molding resolve within the week following delivery, although persistent cases have been described (Graham and Kumar, 2006).

CHARACTERISTICS OF NORMAL LABOR

The greatest impediment to understanding normal labor is recognizing its start. The strict definition of labor—*uterine contractions that bring about demonstrable effacement and dilatation*







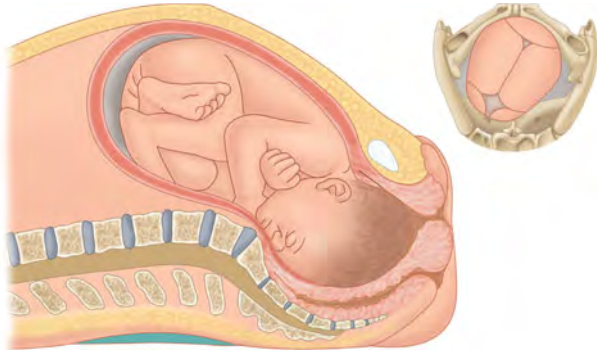


FIGURE 17-10 Differentiating the fontanels by vaginal examination.

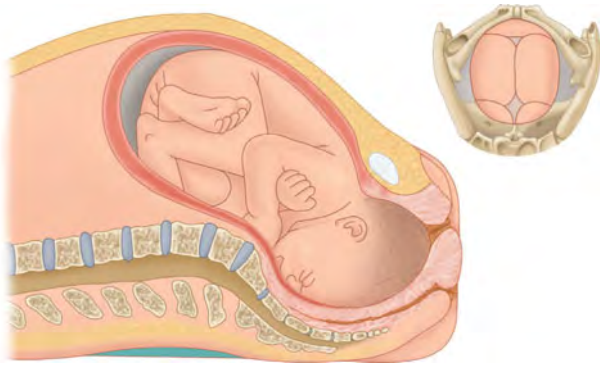
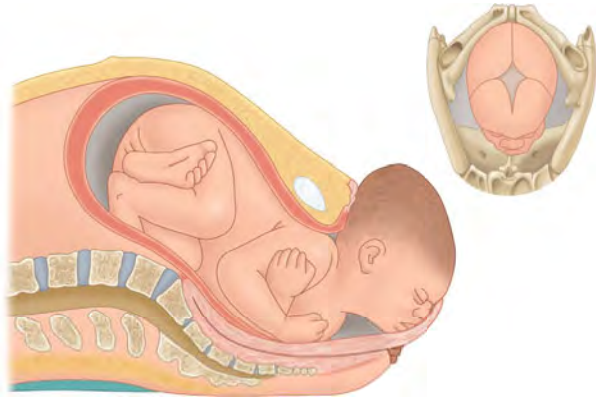
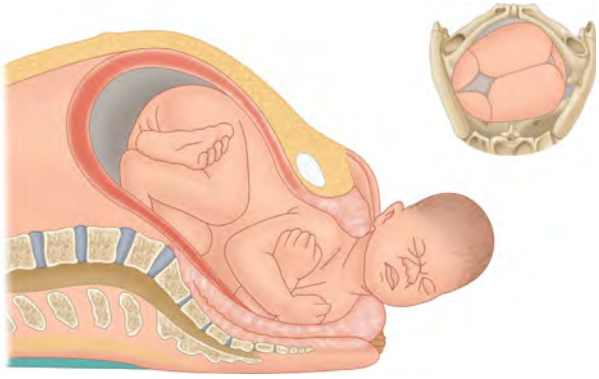


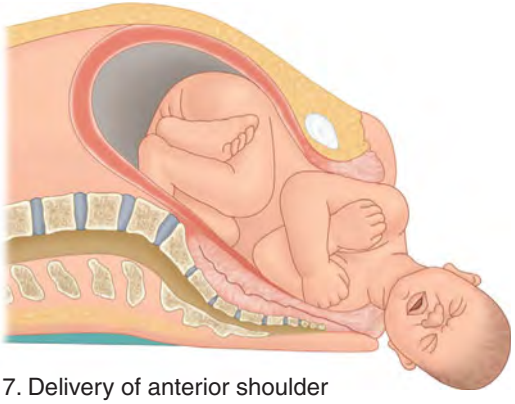
1. Head floating, before engagement



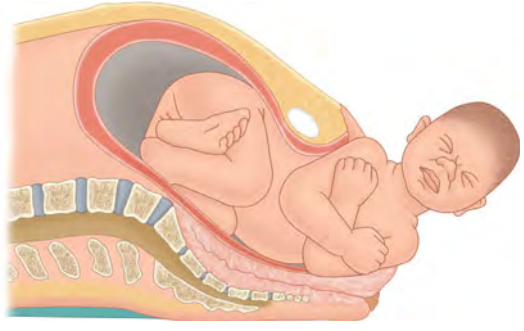
2. Engagement, descent, flexion



3. Further descent, internal rotation



4. Complete rotation, beginning extension



5. Complete extension

6. Restitution (external rotation)

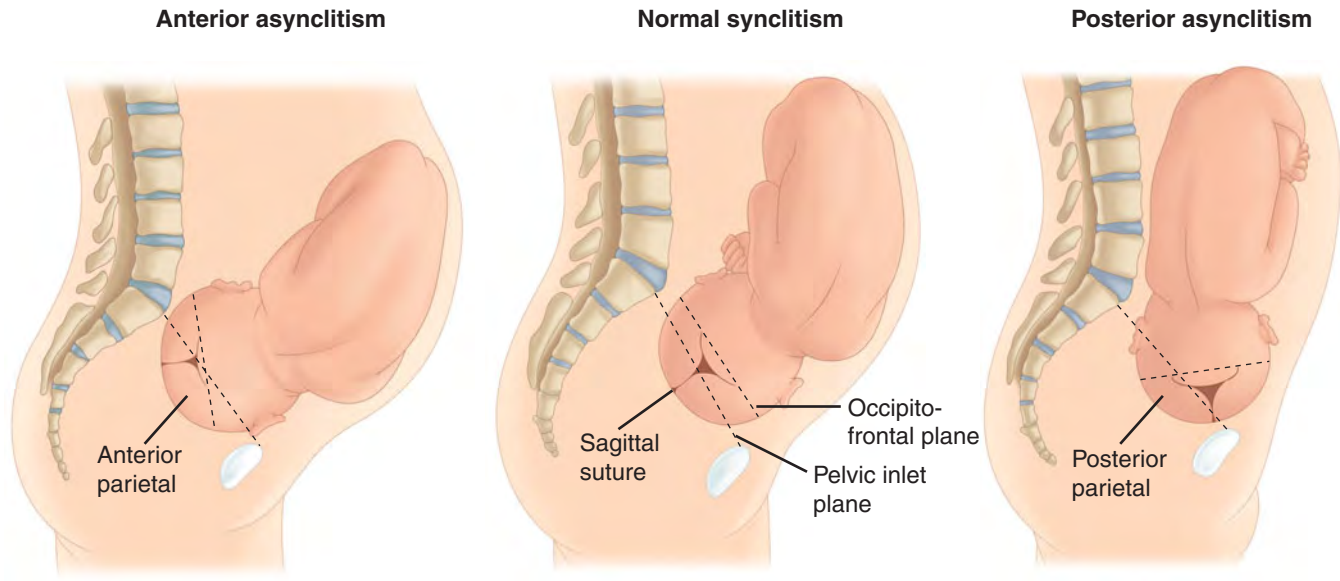

FIGURE 17-12 Synclitism and asynclitism.

of the cervix—does not easily aid the clinician in determining when labor has actually begun, because this diagnosis is confirmed only retrospectively. Several methods may be used to define its start. One defines onset as the clock time when painful contractions become regular. Unfortunately, uterine activity that causes discomfort, but that does not represent true labor, may develop at any time during pregnancy. False labor often stops spontaneously, or it may proceed rapidly into effective contractions.

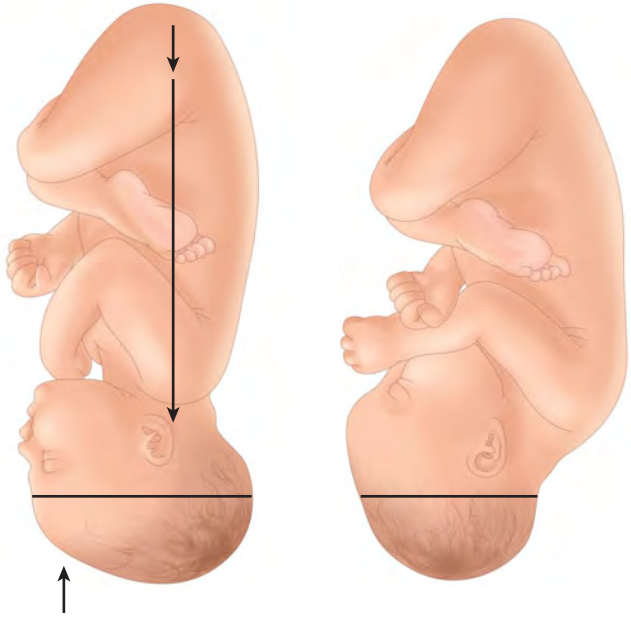

FIGURE 17-13 Lever action produces flexion of the head. Conversion from occipitofrontal to suboccipitobregmatic diameter typically reduces the anteroposterior diameter from nearly 12 to 9.5 cm.

A second method defines the onset of labor as beginning at the time of admission to the labor unit. At the National Maternity Hospital in Dublin, efforts have been made to codify admission criteria (O'Driscoll and colleagues, 1984). These criteria at term require painful uterine contractions accompanied by any one of the following: (1) ruptured membranes, (2) bloody "show," or (3) complete cervical effacement.

In the United States, admission for labor is frequently based on the extent of dilatation accompanied by painful contractions. When a woman presents with intact membranes, a cervical dilatation of 3 to 4 cm or greater is presumed to be a reasonably reliable threshold for the diagnosis of labor. In this case, labor onset commences with the time of admission. This presumptive method obviates many of the uncertainties in diagnosing labor during earlier stages of cervical dilatation.

