CHAPTER 55

Neurological and Psychiatric Disorders

NEUROLOGICAL DISORDERS 1164
PSYCHIATRIC DISORDERS 1175

Neurological and psychiatric disorders encountered during pregnancy are those that are common to reproductive-aged women. Some may be even more common in pregnancy. Examples are Bell palsy, some types of stroke, and depression.

NEUROLOGICAL DISORDERS

A number of neurological diseases are relatively common in women of childbearing age. Many of these once precluded childbearing, but less so now. Somewhat related, neurological disorders can profoundly disrupt normal sexual function (Rees and colleagues, 2007). That said, many women with chronic neurological disease become pregnant and have successful pregnancy outcomes. Conversely, neurological diseases do contribute to maternal mortality rates, and there are specific risks with which the clinician should be familiar.

Diagnosis of Neurological Disease During Pregnancy

Many women with chronic neurological disease have been diagnosed before pregnancy. In others, neurological symptoms appear for the first time and must be distinguished from pregnancy complications. Because these symptoms may involve cognitive as well as neuromuscular functions, they must also be distinguished from psychiatric disorders. In general, pregnant women should receive the same evaluation as any other patient.

Central Nervous System Imaging

Computed tomography (CT) and *magnetic resonance (MR) imaging* have opened new vistas for the diagnosis, classification, and management of many neurological and psychiatric disorders (Dineen and colleagues, 2005). As discussed in Chapter 41 (p. 918), both imaging methods can be used safely during pregnancy. Computed tomography is commonly used whenever rapid diagnosis is necessary. However, in less acute situations, MR imaging is often preferred because of its low radiation exposure. It is particularly helpful to diagnose demyelinating diseases, screen for arteriovenous malformations, evaluate congenital and developmental nervous system abnormalities, identify posterior fossa lesions, and diagnose spinal cord diseases. MR imaging is superior for detecting acute ischemia and acute and chronic hemorrhage, and therefore, is preferable for stroke evaluation (Chalela and associates, 2007). For either test, the woman should be positioned in a left lateral tilt with a wedge under one hip to prevent hypotension as well as to diminish aortic pulsations, which may degrade the image.

Cerebral angiography with contrast injection, usually via the femoral artery, is a valuable adjunct to the diagnosis and treatment of some cerebrovascular diseases. *Fluoroscopy* involves more radiation but can be performed if necessary with careful abdominal shielding.

Headache

According to the National Health Interview Survey updated annually by the Centers for Disease Control and Prevention (2006a, b), a fourth of women aged 18 to 44 years report a severe headache or migraine within the past 3 months. And the most common neurological complaint during pregnancy is headache. The classification of headaches by the International Headache Society (2004) is shown in **Table 55-1**. *Cluster headaches* are not commonly reported in pregnancy and were reviewed by Giraud and Chauvet (2009). *Thunderclap headaches*

TABLE 55-1. Classification of Headache

can be primary or may be due to other causes in Table 55-1 (Singhal and colleagues, 2009).

Tension-Type Headache

These are common, and characteristic features include muscle tightness and mild to moderate pain that can persist for hours in the back of the neck and head. There are no associated neurological disturbances or nausea. The pain usually responds to rest, massage, application of heat or ice, anti-inflammatory medications, or mild tranquilizers. In 95 women with a headache postpartum, 39 percent were tension-type headaches (Stella and colleagues, 2007). Headaches from depression may be attributed to tension headaches.

Migraine Headache

The term *migraine* describes a periodic, sometimes incapacitating neurological disorder characterized by episodic attacks of severe headache and autonomic nervous system dysfunction. The International Headache Society (2004) classifies three migraine types based on the presence or absence of an aura as well as chronicity:

1. Migraine without aura—formerly common migraine—is characterized by a unilateral throbbing headache, nausea and vomiting, or photophobia
2. Migraine with aura—formerly classical migraine—has similar symptoms preceded by premonitory neurological phenomena such as visual scotoma or hallucinations. A third of patients have this type of migraine, which sometimes can be averted if medication is taken at the first premonitory sign
3. Chronic migraine is defined by headache occurring at least 15 days each month, for more than 3 months, and without obvious cause.

Migraines may begin in childhood, peak in adolescence, and tend to diminish in both frequency and severity with advancing years. The annual prevalence is 17 percent in women and 6 percent in men (Lipton and colleagues, 2007). Another 5 percent of women have *probable migraine*—they have all criteria but one (Silberstein and co-workers, 2007). Migraines are especially common in young women and have been linked to hormone levels in an as yet unclear relationship. For example, migraine headaches are worsened in at least half of women at the time of menstruation (Brandes, 2006).

The exact pathophysiology of migraines is uncertain, but they occur when neuronal dysfunction leads to decreased cortical blood flow, activation of vascular and meningeal nociceptors, and stimulation of trigeminal sensory neurons (Brandes and associates, 2007; Silberstein, 2004a). A predilection for the posterior circulation has been described by Kruit and co-workers (2004). Migraines—especially those with aura in young women—are associated with increased risk for ischemic strokes. The risk is greater in those who smoke or use oral contraceptives.

Migraine in Pregnancy. At least two comprehensive reviews document that 50 to 70 percent of *migraineurs* have improvement of headaches during pregnancy (Adeney and Williams, 2006; Silberstein, 2004b). However, migraines—usually with an aura—occasionally appear for the first time during pregnancy. Pregnant women with preexisting migraine symptoms may have other symptoms suggestive of a more serious disorder. Thus, the onset of new neurological symptoms should prompt a complete evaluation (Detsky and colleagues, 2006; Marcus, 2007).

Banhidy and associates (2006) reported preliminary data that possibly link severe migraine in the first 8 weeks with a slightly increased risk for a fetus with limb-reduction defects. Data has accrued linking migraine headaches with other serious pregnancy complications such as preeclampsia and other cardiovascular morbidities (Adeney and Williams, 2006; Faccinetti and colleagues, 2009; Scher and associates, 2005). In a case-control study done from nearly 18.5 million pregnancy-related discharges from 2000 through 2003, Bushnell and co-workers (2009) identified ICD-9 (International Classification of Disease, 9th edition) migraine codes in 185 per 100,000 discharges. Associated diagnoses and significant odds ratios were found for migraines and stroke—15; migraines and myocardial infarction or heart disease—2.1; and venous thromboembolism—3.2; hypertension—8.6; smoking—2.9; and gestational hypertension including preeclampsia—2.3.

Management. Most migraine headaches respond to simple analgesics such as aspirin, ibuprofen, or acetaminophen, especially if given early. Severe headaches should be treated aggressively with intravenous hydration, parenteral antiemetics, and opioids if necessary (American College of Obstetricians and Gynecologists, 2002a). Antiemetics such as promethazine, prochlorperazine, or metoclopramide are frequently needed and are commonly given with meperidine.

Ergotamine derivatives are potent vasoconstrictors that should be avoided in pregnancy, although inadvertent use in early pregnancy does not appear to pose significant risk (Briggs and colleagues, 2005).

Triptans are serotonin 5-$HT_{1B/2D}$-receptor agonists that are highly effective to relieve headaches by causing intracranial

vasoconstriction (Silberstein, 2004a). They also relieve nausea and vomiting and greatly reduce the need for analgesics. They can be given orally, by injection, as a rectal suppository, or as a nasal spray. The greatest experience is with sumatriptan, and although not studied extensively in pregnancy, it appears to be safe (Briggs and co-workers, 2005). In nonpregnant adults, Brandes and colleagues (2007) showed superior efficacy of sumatriptan 85 mg plus naproxen 500 mg—about 60-percent of migraineurs gained relief at 2 hours—compared with either drug given alone. The manufacturer's Sumatriptan and Naratriptan Pregnancy Registry (2004) of 414 prospectively enrolled pregnancies has reported no adverse effects. There is correspondingly less experience with other triptans in pregnancy.

For women with frequent migraine headaches, prophylactic therapy is indicated (American College of Obstetricians and Gynecologists, 2002a). Amitriptyline, 10 to 150 mg/day; propranolol, 20 to 80 mg three times daily; atenolol, 50 to 100 mg/day; or labetalol, 50 to 150 mg two times daily, are safe in pregnancy and have been used with success (Dey and associates, 2002; Marcus, 2007).

Seizure Disorders

The Centers for Disease Control and Prevention reported that the prevalence of epilepsy in adults in 2005 was 1.65 percent (Kobau and colleagues, 2008). This is estimated to include 1.1 million American women of childbearing age, and seizure disorders complicate 1 in 200 pregnancies (Brodie and Dichter, 1996; Yerby, 1994). After headaches, these are the second most prevalent—and a more serious—neurological condition encountered in pregnant women. Epilepsy itself can alter fetal development and can affect the course of pregnancy, labor, and delivery. Importantly, the teratogenic effects of several anticonvulsant medications are unquestioned.

Pathophysiology

A seizure is defined as a paroxysmal disorder of the central nervous system characterized by an abnormal neuronal discharge with or without loss of consciousness. Epilepsy encompasses a number of different syndromes whose cardinal feature is a predisposition to recurrent unprovoked seizures (Chang and Lowenstein, 2003). Epileptic syndromes fit into two broad categories—*partial* or *generalized seizures.* Accurate classification is important when therapy is selected.

Partial Seizures. These originate in one localized area of the brain and affect a correspondingly localized area of neurological function. They are believed to result from trauma, abscess, tumor, or perinatal factors, although a specific lesion is rarely demonstrated. *Simple motor seizures* start in one region of the body and progress toward other ipsilateral areas of the body, producing tonic and then clonic movements. Simple seizures can affect sensory function or produce autonomic dysfunction or psychological changes. Consciousness is usually not lost, and recovery is rapid. *Partial seizures* can secondarily generalize, producing loss of consciousness and convulsions. *Complex partial seizures,* also called *temporal lobe* or *psychomotor seizures*, usually involve clouding of consciousness.

Generalized Seizures. These involve both brain hemispheres simultaneously and may be preceded by an aura before an abrupt loss of consciousness. There is a strong hereditary component. In grand mal seizures, loss of consciousness is followed by tonic contraction of the muscles and rigid posturing, and then by clonic contractions of all extremities while the muscles gradually relax. Return to consciousness is gradual, and the patient may remain confused and disoriented for several hours. *Absence* seizures, also called *petit mal seizures*, are a form of generalized epilepsy that involve a brief loss of consciousness without muscle activity and are characterized by immediate recovery of consciousness and orientation.

Causes of Seizures

Some identifiable causes of convulsive disorders in young adults include trauma, alcohol- and other drug-induced withdrawals, brain tumors, biochemical abnormalities, and arteriovenous malformations. A search for these is prudent with a new-onset seizure disorder in a pregnant woman. The diagnosis of idiopathic epilepsy is one of exclusion.

Epilepsy During Pregnancy

The major pregnancy-related threats to women with epilepsy are increased seizure rates and risks for fetal malformations. Although earlier studies described a worsening of seizure activity during pregnancy, this is not so now because of better prenatal management. In a recent community-based, prospective study from Finland, Viinikainen and co-workers (2006) reported that epilepsy either was better controlled or showed no change in 83 percent of pregnant women. Meador and co-workers (2006) reported an 81-percent seizure-free rate in pregnancy for 333 women enrolled in multicenter observational studies. Prepregnancy control seems important too. From the Australian Registry, Vajda and colleagues (2008) reported that the risk of seizures during pregnancy was decreased by 50 to 70 percent if the year before was seizure free.