First Stage of Labor

Assuming that the diagnosis has been confirmed, then what are the expectations for the progress of normal labor? A scientific approach was begun by Friedman (1954), who described a characteristic sigmoid pattern for labor by graphing cervical dilatation against time. This graphic approach, based on statistical observations, changed labor management. Friedman developed the concept of three functional divisions of labor to describe the physiological objectives of each division as shown in **Figure 17-20**:

1. During the *preparatory division,* although the cervix dilates little, its connective tissue components change considerably (see Chap. 6, p. 138). Sedation and conduction analgesia are capable of arresting this division of labor.
2. The *dilatational division,* during which dilatation proceeds at its most rapid rate, is unaffected by sedation or conduction analgesia.
3. The *pelvic division* commences with the deceleration phase of cervical dilatation. The classic mechanisms of labor that

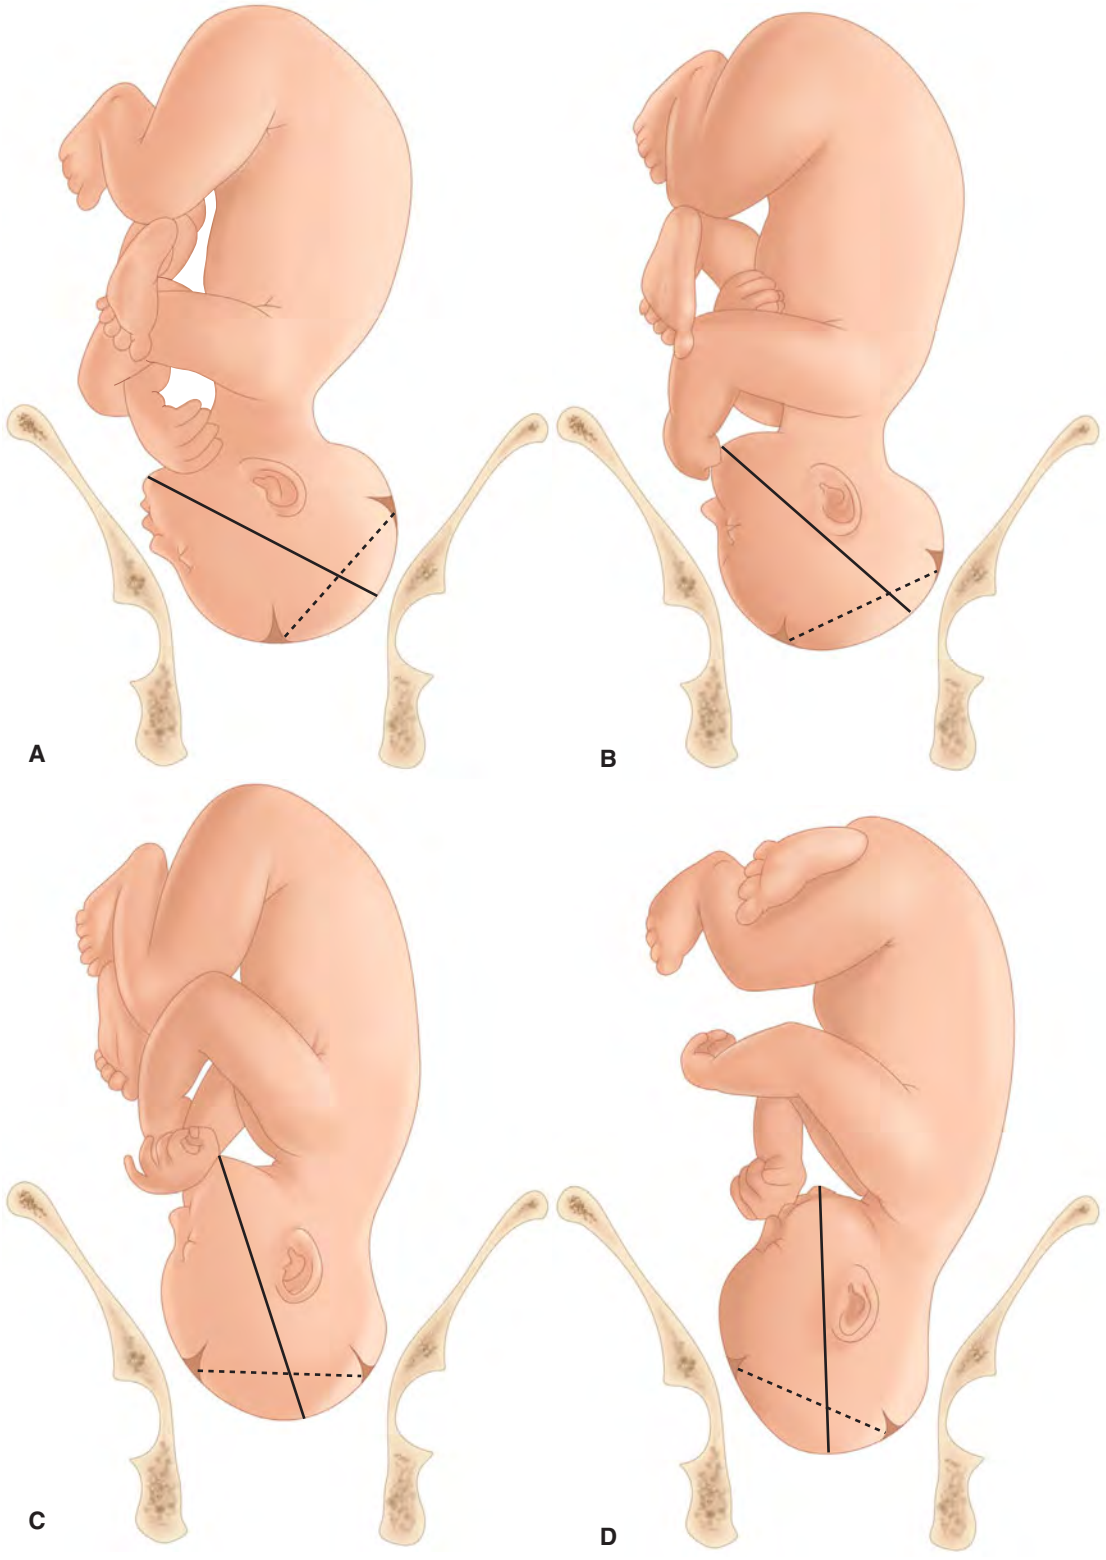

FIGURE 17-14 Four degrees of head flexion. The solid line represents the occipitomental diameter, whereas the broken line connects the center of the anterior fontanel with the posterior fontanel. **A.** Flexion poor. **B.** Flexion moderate. **C.** Flexion advanced. **D.** Flexion complete. Note that with complete flexion, the chin is on the chest. The suboccipitobregmatic diameter, the shortest anteroposterior diameter of the fetal head, is passing through the pelvic inlet.

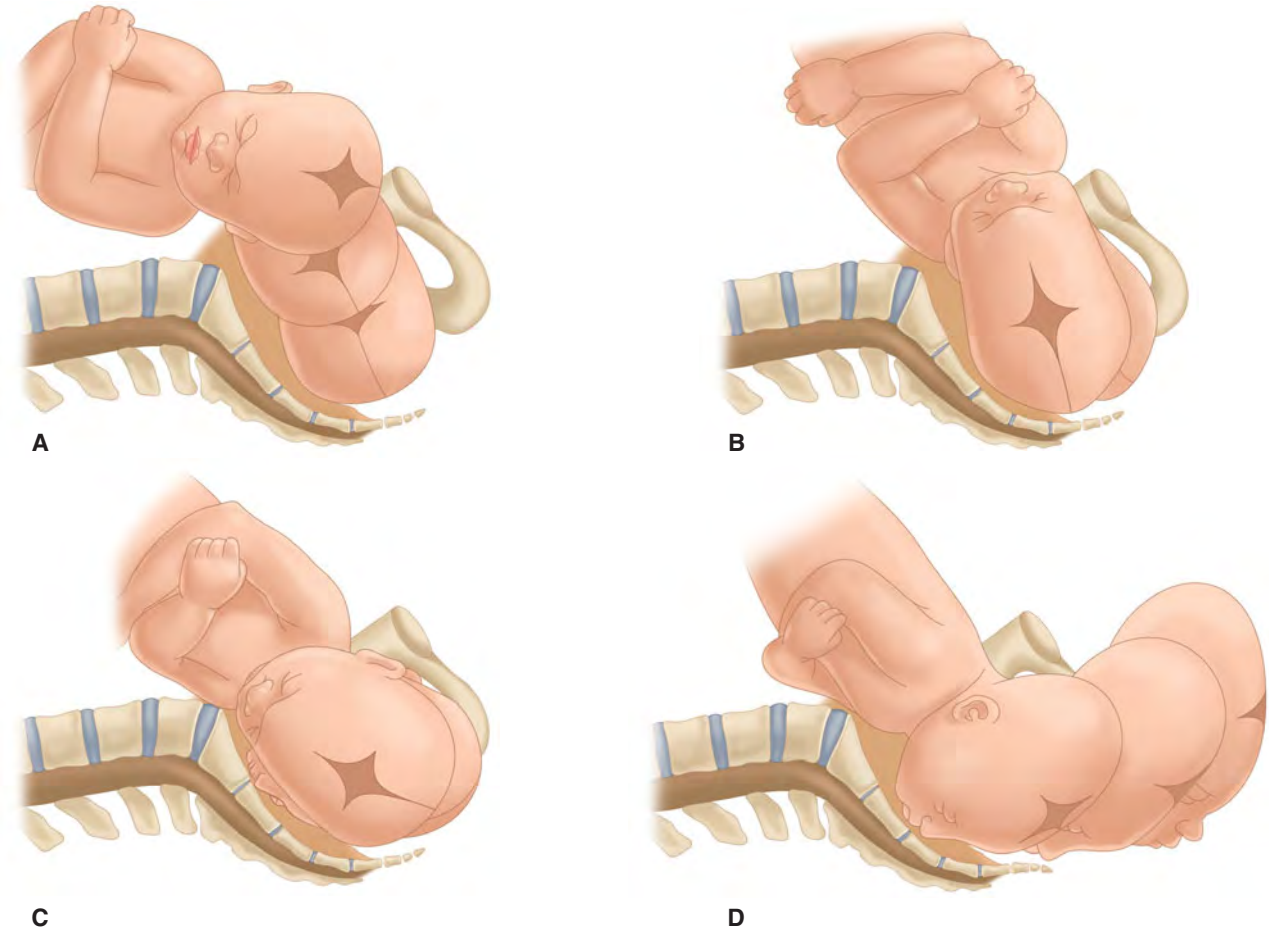

FIGURE 17-15 Mechanism of labor for the left occiput transverse position, lateral view. **A.** Engagement. **B.** Posterior asynclitism at the pelvic brim followed by lateral flexion. **C.** After engagement, further descent. **D.** Rotation and extension.

involve the cardinal fetal movements of the cephalic presentation—engagement, flexion, descent, internal rotation, extension, and external rotation—take place principally during the pelvic division. In actual practice, however, the onset of the pelvic division is seldom clearly identifiable.