Increased seizure frequency is often associated with lowered and thus subtherapeutic anticonvulsant levels, a lower seizure threshold, or both. Subtherapeutic levels can be caused by nausea and vomiting; decreased gastrointestinal motility and use of antacids that diminish drug absorption; pregnancy hypervolemia offset by protein binding; induction of hepatic, plasma, and placental enzymes that increase drug metabolism; and increased glomerular filtration that hastens drug clearance. Importantly, some women discontinue medication because of teratogenicity concerns. Finally, the seizure threshold can be affected by pregnancy-related sleep deprivation as well as hyperventilation and pain during labor.

Embryofetal Malformations. Recent evidence suggests that untreated epilepsy is not associated with increased malformations (Thomas and co-workers, 2008; Viinikainen and colleagues, 2006). *But the fetus of an epileptic mother who takes anticonvulsant medications has an indisputably increased risk of congenital malformations.* Monotherapy is associated with a lower birth defect rate compared with multiagent therapy. And if necessary, increasing monotherapy dosage initially is preferable

to adding another agent (Buhimschi and Weiner, 2009). When given alone, therapy with phenytoin, carbamazepine, and probably phenobarbital increases the major malformation rate two- to threefold above baseline (Perucca, 2005; Thomas and associates, 2008). Early data indicate a similar risk with lamotrigine. The major exception is valproate, which is dose dependent and increases the risk to as high as four- to eightfold (Eadie, 2008; Wyszynski and colleagues, 2005). Fetal exposure to monotherapy with valproate—but not phenytoin, carbamazepine, or lamotrigine—was recently linked with impaired cognitive function at age 3 years (Meador and co-workers, 2009). When polytherapy is used, the risk increases with each drug used. These are discussed in greater detail in Chapter 14 (p. 317).

Pregnancy Complications. Women with epilepsy have a small increased risk of some pregnancy complications other than seizures (Harden and associates, 2009). Olafsson and colleagues (1998) performed a population-based study and found that Icelandic epileptic women had a twofold increased cesarean delivery rate. In a cohort study from Montreal, Richmond and co-workers (2004) reported an increased incidence of nonproteinuric hypertension and labor induction. From a Swedish study of 1207 epileptic women, Pilo and colleagues (2006) reported a 1.5-fold increased incidence of cesarean delivery, preeclampsia, and postpartum hemorrhage. Postpartum depression has also been reported as increased (Turner and associates, 2009). Finally, children of epileptic mothers have a 10-percent risk of developing a seizure disorder.

Preconceptional Counseling. Women with epilepsy should benefit from preconceptional counseling (see Chap. 7, p. 176). According to findings in their Cochrane review, however, Winterbottom and associates (2009) found no objective evidence of its effectiveness. Topics addressed include optimal anticonvulsant management, preferably monotherapy with the least teratogenic drug, or at least a reduction in the number of drugs taken. Although some recommend that these be limited to the older and more traditional anticonvulsants—phenytoin, carbamazepine, and phenobarbital—there are newer drugs that may actually have less teratogenic potential. For example, Cunnington and Tennis (2005) described outcomes from the International Lamotrigine Pregnancy Registry. When used as monotherapy, *lamotrigine* was associated with a 2.9-percent rate of malformations, and as polytherapy with other drugs, except valproate, the risk was 2.7 percent. Hunt and associates (2006) presented preliminary data that *levetiracetam* use was associated with a 2.7-percent birth defect rate. Other new anticonvulsants were reviewed by Stefan and Feuerstein (2007).

Physical activity should exclude driving during early pregnancy if associated vomiting prevents drug ingestion. Folic acid supplementation is emphasized, and it likely decreases malformation rates in women taking anticonvulsants (Kjaer and associates, 2008). Plans for fetal evaluation and optimal pregnancy management are outlined.

Contraception should be discussed. Anticonvulsants such as phenobarbital, primidone, phenytoin, and carbamazepine may cause breakthrough bleeding and hormonal contraceptive failure (Table 32-5, p. 678). They do this by induction of hepatic P_{450} microsomal enzyme systems, which increase estrogen metabolism. For these reasons, some recommend that oral contraceptives containing 50 μg of estrogen be used with anticonvulsants (Harden and Leppik, 2006). Conversely, anticonvulsants may adversely affect both male and female fertility (Artama and co-workers, 2006).

Management in Pregnancy. The major goal is seizure prevention. To accomplish this, treatment for nausea and vomiting should be provided, seizure-provoking stimuli should be avoided, and medication compliance should be emphasized. Anticonvulsants should be maintained at the lowest dosage associated with seizure control. Although some routinely monitor serum drug levels during pregnancy, these may be unreliable because of altered protein binding. Free or unbound drug levels, although more helpful, are not widely available. And also, there is no evidence that such monitoring improves seizure control (Adab, 2006). For these reasons, drug levels may be measured only following seizures or if noncompliance is suspected. Exceptions may be newer agents such as lamotrigine and oxcarbazepine (Battino and Tomson, 2007; Pennell and associates, 2007).

At midpregnancy, specialized sonographic examination may aid in identifying anomalies (see Chap. 16, p. 351). Tests of fetal well-being are generally not performed for uncomplicated epilepsy.

Cerebrovascular Diseases

Most malformations of blood vessels of the brain involve the arterial system. They can cause a *stroke*, defined as an abrupt neurological deficit caused by embolization or occlusion. Embolization causes an *ischemic stroke*, and rupture of a cerebral vessel causes a *hemorrhagic stroke* (Smith and colleagues, 2008a). The Centers for Disease Control and Prevention (2007) estimates that in 2005, 0.8 percent of all women aged 18 to 44 years had a history of a stroke.

Stroke is relatively uncommon in pregnant women, but contributes disparately to maternal mortality. The reported incidence ranges from 15 to 35 per 100,000 pregnancies (James, 2005; Liang, 2006; Simolke, 1994, and all their co-workers). According to data from the Centers for Disease Control and Prevention reported by Chang and colleagues (2003), stroke caused 5 percent of 4200 pregnancy-related maternal deaths in the United States from 1991 through 1999. From indicators of severe obstetrical morbidity described in two reports from the Centers for Disease Control and Prevention, strokes were responsible for 2.5 percent of hospitalizations for severe maternal morbidity in the United States from 1991 through 2003 (Callaghan and co-workers, 2008). Importantly, the prevalence of stroke-related hospitalization did not increase from 1998 through 2005 (Kuklina and associates, 2009).

Risk Factors

Various risk factors—unrelated and related to pregnancy—from three large studies that included more than 10 million pregnancies are shown in Table 55-2. By far, in aggregate, the most common risk factor is some form of hypertension—chronic, gestational, or preeclampsia. In their study of 2850 pregnancy-related strokes, James and co-workers (2005) reported that about 10 percent of

TABLE 55-2. Risk Factors for Strokes During Pregnancy

Not Pregnancy Related	Pregnancy Related
Age	Gestational hypertension
Migraine headaches	Preeclampsia
Thrombophilias	Hemorrhage
Heart disease	Transfusions
Valve prosthesis	Cesarean delivery
Patent foramen ovale	Puerperal sepsis
Lupus erythematosus	
Sickle-cell disease	
Hypertension	

From De La Vega (2007); James (2005); Lanska and Kryscio (2000); Lin (2008); Ros (2002), and all their associates.

all strokes developed antepartum, 40 percent intrapartum, and almost 50 percent postpartum. Ros and associates (2002) computed a 100-fold risk of stroke at the time of delivery. Peripartum stroke is about 1.5-fold more common in cesarean compared with vaginal delivery (Lin and colleagues, 2008).

Types of Stroke

Causes of the two major types of stroke are shown in Table 55-3. Their distribution differs depending on definition and classification, but they are almost equal in incidence.

Ischemic Stroke

These are most common in older patients. In young pregnant women, however, they constitute a relatively smaller proportion of the total number of strokes. Ischemic strokes usually result from arterial or venous thrombosis or arterial embolism.

TABLE 55-3. Types of Strokes During Pregnancy or Puerperium

Type	Comments
Ischemic Strokes	
Preeclampsia-eclampsia	Common
Arterial thrombosis	Common
Venous thrombosis	Uncommon
Others—vasculopathy, arterial dissection, metastatic malignancy, unknown	Uncommon
Hemorrhagic Strokes	
Hypertension	Common

Saccular aneurysm	Less common
Others—cocaine, angioma, vasculopathy, unknown	Uncommon

From Ishimori (2006); Jaigobin (2000); James (2005); Jeng (2004); Kittner (1996); Liang (2006); Pervulov, 2009; Saad (2006); Sharshar (1995); Simolke (1991); Witlin (2000), and all their colleagues.

Particular to pregnancy, evidence has accrued in the past 10 years that some women with eclampsia suffer from areas of cerebral infarction (Zeeman and colleagues, 2004a). Aukes and associates (2007, 2009) have shown that such women may have increased white-matter lesions that persist at follow-up several years later, and some suffer residual cognitive dysfunction (see Chap. 34, p. 749). A few women with eclampsia will suffer symptomatic strokes from larger cortical infarctions (see Chap. 34, p. 721 and Fig. 34-14). The *reversible cerebral vasoconstriction syndrome*—also termed *postpartum angiopathy*—can cause extensive cerebral edema with necrosis and widespread infarction with areas of hemorrhage (Ramnarayan and Sriganesh, 2009; Singhal and colleagues, 2009).

Cerebral Artery Thrombosis. Most thrombotic strokes occur in older individuals. They are caused by atherosclerosis, and the internal carotid artery is the most commonly affected site. Most cases are preceded by one or more transient ischemic attacks. With stroke, patients usually present with sudden onset of severe headache, hemiplegia or other neurological deficits, or seizures. In contrast, focal neurological symptoms accompanied by an aura usually signify a first-episode migraine (Liberman and co-workers, 2008). Evaluation includes serum lipid profile, echocardiography, and cranial imaging with CT, MR imaging, or angiography. Because antiphospholipid antibodies cause up to a third of ischemic strokes in otherwise healthy young patients, pregnant women with this stroke type are usually evaluated for these (see Chap. 54, p. 1151). In some, vasculopathy such as Moyamoya disease may be found (Ishimori and colleagues, 2006).

Over the past decade, thrombolytic therapy has become standard care for ischemic stroke seen within the first 3 hours (Khaja and Grotta, 2007). Recombinant tissue plasminogen activator—rt-PA or alteplase—is recommended if the patient is within the 3-hour window, if there is measurable neurological deficit, and if neuroimaging has excluded hemorrhage. A principal risk is hemorrhagic transformation of an ischemic stroke in about 5 percent of treated patients (van der Worp and van Gijn, 2007). There is limited experience with thrombolytic treatment for ischemic stroke in pregnancy. Leonhardt (2006) and Murugappan (2006) and their associates found only three case reports and added another eight. Outcomes were similar to those in nonpregnant patients. One woman at 12 weeks' gestation developed an "intrauterine hematoma" and elected pregnancy termination.

The recurrence risk for ischemic stroke in association with pregnancy is low unless a specific, persistent cause is identified. Lamy and colleagues (2000) studied 489 consecutive women of reproductive age with stroke. There were 37 women with an ischemic stroke during pregnancy or the puerperium, and none of their 24 subsequent pregnancies was complicated by recurrent stroke. Coppage and associates (2004) described 23 women with strokes before pregnancy due to a variety of causes. They had 35 subsequent pregnancies without a recurrent stroke. This may even be the case if antiphospholipid antibodies are detected. For example, the Antiphospholipid Antibodies and Stroke Study observed 1770 nonpregnant patients with ischemic stroke (APASS Investigators, 2004). In these subjects,

there was no difference in the recurrence risk whether anticardiolipin or antiphospholipid antibodies were present as long as preventative treatment was given with warfarin or aspirin. Currently, there are no firm guidelines regarding prophylaxis in pregnant women with a stroke history (Helms and co-workers, 2009).