As shown in Figure 17-20, the pattern of cervical dilatation during the preparatory and dilatational divisions of normal labor is a sigmoid curve. Two phases of cervical dilatation are defined. The *latent phase* corresponds to the preparatory division, and the *active phase,* to the dilatational division. Friedman subdivided the active phase into the *acceleration phase,* the *phase of maximum slope,* and the *deceleration phase* (Fig. 17-21).

Latent Phase

The onset of latent labor, as defined by Friedman (1972), is the point at which the mother perceives regular contractions. The latent phase for most women ends at between 3 and 5 cm of dilatation. This threshold may be clinically useful, for it defines cervical dilatation limits beyond which active labor can be expected.

This concept of a latent phase has great significance in understanding normal human labor because labor is considerably longer when a latent phase is included. To better illustrate this,

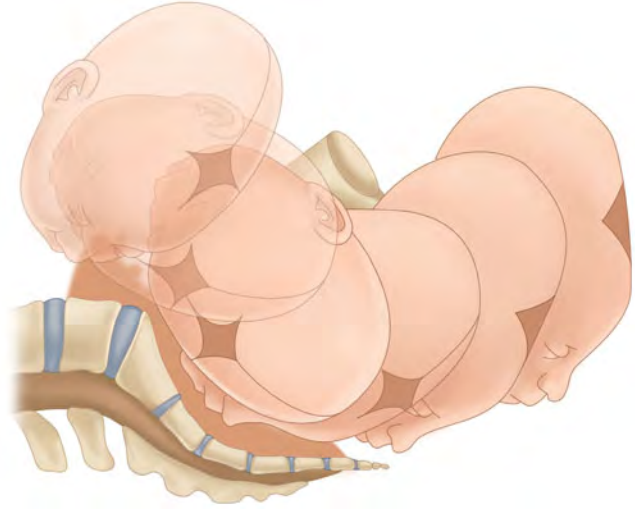

FIGURE 17-16 Mechanism of labor for left occiput anterior position.

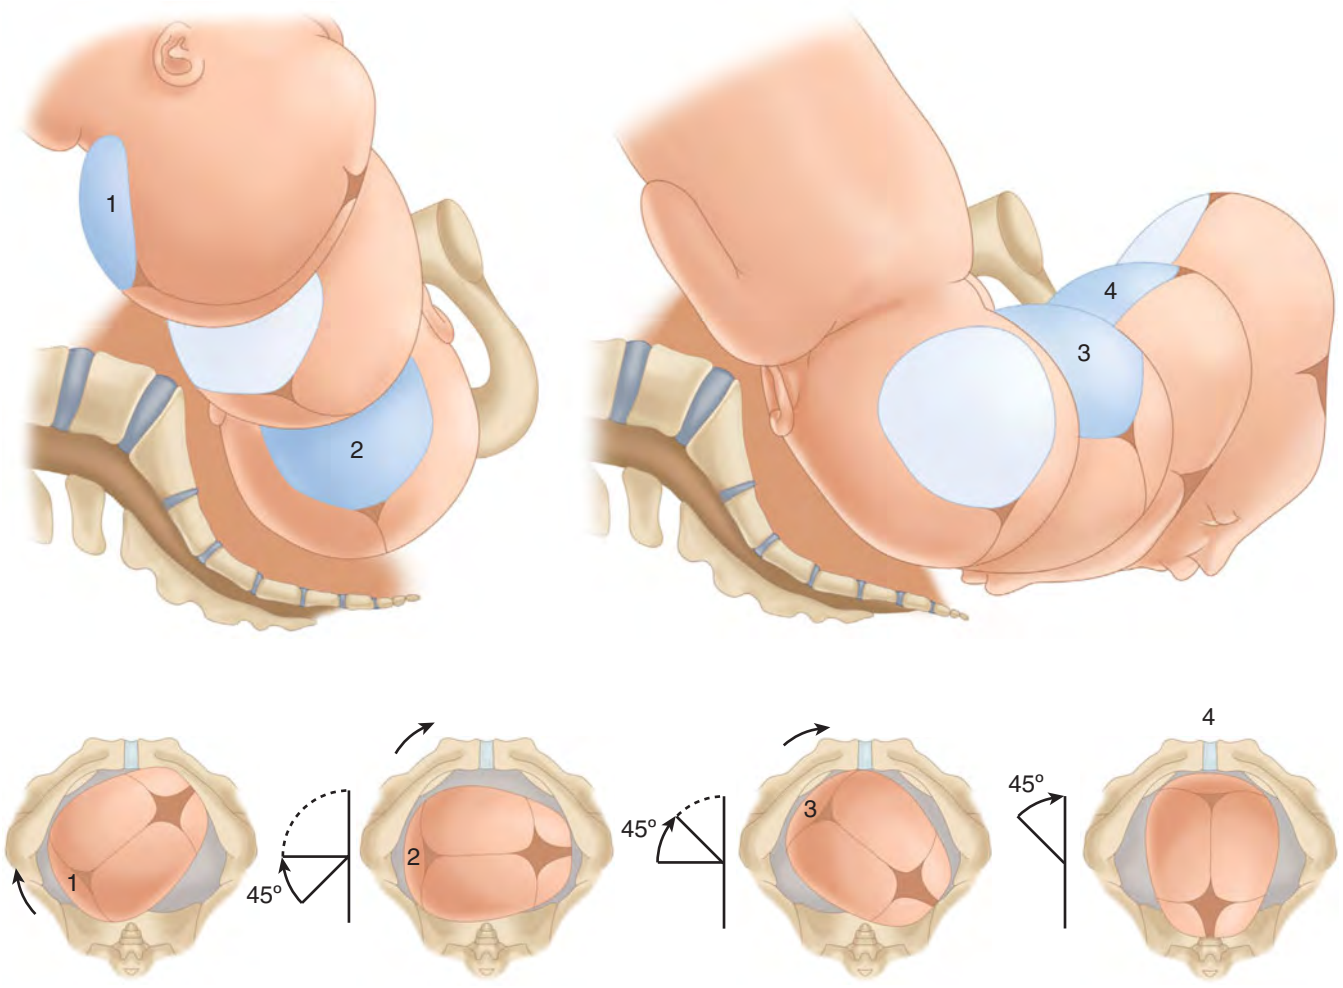

FIGURE 17-17 Mechanism of labor for right occiput posterior position showing anterior rotation.

FIGURE 17-18 Formation of caput succedaneum.

FIGURE 17-19 Considerable molding of the head and caput succedaneum formation in a recently delivered newborn.

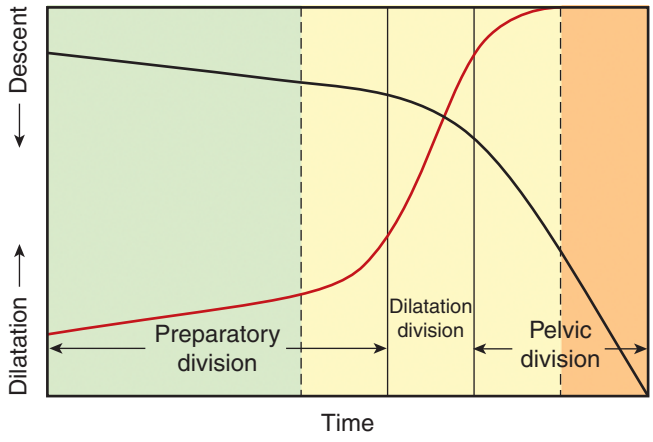

FIGURE 17-20 Labor course divided functionally on the basis of dilatation and descent curves into: (1) a preparatory division, including latent and acceleration phases; (2) a dilatational division, occupying the phase of maximum slope; and (3) a pelvic division, encompassing both deceleration phase and second stage concurrent with the phase of maximum slope of descent. (Courtesy of Dr. L. Casey; redrawn from Friedman, 1978.)

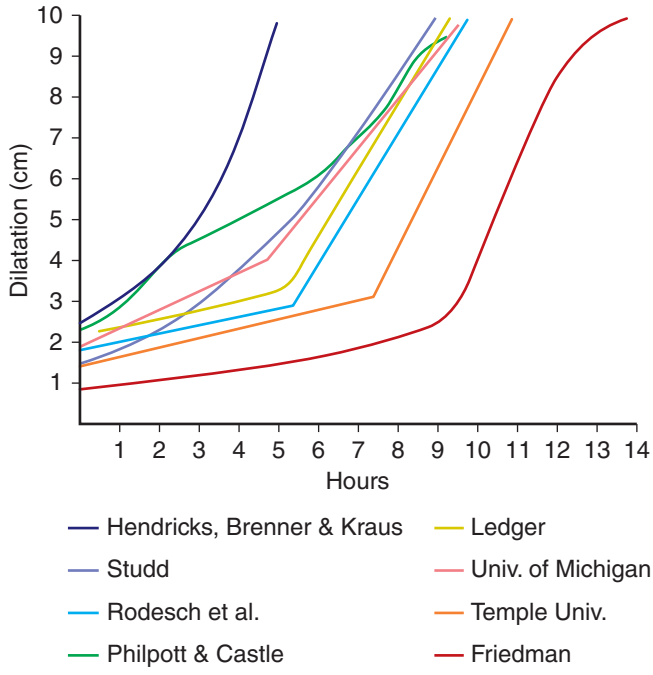

FIGURE 17-22 Progress of labor in primigravid women from the time of admission. When the starting point on the abscissa begins with admission to the hospital, a latent phase is not observed.

Figure 17-22 shows eight labor curves from nulliparas in whom labor was diagnosed beginning with their admission, rather than with the onset of regular contractions. When labor is defined similarly, there is remarkable similarity of individual labor curves.

Prolonged Latent Phase. Friedman and Sachtleben (1963) defined this by a latent phase exceeding 20 hours in the nullipara and 14 hours in the multipara. These times corresponded to the 95th percentiles. Factors that affected duration of the latent phase included excessive sedation or epidural analgesia; unfavorable cervical condition, that is, thick, uneffaced, or undilated; and false labor. Following heavy sedation, 85 percent of women progressed to active labor. In another 10 percent, uterine contractions ceased, suggesting that they had false labor. The remaining 5 percent experienced persistence of an abnormal latent phase and required oxytocin stimulation. Amniotomy was discouraged because of the 10-percent incidence of false labor. Sokol and colleagues (1977) reported a 3- to 4-percent incidence of prolonged latent phase, regardless of parity. Friedman (1972) reported that prolongation of the latent phase did not adversely influence fetal or maternal morbidity or mortality rates, but Chelmow and co-workers (1993) disputed the long-held belief that prolongation of the latent phase is benign.

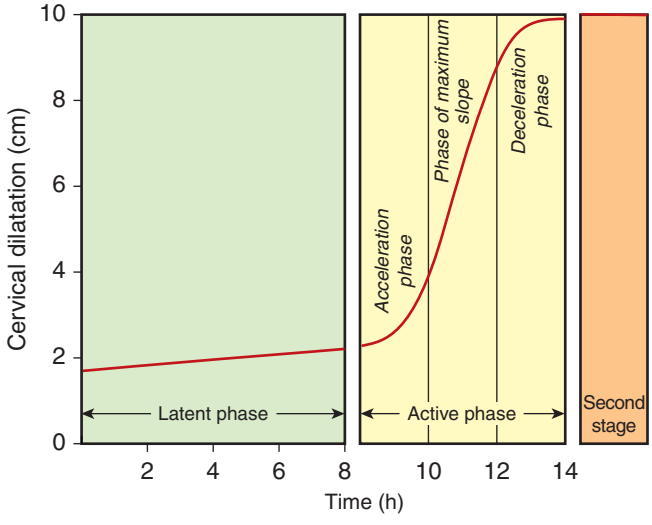

FIGURE 17-21 Composite of the average dilatation curve for nulliparous labor. The first stage is divided into a relatively flat latent phase and a rapidly progressive active phase. In the active phase, there are three identifiable component parts that include an acceleration phase, a phase of maximum slope, and a deceleration phase. (Courtesy of Dr. L. Casey; redrawn from Friedman, 1978.)

Active Labor

As shown in Figure 17-22, the progress of labor in nulliparous women has particular significance because these curves all reveal a rapid change in the slope of cervical dilatation rates between 3 and 5 cm. *Thus, cervical dilatation of 3 to 5 cm or more, in the presence of uterine contractions, can be taken to reliably represent the threshold for active labor.* Similarly, these curves provide useful guideposts for labor management.

Turning again to Friedman (1955), the mean duration of active-phase labor in nulliparas was 4.9 hours. But the standard deviation of 3.4 hours is large; hence, the active phase was reported to have a statistical maximum of 11.7 hours. Indeed, rates of cervical dilatation ranged from a minimum of 1.2 up to 6.8 cm/hr. Friedman (1972) also found that multiparas progress somewhat faster in active-phase labor, with a *minimum* normal

rate of 1.5 cm/hr. His analysis of active-phase labor concomitantly describes rates of fetal descent and cervical dilatation (see Fig. 17-20). Descent begins in the later stage of active dilatation, commencing at 7 to 8 cm in nulliparas and becoming most rapid after 8 cm.

Active-Phase Abnormalities. Abnormalities in this labor phase are common. Sokol and co-workers (1977) reported that 25 percent of nulliparous and 15 percent of multiparous labors were complicated by an active-phase abnormality. Friedman (1972) subdivided active-phase problems into *protraction* and *arrest disorders*. He defined protraction as a *slow rate* of cervical dilatation or descent, which for nulliparas was less than 1.2 cm dilatation per hour or less than 1 cm descent per hour. For multiparas, protraction was defined as less than 1.5 cm dilatation per hour or less than 2 cm descent per hour. He defined arrest as a *complete cessation* of dilatation or descent. *Arrest of dilatation* was defined as 2 hours with no cervical change, and *arrest of descent* as 1 hour without fetal descent.

The prognosis for protraction and arrest disorders differed considerably. Friedman found that approximately 30 percent of women with protraction disorders had cephalopelvic disproportion, compared with 45 percent of women in whom an arrest disorder developed. Abnormal labor patterns, diagnostic criteria, and treatment methods according to Cohen and Friedman (1983) are summarized in Chapter 20 (see p. 465 and Table 20-2).

Factors contributing to both protraction and arrest disorders were excessive sedation, epidural analgesia, and fetal malposition. In both protraction and arrest disorders, Friedman recommended fetopelvic evaluation to identify cephalopelvic disproportion. Recommended therapy for protraction disorders was expectant management, whereas oxytocin was advised for arrest disorders in the absence of cephalopelvic disproportion. During those times, x-ray pelvimetry was frequently used to identify cephalopelvic disproportion—a method now known to be notoriously inaccurate (see Chap. 20, p. 472). Still, it is remarkable that of the 500 women studied, only 2 percent had a cesarean delivery. By way of comparison, Henry and colleagues (2008) recently described a 67-percent cesarean delivery rate for 1014 women with active-phase arrest. These differences must be kept in mind when considering the significance of various labor abnormalities described by Friedman.

Hendricks and co-workers (1970) challenged Friedman's conclusions about the course of normal human labor. Their principal differences included: (1) absence of a latent phase, (2) no deceleration phase, (3) brevity of labor, and (4) dilatation at similar rates for nulliparas and multiparas after 4 cm. They disputed the concept of a latent phase because they observed that the cervix dilated and effaced slowly during the 4 weeks preceding labor. They contended that the *latent phase* actually progressed over several weeks. They also reported that labor was relatively rapid. Specifically, the average time from admission to complete dilatation was 4.8 hours for nulliparas and 3.2 hours for multiparas.

There have been other reports in which investigators have reassessed the Friedman labor curves. Zhang and colleagues (2002) plotted detailed data on 1329 nulliparous women in spontaneous labor at term and found that the average curve differed markedly from the Friedman curve. Specifically, the cervix dilated more slowly in the active phase, and it took 5.5 hours to progress from 4 cm to 10 cm compared with only 2.5 hours in the Friedman curve. Alexander and colleagues (2002), in a study performed at Parkland Hospital, found that epidural analgesia lengthened the active phase of the Friedman labor curve by 1 hour. This increase was the result of a slightly slower, but significant rate of cervical dilatation—1.4 cm/hr in women given epidural analgesia compared with 1.6 cm/hr in those without such analgesia. Gurewitsch and colleagues (2002, 2003) studied the labor and descent curves of women with greater and lesser parity. They concluded that poor progress from 4 to 6 cm should not be considered abnormal and that women with high parity should not be expected to progress faster than those with lower parity. Greenberg and colleagues (2006) studied ethnic differences in the labor length in 27,521 women and concluded that the Friedman curves should be modified to account for ethnic differences.

Second Stage of Labor

This stage begins when cervical dilatation is complete and ends with fetal delivery. The median duration is approximately 50 minutes for nulliparas and about 20 minutes for multiparas, but it is highly variable (Kilpatrick and Laros, 1989). In a woman of higher parity with a previously dilated vagina and perineum, two or three expulsive efforts after full cervical dilatation may suffice to complete delivery. Conversely, in a woman with a contracted pelvis, a large fetus, or with impaired expulsive efforts from conduction analgesia or sedation, the second stage may become abnormally long. Abnormalities of the second stage of labor are described in Chapter 20 (see p. 468).

Duration of Labor

Our understanding of the normal duration of labor may be clouded by the many clinical variables that affect conduct of labor in modern obstetrical units. Kilpatrick and Laros (1989) reported that the mean length of first- and second-stage labor was approximately 9 hours in nulliparous women without regional analgesia, and that the 95th percentile upper limit was 18.5 hours. Corresponding times for multiparous women were a mean of 6 hours with a 95th percentile maximum of 13.5 hours. These authors defined labor onset as the time when a woman recalled regular, painful contractions every 3 to 5 minutes that led to cervical change.

Spontaneous labor was analyzed in nearly 25,000 women delivered at term at Parkland Hospital in the early 1990s. Almost 80 percent of women were admitted with a cervical dilatation of 5 cm or less. Parity—nulliparous versus multiparous—and cervical dilatation at admission were significant determinants of the length of spontaneous labor. The median time from admission to spontaneous delivery for all parturients was 3.5 hours, and 95 percent of all women delivered within 10.1 hours. These results suggest that normal human labor is relatively short. Zhang and associates (2009a, b) described similar findings in their study of 126,887 deliveries from 12 institutions over the United States.

Summary of Normal Labor

Labor is characterized by brevity and considerable biological variation. Active labor can be reliably diagnosed when cervical dilatation is 3 cm or more in the presence of uterine contractions. Once this cervical dilatation threshold is reached, normal progression to delivery can be expected, depending on parity, in the ensuing 4 to 6 hours. Anticipated progress during a 1- to 2-hour second stage is monitored to ensure fetal safety. Finally, most women in spontaneous labor, regardless of parity, if left unaided, will deliver within approximately 10 hours after admission for spontaneous labor. Insufficient uterine activity is a common and correctable cause of abnormal labor progress. *Therefore, when time breaches in normal labor boundaries are the only pregnancy complications, interventions other than cesarean delivery must be considered before resorting to this method of delivery for failure to progress.*

MANAGEMENT OF NORMAL LABOR AND DELIVERY

The ideal management of labor and delivery requires two potentially opposing viewpoints on the part of clinicians. First, birthing should be recognized as a normal physiological process that most women experience without complications. Second, intrapartum complications, often arising quickly and unexpectedly, should be anticipated. Thus, clinicians must simultaneously make every woman and her supporters feel comfortable, yet ensure safety for the mother and newborn should complications suddenly develop. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) have collaborated in the development of *Guidelines for Perinatal Care*. These provide detailed information on the appropriate content of intrapartum care, including both personnel and facility requirements. Shown in Table 17-2 are the recommended nurse-to-patient ratios recommended for labor and delivery. Shown in Table 17-3 are the recommended room dimensions for these functions.