Cerebral Embolism. This usually involves the middle cerebral artery and is more common during the latter half of pregnancy or early puerperium (Lynch and Nelson, 2001). The diagnosis can be made with confidence only after thrombosis and hemorrhage have been excluded. The latter can be difficult to distinguish because cerebral artery embolization and thrombosis are both followed by infarction. The diagnosis of thromboembolism is more certain if an embolic source is identified. Paradoxical embolism is thought to be a common cause because more than a fourth of adults have a patent foramen ovale. This allows right-sided venous thromboemboli to bypass filtration by the lungs (Kizer and Devereux, 2005). Foraminal closure prevents recurrences, and Schrale and co-workers (2007) described percutaneous closure in three women in their third trimester. Other causes of embolism include an arrhythmia—especially atrial fibrillation, rheumatic valvular damage, or mitral valve prolapse. Finally, emboli from infective endocarditis must be considered (Cox and associates, 1988).

Management of embolic stroke consists of supportive measures and antiplatelet therapy. Anticoagulation is controversial (Kizer and Devereux, 2005).

Cerebral Venous Thrombosis. In a 10-center study in the United States, 7 percent of cerebral venous thromboses were associated with pregnancy (Wasay and co-workers, 2008). Even so, pregnancy-associated cerebral venous thrombosis is rare in developed countries—reported incidences range from 1 in 11,000 to 1 in 45,000 pregnancies (Cross, 1968; Lanska and Kryscio, 1997; Simolke, 1991, and all their colleagues). In the Nationwide Inpatient Sample of more than 8 million deliveries, James and associates (2005) observed that venous thrombosis caused only 2 percent of strokes during pregnancy. According to Ehtisham and Stern (2006), more than 100 causes have been documented.

Lateral or superior sagittal venous sinus thrombosis usually occurs in the puerperium, and often in association with preeclampsia, sepsis, or thrombophilias. It is more common in patients with inherited thrombophilias, lupus anticoagulant, or antiphospholipid antibodies (see Chap. 54, p. 1151). Headache is the most common presenting symptom, neurological deficits are common, and up to a third of patients have convulsions (Wasay and colleagues, 2008). MR imaging is the preferred radiological procedure (Ehtisham and Stein, 2006).

Management includes anticonvulsants for seizures, and antimicrobials if septic thrombophlebitis is suspected. Heparin anticoagulation is recommended by most, but its efficacy is controversial (de Freitas and Bogousslavsky, 2008; Smith and co-workers, 2008a). Thrombolytic therapy as discussed above has also been used. The clinical course is unpredictable and the prognosis guarded. Mortality rates are 15 to 30 percent, and survivors have a recurrence rate of 1 to 2 percent, including during subsequent pregnancy (Mehraein and colleagues, 2003).

Hemorrhagic Stroke

The two distinct categories of spontaneous intracranial bleeding are *intracerebral* and *subarachnoid hemorrhage*. Trauma-associated subdural and epidural hemorrhage are not considered.

Intracerebral Hemorrhage. Bleeding into the substance of the brain most commonly is caused by spontaneous rupture of small vessels damaged by chronic hypertension (Qureshi and colleagues, 2001; Takebayashi and Kaneko, 1983). In pregnancy-associated hemorrhagic strokes such as the one shown in Figure 55-1, there often is chronic hypertension with superimposed preeclampsia (Cunningham, 2005). Intracerebral hemorrhage has much higher morbidity and mortality rates than subarachnoid hemorrhage because of its location. And chronic hypertension is associated with *Charcot-Bouchard microaneurysms* of the penetrating branches of the middle cerebral artery. Pressure-induced rupture causes bleeding in the putamen, thalamus, adjacent white matter, pons, and cerebellum. In the 28 women described by Martin and associates (2005), half died and most survivors had permanent disabilities. They underscored the importance of proper management for gestational hypertension—especially systolic hypertension—to prevent cerebrovascular pathology (see Chap. 34, p. 721).

Subarachnoid Hemorrhage. These bleeds are more likely caused by an underlying cerebrovascular malformation in an otherwise normal patient. Ruptured saccular or "berry" aneurysms cause 80 percent of all subarachnoid hemorrhages, and ruptured arteriovenous malformations (AVMs), coagulopathies, angiopathies, venous thromboses, infections, drug abuse, tumors, and trauma cause the remainder. Rupture of a cerebral aneurysm or angioma or bleeding from a vascular malformation occurs in 1 in 75,000 pregnancies. This incidence does not differ from that in

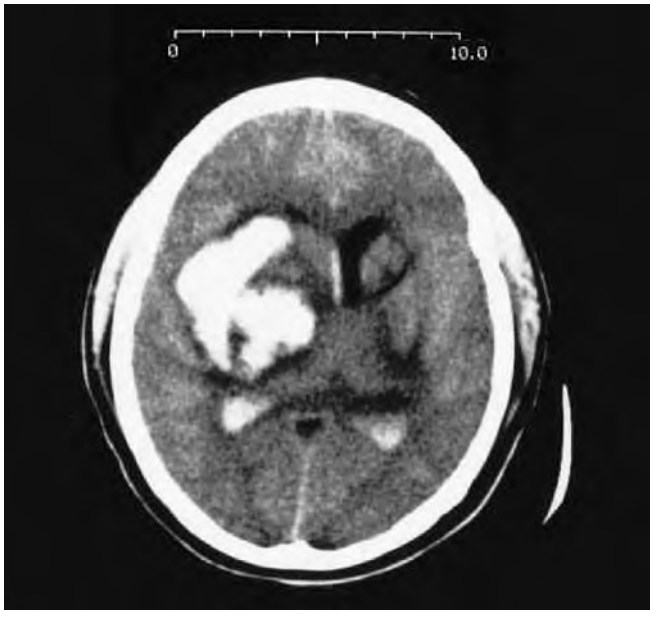

FIGURE 55-1 Large intracerebral hemorrhage caused by hypertensive stroke in a nulliparous woman whose blood pressure was recorded at 270/140 mm Hg.