TABLE 17-2. Recommended Nurse/Patient Ratios for Labor and Delivery

Nurse/Patient Ratio	Clinical Setting
1:2	Patients in labor
1:1	Patients in second-stage labor
1:1	Patients with medical or obstetrical complications
1:2	Oxytocin induction or augmentation of labor
1:1	Coverage initiation of epidural analgesia
1:1	Circulation for cesarean delivery

Admission Procedures

Pregnant women should be urged to report early in labor rather than to procrastinate until delivery is imminent for fear that they might be experiencing false labor. Early admittance to the labor and delivery unit is important, especially if during antepartum care the woman, her fetus, or both have been identified as being at risk.

Identification of Labor

Although the differentiation between false and true labor is difficult at times, the diagnosis usually can be clarified by contraction frequency and intensity and by cervical dilatation as shown in Table 17-4. Use of an algorithm to help diagnose active labor was associated with more home discharges after initial prelabor assessment (Cheyne and colleagues, 2008). Another study showed that a formalized approach to labor assessment improved patient satisfaction with little effect on pregnancy outcomes (Hodnett and co-workers, 2008). In those instances when a diagnosis of labor cannot be established with certainty, observation for a longer period of time is often wise.

Pates and colleagues (2007) studied the commonly used recommendations given to pregnant women that, in the absence of ruptured membranes or bleeding, uterine contractions 5 minutes apart for 1 hour—that is, ≥ 12 contractions in 1 hour—may signify labor onset. Among 768 women studied at Parkland Hospital, active labor defined as cervical dilatation ≥ 4 cm

TABLE 17-4. Characteristics of True versus False Labor

Characteristic	True Labor	False Labor
Contractions		
Rhythm	Regular	Irregular
Intervals	Gradually shorten	Unchanged
Intensity	Gradually increases	Unchanged
Discomfort		
Location	Back and abdomen	Lower abdomen
Sedation	No effect	Usually relieved
Cervical dilatation	Yes	No

was diagnosed within 24 hours in three fourths of women with 12 or more contractions per hour. Bailit and colleagues (2005) compared labor outcomes of 6121 women who presented in active labor defined as uterine contractions plus cervical dilatation ≥ 4 cm with those of 2697 women who presented in the latent phase. Women admitted during latent-phase labor had more active-phase arrest, need for oxytocin labor stimulation, and chorioamnionitis. It was concluded that physician interventions in women presenting in the latent phase may have been the cause of subsequent labor abnormalities.

Emergency Medical Treatment and Labor Act (EMTALA)

Congress enacted EMTALA in 1986 to ensure public access to emergency services regardless of the ability to pay. All Medicare-participating hospitals with emergency services must provide an appropriate screening examination for any pregnant woman experiencing contractions who comes to the emergency department for evaluation. The most recent iteration of these regulations went into effect on November 10, 2003 (Federal Register, 2003).

The definition of an emergency condition makes specific reference to a pregnant woman who is having contractions. Labor is defined as "the process of childbirth beginning with the latent phase of labor continuing through delivery of the placenta. A woman experiencing contractions is in true labor unless a physician certifies that after a reasonable time of observation the woman is in false labor." A woman in true labor is considered "unstable" for interhospital transfer purposes until the newborn and placenta are delivered. An unstable woman may, however, be transferred at the direction of the patient or by a physician who certifies that the benefits of treatment at another facility outweigh the risks of transfer. Physicians and hospitals violating these federal requirements are subject to civil penalties of up to $50,000 and termination from the Medicare program.

Preadmission and Admission Electronic Fetal Heart Rate Monitoring

As discussed in Chapter 18 (p. 410), electronic fetal heart rate monitoring is routinely used for high-risk pregnancies commencing at admission. Some investigators recommend monitoring women with low-risk pregnancies upon admission as a test of fetal well-being—the so-called *fetal admission test.* If no fetal rate abnormalities are detected, continuous electronic monitoring is replaced by intermittent assessment for the remainder of labor. We are of the view that electronic fetal heart rate monitoring is reasonable in the preadmission evaluation of women, including those who subsequently are discharged. At Parkland Hospital, external electronic monitoring is performed for at least 1 hour before discharging the woman who was ascertained to have false labor.

Home Births

A major emphasis of obstetrical care during the 20th century was the movement to birthing in hospitals rather than in homes. In 2006, 99 percent of births in the United States took place in hospitals (Martin and colleagues, 2009). Of the other 1 percent, 65 percent were in homes and 28 percent in birthing centers. The results of studies comparing neonatal and perinatal mortality rates associated with intended home deliveries with those of hospital deliveries have been conflicting. Most suggest an increased risk with home delivery. In their recent evidence-based systematic review, Berghella and colleagues (2008) found good-quality data to favor hospital birth.

Vital Signs and Review of Pregnancy Record

Maternal blood pressure, temperature, pulse, and respiratory rate are recorded. The pregnancy record is promptly reviewed to identify complications. Problems identified or anticipated during prenatal care should be displayed prominently in the pregnancy record.

Vaginal Examination

Most often, *unless there has been bleeding in excess of bloody show,* a vaginal examination is performed. The gloved index and second fingers are then introduced into the vagina while avoiding the anal region (**Fig. 17-23**). The number of vaginal examinations correlates with infection-related morbidity, especially in cases of early membrane rupture.

FIGURE 17-23 To perform vaginal examination, the labia have been separated with one hand, and the first and second fingers of the other hand are carefully inserted into the introitus.

Detection of Ruptured Membranes

The woman should be instructed during the antepartum period to be aware of fluid leakage from the vagina and to report such an event promptly. Rupture of the membranes is significant for three reasons. First, if the presenting part is not fixed in the pelvis, the possibility of umbilical cord prolapse and compression is greatly increased. Second, labor is likely to begin soon if the pregnancy is at or near term. Third, if delivery is delayed after membrane rupture, intrauterine infection is more likely as the time interval increases (Herbst and Källén, 2007).

Upon sterile speculum examination, ruptured membranes are diagnosed when amnionic fluid is seen pooling in the posterior fornix or clear fluid is flowing from the cervical canal. Although several diagnostic tests for the detection of ruptured membranes have been recommended, none is completely reliable. If the diagnosis remains uncertain, another method involves pH determination of vaginal fluid. The pH of vaginal secretions normally ranges from 4.5 to 5.5, whereas that of amnionic fluid is usually 7.0 to 7.5. The use of the indicator *nitrazine* to identify ruptured membranes is a simple and fairly reliable method. Test papers are impregnated with the dye, and the color of the reaction between these paper strips and vaginal fluids is interpreted by comparison with a standard color chart. A pH above 6.5 is consistent with ruptured membranes. False-positive test results may occur with coexistent blood, semen, or bacterial vaginosis, whereas false-negative tests may result with scant fluid (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2007).

Other tests include arborization or ferning of vaginal fluid, which suggests amnionic rather than cervical fluid. Amnionic fluid crystallizes to form a fernlike pattern due to its relative concentrations of sodium chloride, proteins, and carbohydrates (see Fig. 8-3, p. 192). Detection of alpha-fetoprotein in the vaginal vault has been used to identify amnionic fluid (Yamada and colleagues, 1998). Identification may also follow injection of indigo carmine into the amnionic sac via abdominal amniocentesis.

Cervical Examination

The degree of *cervical effacement* usually is expressed in terms of the length of the cervical canal compared with that of an uneffaced cervix. When the length of the cervix is reduced by one half, it is 50-percent effaced. When the cervix becomes as thin as the adjacent lower uterine segment, it is completely, or 100-percent, effaced.

Cervical dilatation is determined by estimating the average diameter of the cervical opening by sweeping the examining finger from the margin of the cervical opening on one side to that on the opposite side. The diameter traversed is estimated in centimeters. The cervix is said to be dilated fully when the diameter measures 10 cm, because the presenting part of a term-size newborn usually can pass through a cervix this widely dilated.

The *position* of the cervix is determined by the relationship of the cervical os to the fetal head and is categorized as posterior, midposition, or anterior. Along with position, the *consistency* of cervix is determined to be soft, firm, or intermediate between these two.

The level—or *station*—of the presenting fetal part in the birth canal is described in relationship to the ischial spines, which are halfway between the pelvic inlet and the pelvic outlet. When the lowermost portion of the presenting fetal part is at the level of the spines, it is designated as being at zero (0) station. In the past, the long axis of the birth canal above and below the ischial spines was arbitrarily divided into thirds by some and into fifths (approximately 1 cm) by other groups. In 1989, the American College of Obstetricians and Gynecologists adopted the classification of station that divides the pelvis above and below the spines into fifths. Each fifth represents a centimeter above or below the spines. Thus, as the presenting fetal part descends from the inlet *toward* the ischial spines, the designation is –5, –4, –3, –2, –1, then 0 station. Below the spines, as the presenting fetal part descends, it passes +1, +2, +3, +4, and +5 stations to delivery. Station +5 cm corresponds to the fetal head being visible at the introitus.

If the leading part of the fetal head is at 0 station or below, most often the fetal head has engaged—thus, the biparietal plane has passed through the pelvic inlet. *If the head is unusually molded or if there is an extensive caput formation or both, engagement might not have taken place although the head appears to be at 0 station.*

In a study done at five teaching centers in Denver, residents, nurses, and faculty were surveyed to determine what definitions were being used to describe fetal station (Carollo and colleagues, 2004). Four different definitions were in use. Disturbingly, these investigators found that few caregivers were aware that others were using different definitions of station! Dupuis and colleagues (2005) tested the reliability of clinical estimations of station using the position of the leading part in centimeters above or below the spines as recommended by the American Academy of Pediatrics and the American college of Obstetricians and Gynecologists (2007). A birth simulator was used in which station could be precisely measured and compared with the vaginal examination done by clinicians. They reported that the clinical examiners were incorrect a third of the time.

These five characteristics: cervical dilatation, effacement, consistency, position, and fetal station are assessed when tabulating the Bishop score. This score is commonly used to predict labor induction outcome and is discussed in Chapter 22 (p. 501).

Laboratory Studies

When the woman is admitted in labor, most often the hematocrit or hemoglobin concentration should be rechecked. The hematocrit can be measured easily and quickly. At Parkland Hospital, blood is collected in a standard collection tube with anticoagulant. From this, a heparinized capillary tube is filled to spin in a microhematocrit centrifuge in the labor and delivery unit. This provides a hematocrit value within 3 minutes. The initial collection tube is also sent to the hematology laboratory for evaluation. Another labeled tube of blood is allowed to clot and is kept available for blood type and screen, if needed. A final sample is collected for routine serology. We obtain a urine specimen for protein determination in hypertensive women only (see Chap. 34, p. 707). In some labor units, however, a clean-catch voided specimen is examined in all women for protein and glucose.

Women who have had no prenatal care should be considered to be at risk for syphilis, hepatitis B, and human immunodeficiency virus (HIV) (see Chap. 59, p. 1235). In patients with no

prior prenatal care, these laboratory studies, as well as a blood type and antibody screen, should be performed (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2002). Some states, for example, Texas, require routine testing for syphilis, hepatitis B, and HIV in all women admitted to labor and delivery units even if these were done during prenatal care.

Management of the First Stage of Labor

As soon as possible after admittance, the remainder of the general examination is completed. A clinician can best reach a conclusion about the normalcy of the pregnancy when all examinations, including record and laboratory review, are completed. A rational plan for monitoring labor then can be established based on the needs of the fetus and the mother. Because there are marked individual variations in lengths of labor, precise statements as to its anticipated duration are unwise.

Monitoring Fetal Well-Being During Labor

This is discussed in detail in Chapter 18. Briefly, the American Academy of Pediatrics and American College of Obstetricians and Gynecologists (2007) recommend that during the first stage of labor, in the absence of any abnormalities, the fetal heart rate should be checked immediately after a contraction at least every 30 minutes and then every 15 minutes during the second stage. If continuous electronic monitoring is used, the tracing is evaluated at least every 30 minutes during the first stage and at least every 15 minutes during second-stage labor. For women with pregnancies at risk, fetal heart auscultation is performed at least every 15 minutes during the first stage of labor and every 5 minutes during the second stage. Continuous electronic monitoring may be used with evaluation of the tracing every 15 minutes during the first stage of labor, and every 5 minutes during the second stage.

Uterine Contractions

Although usually assessed by electronic monitoring as also discussed in Chapter 18, contractions can be both quantitatively and qualitatively evaluated manually. With the palm of the hand resting lightly on the uterus, the time of contraction onset is determined. Its intensity is gauged from the degree of firmness the uterus achieves. At the acme of effective contractions, the finger or thumb cannot readily indent the uterus during a "firm" contraction. The time at which the contraction disappears is noted next. This sequence is repeated to evaluate the frequency, duration, and intensity of uterine contractions.

Maternal Vital Signs

Temperature, pulse, and blood pressure are evaluated at least every 4 hours. If membranes have been ruptured for many hours before labor onset or if there is a borderline temperature elevation, the temperature is checked hourly. Moreover, with prolonged membrane rupture, defined as greater than 18 hours, antimicrobial administration for prevention of group B streptococcal infections is recommended. This is discussed in Chapter 58 (see p. 1220).

Subsequent Vaginal Examinations

During the first stage of labor, the need for subsequent vaginal examinations to monitor cervical change and presenting part position will vary considerably. When the membranes rupture, an examination should be performed expeditiously if the fetal head was not definitely engaged at the previous vaginal examination. This excludes umbilical cord prolapse. The fetal heart rate should also be checked immediately and during the next uterine contraction to help detect occult umbilical cord compression. At Parkland Hospital, periodic pelvic examinations are typically performed at 2- to 3-hour intervals to evaluate labor progress (see p. 405).

Oral Intake

Food should be withheld during active labor and delivery. Gastric emptying time is remarkably prolonged once labor is established and analgesics are administered. As a consequence, ingested food and most medications remain in the stomach and are not absorbed. Instead, they may be vomited and aspirated (see Chap. 19, p. 460). According to the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007), sips of clear liquids, occasional ice chips, and lip moisturizers are permitted.

Intravenous Fluids

Although it has become customary in many hospitals to establish an intravenous infusion system routinely early in labor, there is seldom any real need for such in the normal pregnant woman at least until analgesia is administered. An intravenous infusion system is advantageous during the immediate puerperium to administer oxytocin prophylactically and at times therapeutically when uterine atony persists. Moreover, with longer labors, the administration of glucose, sodium, and water to the otherwise fasting woman at the rate of 60 to 120 mL/hr prevents dehydration and acidosis. Shrivastava and associates (2009) noted shorter labors in nulliparas delivering vaginal who were provided an intravenous normal saline (NS) with dextrose solution compared with those given NS solution only. Garite and colleagues (2000) randomly assigned 195 women in labor to receive either 125 or 250 mL/hr of lactated Ringer or isotonic sodium chloride solution. The mean volume of total intravenous fluid was 2008 mL in the 125 mL/hr group and 2487 mL in the 250 mL/hr group. Labor lasted more than 12 hours in significantly more (26 versus 13 percent) of the women given a 125 mL/hr infusion compared with those given 250 mL/hr—26 versus 13 percent, respectively.

Maternal Position

The normal laboring woman need not be confined to bed early in labor. A comfortable chair may be beneficial psychologically and perhaps physiologically. In bed, the laboring woman should be allowed to assume the position she finds most comfortable—this will be lateral recumbency most of the time. She must not be restricted to lying supine because of resultant aortocaval compression and its potential to lower uterine perfusion (see Chap. 5, p. 120). Bloom and colleagues (1998) conducted a randomized trial of walking during labor in more than 1000 women with low-risk pregnancies. They found that walking

neither enhanced nor impaired active labor and that it was not harmful. Lawrence and associates (2009) reached similar findings in their Cochrane database review.

Analgesia

This is discussed in detail in Chapter 19. In general, pain relief should depend on the needs and desires of the woman. The American College of Obstetricians and Gynecologists (2009) has specified optimal goals for anesthesia care in obstetrics.

Amniotomy

If the membranes are intact, there is a great temptation, even during normal labor, to perform amniotomy. The presumed benefits are more rapid labor, earlier detection of meconium-stained amnionic fluid, and the opportunity to apply an electrode to the fetus or insert a pressure catheter into the uterine cavity for monitoring. The advantages and disadvantages of amniotomy are discussed in Chapter 22 (p. 508). Importantly, the fetal head must be well applied to the cervix and not be dislodged from the pelvis during the procedure to avert umbilical cord prolapse.

Urinary Bladder Function

Bladder distension should be avoided because it can hinder descent of the fetal presenting part and lead to subsequent bladder hypotonia and infection. During each abdominal examination, the suprapubic region should be inspected and palpated to detect distension. If the bladder is readily seen or palpated above the symphysis, the woman should be encouraged to void. At times, she can ambulate with assistance to a toilet and successfully void, even though she cannot void on a bedpan. If the bladder is distended and she cannot void, catheterization is indicated. Carley and colleagues (2002) found that 51 of 11,332 vaginal deliveries (1 in 200) were complicated by urinary retention. Most women resumed normal voiding before discharge from the hospital. Musselwhite and associates (2007) reported retention in 4.7 percent of women who had labor epidural analgesia. Risk factors that increased likelihood of retention were primiparity, oxytocin-induced or -augmented labor, perineal lacerations, instrumented delivery, catheterization during labor, and labor with duration more than 10 hours.

Management of the Second Stage of Labor

With full cervical dilatation, which signifies the onset of the second stage, a woman typically begins to bear down. With descent of the presenting part, she develops the urge to defecate. Uterine contractions and the accompanying expulsive forces may now last 1½ minutes and recur at an interval no longer than 1 minute. As discussed on page 389, the median duration of the second stage is 50 minutes in nulliparas and 20 minutes in multiparas, although the interval can be highly variable. Monitoring of the fetal heart rate is discussed on page 393, and interpretation of second-stage electronic fetal heart rate patterns is discussed in Chapter 18 (p. 425).

Expulsive Efforts

In most cases, bearing down is reflexive and spontaneous during second-stage labor. Occasionally, a woman may not employ her expulsive forces to good advantage and coaching is desirable. Her legs should be half-flexed so that she can push with them against the mattress. When the next uterine contraction begins, she is instructed to exert downward pressure as though she were straining at stool. In a randomized study from Istanbul, Yildirim and Beji (2008) reported that open-glottis pushing while breathing out was superior to the closed-glottis breath-held Valsalva-type pushing. The former method resulted in a shorter second stage and better cord acid-base values. A woman is not encouraged to push beyond the completion of each contraction. Instead, she and her fetus should be allowed to rest and recover. During this period of actively bearing down, the fetal heart rate auscultated immediately after the contraction is likely to be slow but should recover to normal range before the next expulsive effort.

A number of positions during the second stage have been recommended to augment pushing efforts. Eason and colleagues (2000) performed an extensive review of various positions and their effect on the incidence of perineal trauma. They found that the supported upright position had no advantages over the recumbent one. Upright positions include sitting, kneeling, squatting, or resting with the back at a 30-degree elevation. Conversely, in their systematic review, Berghella and colleagues (2008) reported good-quality data that supported the upright position. Fetal and obstetrical outcomes appear to be unaffected whether pushing is coached or uncoached during second-stage labor (Bloom and co-workers, 2006; Hansen and associates, 2002). The maternal effects of coached pushing were reported by Schaffer and colleagues (2005), who performed urodynamic testing in primiparas 3 months following delivery. Those coached to push during second-stage labor had decreased bladder capacity and decreased first urge to void compared with women encouraged to push or rest as desired. The long-term effects of this practice are yet to be defined.

As the head descends through the pelvis, feces frequently are expelled by the woman. With further descent, the perineum begins to bulge and the overlying skin becomes stretched. Now the scalp of the fetus may be visible through the vulvar opening. At this time, the woman and her fetus are prepared for delivery.