the general nonobstetrical population, but the mortality rate during pregnancy is reported to be as high as 35 percent (Dias and Sekhar, 1990). Case-control studies from Japan and New Zealand found that nulligravidity significantly increased the risk of subarachnoid hemorrhage (Mhurchu and co-workers, 2001; Okamoto and colleagues, 2001).

Pregnancy-induced effects on cerebrovascular hemodynamics are unclear as related to intracranial hemorrhage. For example, Zeeman and co-workers (2003) reported that cerebral blood flow *decreased* by 20 percent from midpregnancy until term. Intuitively, this would "protect" against bleeding from vascular malformations. With gestational hypertension, however, Zeeman and colleagues (2004b) showed that cerebral blood flow *increased* significantly. Although such hyperperfusion is assumed to be dangerous with vascular anomalies, most saccular aneurysm ruptures are not associated with preeclampsia.

Intracerebral Aneurysm. Approximately 2 percent of adults have an intracranial aneurysm. Only a small percentage of these rupture—approximately 0.1 percent for aneurysms <10 mm and 1 percent for those >10 mm (Smith and colleagues, 2008a). Aneurysms are not more likely to bleed during pregnancy (Groenestege and co-workers, 2009). Still, during pregnancy, bleeding from aneurysms is more common than that from AVMs. Aneurysms are more likely to bleed during the second half of pregnancy—only about 20 percent bleed during the first half (Dias and Sekhar, 1990). As in the nonpregnant population, most aneurysms identified during pregnancy are in the circle of Willis and 20 percent are multiple (Stoodley and coworkers, 1998). The cardinal symptom is sudden severe headache, accompanied by visual changes, cranial nerve abnormalities, focal neurological deficits, or altered consciousness. Patients typically have signs of meningeal irritation, tachycardia, transient hypertension, low-grade fever, leukocytosis, and proteinuria.

Prompt diagnosis and treatment may prevent potentially lethal complications. A recent comparative study showed MR imaging to be superior to CT scanning for all varieties of stroke (Chalela and associates, 2007). If the initial study is normal but the clinical picture strongly suggests subarachnoid hemorrhage, the cerebrospinal fluid should be examined, and if it is bloody, angiography is done to locate the lesion (Roman and associates, 2004).

Treatment includes bed rest, analgesia, and sedation, with neurological monitoring and strict control of blood pressure. The decision to attempt repair of a potentially accessible aneurysm during pregnancy depends in part on the risk of recurrent hemorrhage and the risks of surgery. In nonpregnant patients, with conservative treatment only, the risk of subsequent bleeding from the aneurysm is 20 to 30 percent for the first month and then 3 percent per year. Recurrent hemorrhage leads to death in 70 percent. Early repair is done with clipping of the aneurysm or by endovascular coil placement. It seems reasonable that for women near term, cesarean delivery followed by either method is a consideration. There appears to be no advantage to pregnancy termination unless there is associated preeclampsia.

It also seems reasonable to allow vaginal delivery if labor occurs remote from aneurysmal repair. A problem is what "remote" implies—although some say 2 months, the time for healing is unknown. For women who survive subarachnoid hemorrhage, but in whom surgical repair is not done, we agree with Cartlidge (2000) and recommend against bearing down—put another way, we favor cesarean delivery.

Arteriovenous Malformations (AVMs). When these congenital vascular anomalies bleed, half do so into the subarachnoid space and half are intraparenchymal hemorrhage with subarachnoid extension (Smith and colleagues, 2008a). The incidence of bleeding from cerebral AVMs probably is not increased during pregnancy (Finnerty and co-workers, 1999; Horton and associates, 1990). Thus, they are very uncommon, and in the study from Parkland Hospital, Simolke and associates (1991) reported only one case in nearly 90,000 deliveries (**Fig. 55-2**). Although some suggest that AVMs bleed with similar frequency throughout gestation, Dias and Sekhar (1990) reported an increase with gestational age. Karlsson and colleagues (1997) reported that the risk of bleeding from an AVM increases with maternal age.

In nonpregnant patients, there is no consensus on whether all of these lesions should be resected, even when accessible. Whether or not the lesion has bled is also a factor. After hemorrhage, the risk of recurrent bleeding in unrepaired lesions is almost 20 percent within the first year and 2 to 3 percent per year thereafter (Smith and associates, 2008a). The mortality rate with bleeding AVMs is 10 to 20 percent. In pregnancy, the decision to operate is usually based on neurosurgical considerations (Finnerty and associates, 1999). Citing a *possible* higher risk of rebleeding during pregnancy, Friedlander

FIGURE 55-2 Magnetic resonance imaging of a left-sided frontal lobe atriovenous malformation. The lesion caused subarachnoid bleeding at 29 weeks in a 24-year-old primigravida who presented with severe headache, nausea, and vomiting. (From Simolke and colleagues, 1991, with permission.)

(2007) recommends strong consideration for treatment during pregnancy. Because of the high risk of recurrent hemorrhage from an unresected or inoperable lesion, we favor cesarean delivery.

Demyelinating or Degenerative Diseases

Demyelinating diseases compose a group of neurological disorders that involve focal or patchy destruction of central nervous system myelin sheaths accompanied by an inflammatory response. The degenerative diseases are multifactorial and are characterized by progressive neuronal death.