Preparation for Delivery

Delivery can be accomplished with the mother in a variety of positions. The most widely used and often the most satisfactory one is the dorsal lithotomy position. At Parkland Hospital, the lithotomy position is not mandated for normal deliveries. In many birthing rooms, delivery is accomplished with the woman lying flat on the bed.

For better exposure, leg holders or stirrups are used. In placing the legs in holders, care should be taken not to separate the legs too widely or place one leg higher than the other. This may exert pulling forces on the perineum that might easily result in extension of a spontaneous tear or of an episiotomy into a fourth-degree laceration. The popliteal region should rest comfortably in the proximal portion and the heel in the distal portion of the leg holder. The legs are not strapped into the stirrups, thereby allowing quick flexion of the thighs backward onto the abdomen should shoulder dystocia develop (see Chapter 20, p. 481). The legs may cramp during the second stage, in part, because of pressure by the fetal head on nerves in the pelvis. They may be relieved by changing the position of the leg or by brief massage, but leg cramps should never be ignored.

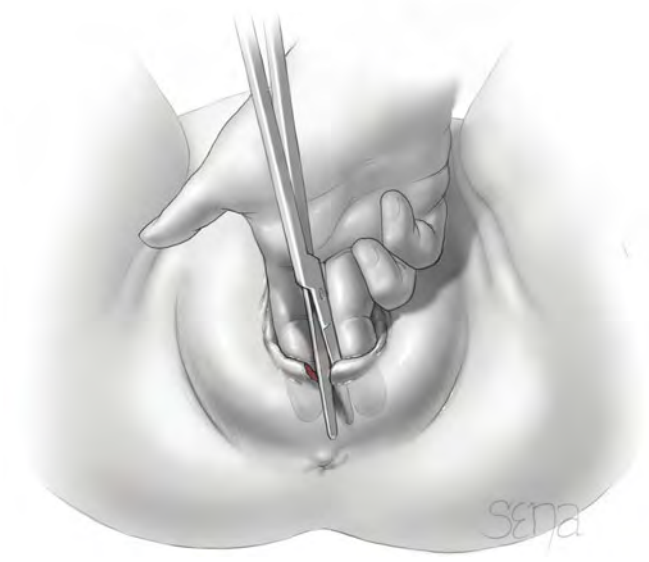

FIGURE 17-24 Midline episiotomy being made. Two fingers are insinuated between the perineum and fetal head, and the episiotomy is then cut vertically downward.

Preparation for delivery should include vulvar and perineal cleansing. If desired, sterile drapes may be placed in such a way that only the immediate area around the vulva is exposed. In the past, the major reason for care in scrubbing, gowning, and gloving was to protect the laboring woman from the introduction of infectious agents. Although these considerations remain valid, infectious disease exposure concerns today must also be extended to healthcare providers.

Spontaneous Delivery

Delivery of the Head

With each contraction, the perineum bulges increasingly. The vulvovaginal opening is dilated by the fetal head (Fig. 17-24), gradually forming an ovoid and, finally, an almost circular opening (Fig. 17-25). This encirclement of the largest head diameter by the vulvar ring is known as *crowning*. Unless an episiotomy has been made as described later, the perineum thins and especially in nulliparous women, may undergo spontaneous laceration. Slow delivery of the head while instructing the mother not to push may decrease lacerations according to Laine and co-workers (2008). The anus becomes greatly stretched and protuberant, and the anterior wall of the rectum may be easily seen through it.

There once was considerable controversy concerning whether an episiotomy should be cut routinely. It is now clear that an episiotomy will increase the risk of a tear into the external anal sphincter or the rectum or both. Conversely, anterior tears involving the urethra and labia are more common in women in whom an episiotomy is not cut. Most, including us, advocate individualization and do not routinely perform episiotomy. This issue is discussed in detail on page 401.

Ritgen Maneuver. When the head distends the vulva and perineum enough to open the vaginal introitus to a diameter of 5 cm or more, a towel-draped, gloved hand may be used to exert forward pressure on the chin of the fetus through the perineum just in front of the coccyx. Concurrently, the other hand exerts pressure superiorly against the occiput (Fig. 17-26). This maneuver is simpler than that originally described by Ritgen (1855), and it is customarily designated the *modified Ritgen maneuver* (Cunningham, 2008).

This maneuver allows controlled delivery of the head (Fig. 17-27). It also favors neck extension so that the head is delivered with its smallest diameters passing through the introitus and over the perineum. Mayerhofer and colleagues (2002) have challenged the use of the Ritgen maneuver because it was associated with more third-degree lacerations and more frequent use of episiotomy. They preferred the "hands-poised" method, in

FIGURE 17-25 Delivery of the head. The occiput is being kept close to the symphysis by moderate pressure to the fetal chin at the tip of the maternal coccyx.

FIGURE 17-26 Near completion of the delivery of the fetal head by the modified Ritgen maneuver. Moderate upward pressure is applied to the fetal chin by the posterior hand covered with a sterile towel, while the suboccipital region of the fetal head is held against the symphysis.

FIGURE 17-27 Delivery of the head. The mouth appears over the perineum.

which the attendant did not touch the perineum during delivery of the head. This method had similar associated laceration rates as the modified Ritgen maneuver, but with a lower incidence of third-degree tears. Recently, Jönsson and associates (2008) reported results of their trial of 1623 women. They found a similar incidence of third- and fourth-degree tears—5.5 versus 4.4 percent—in women assigned to the Ritgen maneuver versus simple perineal support.

Delivery of the Shoulders

After its delivery, the fetal head falls posteriorly, bringing the face almost into contact with the maternal anus. As described on page 380, the occiput promptly turns toward one of the maternal thighs, and the head assumes a transverse position (Fig. 17-28). This movement of restitution—external rotation—indicates that the bisacromial diameter, which is the transverse diameter of the thorax, has rotated into the anteroposterior diameter of the pelvis.

FIGURE 17-28 Aspirating the nose and mouth immediately after delivery of the head.

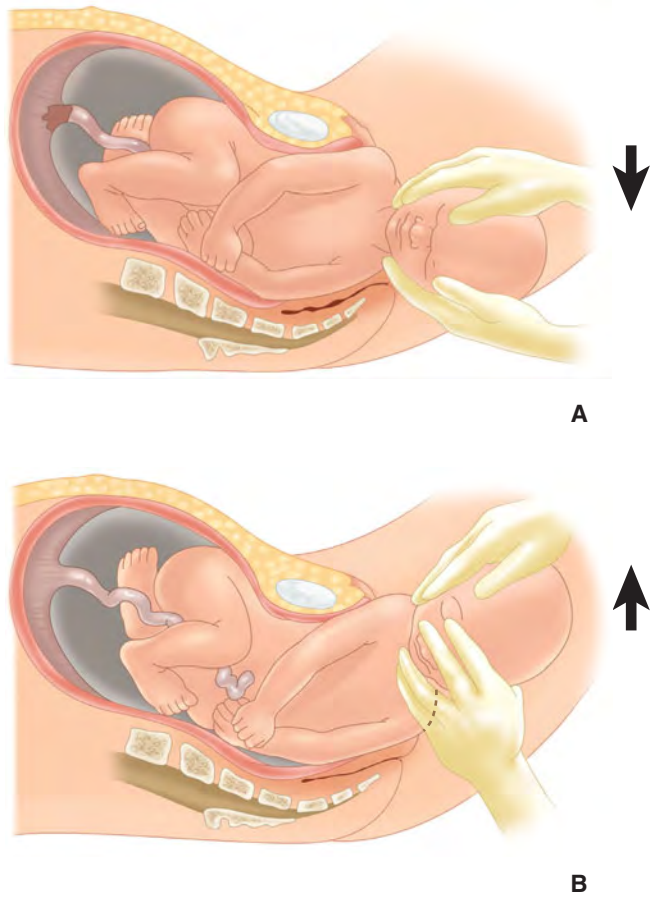

FIGURE 17-29 A. Gentle downward traction to effect descent of the anterior shoulder. **B.** Delivery of the anterior shoulder completed. Gentle upward traction to deliver the posterior shoulder.

Most often, the shoulders appear at the vulva just after external rotation and are born spontaneously. If delayed, immediate extraction may appear advisable. The sides of the head are grasped with two hands, and gentle downward traction is applied until the anterior shoulder appears under the pubic arch (Fig. 17-29). Some prefer to deliver the anterior shoulder prior to suctioning the nasopharynx or checking for a nuchal cord to avoid shoulder dystocia. Next, by an upward movement, the posterior shoulder is delivered (see Fig. 17-29).

The rest of the body almost always follows the shoulders without difficulty. With prolonged delay, however, its birth may be hastened by moderate traction on the head and moderate pressure on the uterine fundus. Hooking the fingers in the axillae should be avoided. This may injure the nerves of the upper extremity and produce a transient or possibly permanent paralysis. Traction, furthermore, should be exerted only in the direction of the long axis of the neonate. If applied obliquely, it causes bending of the neck and excessive stretching of the brachial plexus (see Chap. 29, p. 636).

Immediately after delivery of the newborn, there is usually a gush of amnionic fluid, often blood-tinged but not grossly bloody.

FIGURE 17-30 The umbilical cord is identified around the neck and is readily slipped over the head.

Clearing the Nasopharynx

Once the thorax is delivered and the newborn can inspire, the face is quickly wiped and the nares and mouth are aspirated, as demonstrated in Figure 17-28. This minimizes fetal aspiration of amnionic fluid, particulate matter, and blood.

Nuchal Cord

Following delivery of the anterior shoulder, a finger should be passed to the fetal neck to determine whether it is encircled by one or more coils of the umbilical cord (Fig. 17-30). A nuchal cord is found in approximately 25 percent of deliveries and ordinarily causes no harm. If a coil of umbilical cord is felt, it should be slipped over the head if loose enough. If applied too tightly, the loop should be cut between two clamps and the neonate promptly delivered.

Clamping the Cord

The umbilical cord is cut between two clamps placed 4 to 5 cm from the fetal abdomen, and later an umbilical cord clamp is applied 2 to 3 cm from the fetal abdomen. A plastic clamp that is safe, efficient, and fairly inexpensive, such as the Double Grip Umbilical Clamp (Hollister), is used at Parkland Hospital.

Timing of Cord Clamping. If after delivery the newborn is placed at or below the level of the vaginal introitus for 3 minutes and the fetoplacental circulation is not immediately occluded by cord clamping, an average of 80 mL of blood may be shifted from the placenta to the neonate (Yao and Lind, 1974). This provides approximately 50 mg of iron, which reduces the frequency of iron-deficiency anemia later in infancy. At the same time, however, increased bilirubin from the added erythrocytes contributes further to hyperbilirubinemia (see Chap. 29, p. 625). In their recent Cochrane Database review of randomized trials, McDonald and Middleton (2008) reported that delaying cord clamping until 1 minute after birth increased the newborn hemoglobin concentration 2.2 g/dL compared with clamping within the first 60 seconds. At the same time, early clamping reduced the risk of phototherapy by 40 percent.

Our policy is to clamp the cord after first thoroughly clearing the airway, all of which usually requires approximately 30 seconds. The newborn is not elevated above the introitus at vaginal delivery or much above the maternal abdominal wall at the time of cesarean delivery.

Management of the Third Stage of Labor

Immediately after delivery of the newborn, the size of the uterine fundus and its consistency are examined. If the uterus remains firm and there is no unusual bleeding, watchful waiting until the placenta separates is the usual practice. Massage is not employed, but the fundus is frequently palpated to make certain that it does not become atonic and filled with blood from placental separation.

Signs of Placental Separation

Because attempts to express the placenta prior to its separation are futile and possibly dangerous, the clinician should be alert to the following signs of placental separation:

1. The uterus becomes globular and as a rule, firmer
2. There is often a sudden gush of blood
3. The uterus rises in the abdomen because the placenta, having separated, passes down into the lower uterine segment and vagina. Here, its bulk pushes the uterus upward
4. The umbilical cord protrudes farther out of the vagina, indicating that the placenta has descended.

These signs sometimes appear within 1 minute after delivery of the newborn and usually within 5 minutes. When the placenta has separated, it should be determined that the uterus is firmly contracted. The mother may be asked to bear down, and the intra-abdominal pressure may be adequate to expel the placenta. If these efforts fail or if spontaneous expulsion is not possible because of anesthesia, then after ensuring that the uterus is contracted firmly, pressure is exerted with the hand on the fundus to propel the detached placenta into the vagina, as depicted and described in Figure 17-31. This approach has been termed *physiological management* as later contrasted with *active management* of the third stage (Thilaganathan and colleagues, 1993).

Delivery of the Placenta

Expression of the placenta should never be forced before placental separation lest the uterus becomes inverted. **Traction on the umbilical cord must not be used to pull the placenta out of the uterus.** Uterine inversion is one of the grave complications associated with delivery, and it constitutes an emergency requiring immediate attention (see Chap. 35, p. 780). As downward pressure toward the vagina is applied to the body of the uterus, the umbilical cord is kept slightly taut (see Fig. 17-31). The uterus is then lifted cephalad with the abdominal hand.

FIGURE 17-31 Expression of placenta. Note that the hand is *not* trying to push the fundus of the uterus through the birth canal! As the placenta leaves the uterus and enters the vagina, the uterus is elevated by the hand on the abdomen while the cord is held in position. The mother can aid in the delivery of the placenta by bearing down. As the placenta reaches the perineum, the cord is lifted, which in turn lifts the placenta out of the vagina.

This maneuver is repeated until the placenta reaches the introitus (Prendiville and associates, 1988b). As the placenta passes through the introitus, pressure on the uterus is stopped. The placenta is then gently lifted away from the introitus (**Fig. 17-32**). Care is taken to prevent the membranes from being torn off and left behind. If the membranes start to tear, they are

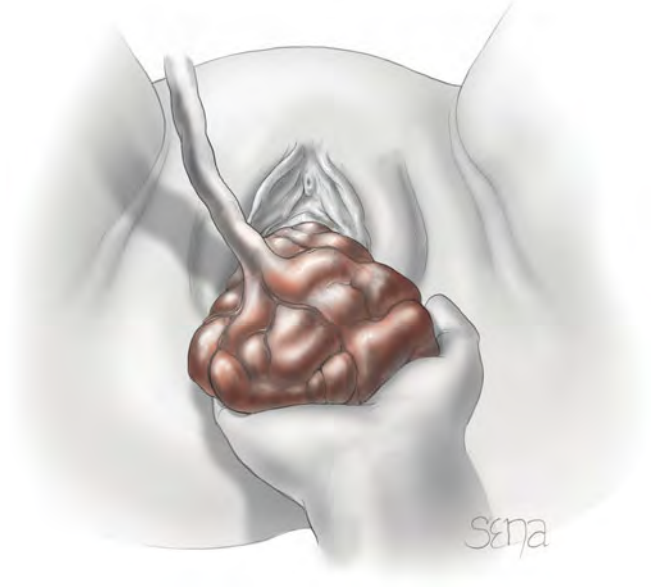

FIGURE 17-32 The placenta is removed from the vagina by lifting the cord.

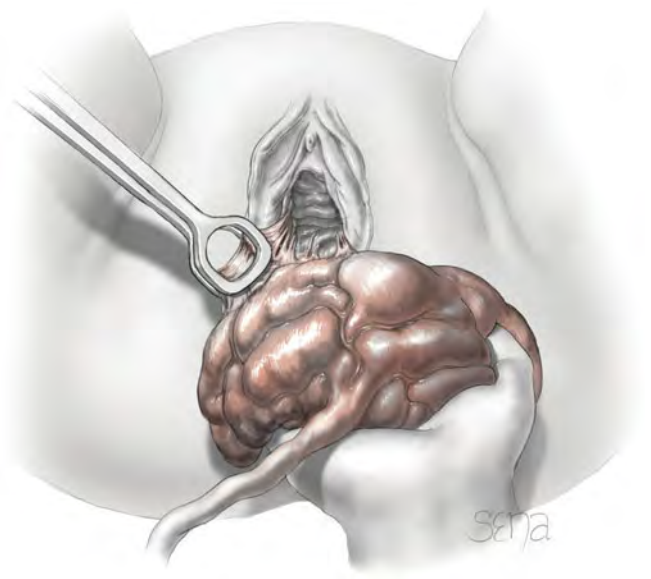

FIGURE 17-33 Membranes that were somewhat adherent to the uterine lining are separated by gentle traction with a ring forceps.

grasped with a clamp and removed by gentle teasing (**Fig. 17-33**). The maternal surface of the placenta should be examined carefully to ensure that no placental fragments are left in the uterus.

Manual Removal of Placenta

Occasionally, the placenta will not separate promptly. This is especially common in cases of preterm delivery (Dombrowski and colleagues, 1995). If there is brisk bleeding and the placenta cannot be delivered by the above technique, manual removal of the placenta is indicated, using the safeguards described in Chapter 35 (p. 774). It is unclear as to the length of time that should elapse in the absence of bleeding before the placenta is manually removed (Deneux-Tharaux and co-workers, 2009). If induction analgesia is still intact, some obstetricians practice routine manual removal of any placenta that has not separated spontaneously by the time they have completed delivery of the newborn and care of the cord. Proof of the benefits of this practice, however, has not been established, and most obstetricians await spontaneous placental separation unless bleeding is excessive. The American College of Obstetricians and Gynecologists (2003b) has concluded that there are no data to either support or refute the use of prophylactic antimicrobials when manual removal is performed.

Management of the Third Stage

Uterine massage following placental delivery is recommended by many to prevent postpartum hemorrhage. We support this but note that evidence for this practice is lacking (Hofmeyr and associates, 2008). Oxytocin, ergonovine, and methylergonovine are all employed widely in the normal third stage of labor, but the timing of their administration differs in various institutions. Oxytocin, and especially ergonovine, given before delivery of the placenta will decrease blood loss (Prendiville and associates, 1988a). If they are given before delivery of the placenta,

however, they may entrap an undiagnosed, undelivered second twin. However, Jackson and colleagues (2001) randomly assigned 1486 women to infusions of 20 units of oxytocin diluted in 500 mL normal saline begun before or after placental delivery and found no differences in outcomes.

If an intravenous infusion is in place, our standard practice has been to add 20 units (2 mL) of oxytocin per liter of infusate. This solution is administered after delivery of the placenta at a rate of 10 mL/min (200 mU/min) for a few minutes until the uterus remains firmly contracted and bleeding is controlled. The infusion rate then is reduced to 1 to 2 mL/min until the mother is ready for transfer from the recovery suite to the postpartum unit. The infusion is usually then discontinued.

Oxytocin

The synthetic form of the octapeptide oxytocin is commercially available in the United States as Syntocinon and Pitocin. Each milliliter of injectable oxytocin, which is not effective by mouth, contains 10 USP units. The half-life of intravenously infused oxytocin is approximately 3 minutes. Before delivery, the spontaneously laboring uterus is typically exquisitely sensitive to oxytocin and dosing is carefully titrated to achieve adequate contractions (see Chap. 22, p. 506). After delivery of the fetus, however, these dangers no longer exist and fixed dosing, as described earlier, may be used.

Cardiovascular Effects

More than 30 years ago, Secher and co-workers (1978) reported that, even in healthy women, an intravenous bolus of 10 units of oxytocin caused a marked transient fall in blood pressure with an abrupt increase in cardiac output. More recently, Svanström and associates (2008) confirmed those findings in 10 otherwise healthy women following cesarean delivery. Mean pulse rate increased 28 bpm, mean arterial pressure decreased 33 mm Hg, and electrocardiogram changes of myocardial ischemia as well as chest pain and subjective discomfort were noted. These hemodynamic changes could be dangerous for women hypovolemic from hemorrhage or those with cardiac disease. **Thus, oxytocin should not be given intravenously as a large bolus.** Rather, it should be given as a dilute solution by continuous intravenous infusion or as an intramuscular injection in a dose of 10 USP units. In cases of postpartum hemorrhage, direct injection into the uterus, either transvaginally or transabdominally, following a vaginal birth or cesarean delivery has proven effective.