Multiple Sclerosis (MS)

In the United States, multiple sclerosis is second to trauma as a cause of neurological disability in middle adulthood (Hauser and Goodin, 2008). Because MS affects women twice as often as men and usually begins in the 20s and 30s, women of reproductive age are most susceptible. The familial recurrence rate of MS is 15 percent, and the incidence in offspring is increased 15-fold.

The demyelinating characteristic of this disorder results from predominately T cell-mediated autoimmune destruction of oligodendrocytes that synthesize myelin. There is a genetic susceptibility and likely an environmental trigger such as exposure to certain bacteria and viruses, for example, *Chlamydophilia pneumoniae,* human herpesvirus 6, or Epstein-Barr virus (Frohman and associates, 2006).

There are four clinical types of MS (Hauser and Goodin, 2008):

1. *Relapsing-remitting MS* accounts for initial presentation in 85 percent of affected individuals. It is characterized by unpredictable recurrent episodes of focal or multifocal neurological dysfunction usually followed by full recovery. Over time, however, relapses lead to persistent deficits.
2. *Secondary progressive MS* disease is when relapsing-remitting disease begins to pursue a progressive downhill course after each relapse. It is likely that all patients eventually develop this type.
3. *Primary progressive MS* accounts for 15 percent of cases. It is characterized by gradual progression of disability from the time of initial diagnosis.
4. *Progressive-relapsing MS* refers to primary progressive MS with apparent relapses.

Classical symptoms include sensory loss, visual symptoms from optic neuritis, weakness, paresthesias, and a host of other neurological symptoms. Almost 75 percent of women with isolated optic neuritis develop multiple sclerosis within 15 years. Clinical diagnosis is confirmed by MR imaging and cerebrospinal fluid analysis. In greater than 95 percent of cases, MR imaging shows characteristic multifocal white matter *plaques* that represent discrete areas of demyelination. Their appearance and extent are less helpful for treatment response. Similarly, Kuhle and colleagues (2007) reported that identification of serum antibodies against myelin oligodendrocyte glycoprotein (MOG) and myelin basic protein (MBP) is not predictive of recurrent disease activity.

Management. Some treatments of MS may need to be modified during pregnancy. Goals are to arrest acute or initial attacks, employ disease modifying agents, and provide symptomatic relief. Acute or initial attacks are treated with high-dose intravenous methylprednisolone—500 to 1000 mg daily for 3 to 5 days, followed by oral prednisone for 2 weeks. Plasma exchange may be considered. Symptomatic relief can be provided by analgesics; carbamazepine, phenytoin, or amitriptyline for neurogenic pain; baclofen for spasticity; α_2-adrenergic blockade to relax the bladder neck; and cholinergic and anticholinergic drugs to stimulate or inhibit bladder contractions.

Several immunomodulators can be used for relapsing MS or exacerbations. These include interferons β1a and β1b, glatiramer acetate, and mitoxantrone (Frohman and colleagues, 2006). Other medications sometimes used include azathioprine, methotrexate, cyclophosphamide, and intravenous immunoglobulin G. Recent clinical trials show that treatment with *natalizumab*—alpha 4 integrin antagonist—especially when combined with interferon B1a, significantly reduced MS clinical relapses (Polman and colleagues, 2006; Rudick and coworkers, 2006).

Data concerning the safety of some of these drugs in pregnancy are limited (Sandberg-Wollheim and associates, 2005). Interferon appears to be safe however, methotrexate and cyclophosphamide should not be given during fetal organogenesis (Briggs and co-workers, 2005; Buhimschi and Weiner, 2009).

Effects of Pregnancy on MS. The *P*regnancy *I*n *M*ultiple *S*clerosis *(PRIMS)* study is a European prospective multicenter effort. From this study, findings from 254 pregnancies that were complicated by MS were reported by Vukusic and Confavreux (2006). They confirmed a decreased relapse rate during pregnancy and significantly increased relapses postpartum (Fig. 55-3). This may be related to increased T helper type 2: type 1 cell ratios during pregnancy (Airas and colleagues, 2008). In an earlier review of eight studies including

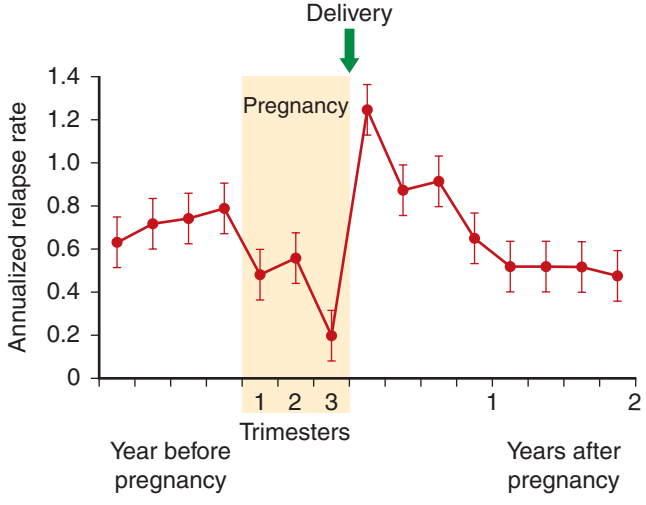

FIGURE 55-3 PRIMS study: Annualized relapse rates for women with multiple sclerosis in the year before, during, and the 2 years after pregnancy. (Data from Vukusic and Confavreux, 2006.)

more than 1000 pregnancies, Abramsky (1994) found that MS worsened during pregnancy in only 10 percent.

Effects of MS on Pregnancy. Uncomplicated MS usually has no adverse effects on pregnancy outcome. Women may become fatigued more easily, and those with bladder dysfunction are prone to urinary infection. Dahl and co-workers (2006) described 449 pregnancies in women with MS. From 1991 through 2002, they reported a higher induction rate and longer second-stage labors. The increased cesarean delivery rate was due to these inductions as well as elective planned operations. It is reasonable to use usual obstetrical indicators for cesarean delivery. Vaginal delivery does not worsen voiding problems (Durufle and associates, 2006). Women with spinal lesions at or above T6 are at risk for autonomic dysreflexia and epidural analgesia is recommended (see p. 1174). Dahl and associates (2005) studied perinatal outcomes in 649 women with MS and reported that despite a lower mean birthweight than controls, neonatal mortality rates were not increased.

There is evidence that intravenous immune globulin (IVIG) therapy—0.4 g/kg for 5 days—given during postpartum weeks 1, 6, and 12 reduces relapse rates (Argyriod and Makris, 2008). Postpartum exacerbations may prevent women from breast feeding. These may also inhibit the ability to provide general newborn care, and the need for assistance during this period should be anticipated.

Huntington Disease

This adult-onset neurodegenerative disease results from an autosomal dominant mutation that encodes the protein *huntingtin* (Walker, 2007). The disorder is characterized by a combination of choreoathetotic movements and progressive dementia. Because the mean age of onset is 40 years, Huntington disease rarely complicates pregnancy. Prenatal diagnosis is discussed in Chapter 12 (p. 276). Prenatal screening is controversial because this usually is a late-onset adult disease (Richards and Rea, 2005).

Myasthenia Gravis (MG)

This autoimmune-mediated neuromuscular disorder affects about 1 in 7500 persons. It is more common in women, and its incidence peaks when they are in their 20s and 30s. The etiology is unknown, but genetic factors likely play a role. The pathological basis of the disease is IgG-mediated damage to acetylcholine receptors. This leads to diminished end-plate action potentials that result in weakened muscle contractions (Conti-Fine and associates, 2006).

Cardinal features of MG are weakness and easy fatigability of facial, oropharyngeal, extraocular, and limb muscles. Deep tendon reflexes are preserved. Cranial muscles are involved early and disparately, and diplopia and ptosis are common. Facial muscle weakness causes difficulty in smiling, chewing, and speaking. In 85 percent of patients, the weakness becomes generalized. Other autoimmune diseases may coexist, and hypothyroidism should be excluded. The clinical course of MG is marked by exacerbations and remissions, especially when it first becomes clinically apparent. Remissions are not always complete and are seldom permanent. Systemic diseases, concurrent infections, and even emotional upset may precipitate exacerbations, of which there are three types:

1. *Myasthenic crises,* characterized by severe muscle weakness, inability to swallow, and respiratory muscle paralysis
2. *Refractory crises,* characterized by the same symptoms but unresponsive to the usual therapy
3. *Cholinergic crises,* in which excessive cholinergic medication leads to nausea, vomiting, muscle weakness, abdominal pain, and diarrhea.

All three of these can be life threatening, but a refractory crisis is a medical emergency. Those with bulbar myasthenia are at particular risk because they may be unable to swallow or even ask for help.

Management. Myasthenia is manageable but not curable. About 75 percent of patients have thymic hyperplasia or a thymoma that can be seen with CT or MR imaging. In these individuals, thymectomy is generally recommended because of long-term benefits (Drachman, 2008). Anticholinesterase medications such as *pyridostigmine*, an analog of neostigmine, bring about improvement by impeding acetylcholine degradation. They seldom produce normal muscle function, and ironically, overdose is manifest by increased weakness that may be difficult to differentiate from myasthenic symptoms. For those refractory to medical therapy, most respond to immunosuppressive therapy with glucocorticoids, azathioprine, cyclosporine, and mycophenolate mofetil. Cyclophosphamide is reserved for refractory cases. When short-term rapid clinical improvement is needed—for example, a surgical procedure or a myasthenic crisis—high-dose immunoglobulin G or plasmapheresis, and possibly methylprednisolone, can be used (Gajdos and colleagues, 2006).

Myasthenia and Pregnancy. Because the greatest period of risk is within the first year following diagnosis, it seems reasonable to postpone pregnancy until there is sustained symptomatic improvement. Antepartum management includes close observation with liberal bed rest and prompt treatment of any infections (Kalidindi and associates, 2007). Most patients respond well to pyridostigmine administered every 3 to 4 hours. Those in remission who become pregnant while taking corticosteroids or azathioprine should continue these. *Thymectomy* has been successfully performed during pregnancy in refractory cases (Ip and colleagues, 1986). Acute onset of myasthenia or its exacerbation demands prompt hospitalization and supportive care. *Plasmapheresis* and high-dose immunoglobulin therapy should be used for emergency situations, taking care not to provoke maternal hypotension or hypovolemia (Drachman, 2008).

Although pregnancy does not appear to affect the overall course of MG, the expanding uterus may compromise respiration, and fatigue common to most pregnancies may be tolerated poorly. The clinical course during pregnancy is unpredictable, and frequent hospitalizations are the norm. In three observational studies of 136 women, about 20 percent worsened during pregnancy (Batocchi, 1999; Djelmis, 2002; Podciechowski, 2005, and all their colleagues). Maternal deaths are usually due to complications of myasthenia or its treatment.

Labor and Delivery. MG does not affect smooth muscle, and most women have normal labor. Oxytocin is given as necessary. Cesarean delivery is reserved for obstetrical indications. Close observation and prompt respiratory support are essential. Narcotics may cause respiratory depression. Any drug with a curare-like effect should be avoided—examples include magnesium sulfate, muscle relaxants used with general anesthesia, and aminoglycosides. Amide-type local anesthetic agents should be used for epidural analgesia. Regional analgesia is preferred unless there is significant bulbar involvement or respiratory compromise. During second-stage labor, some women may have impaired voluntary expulsive efforts, and forceps delivery may be indicated.

Neonatal Effects. Anti-acetylcholine-receptor IgG antibodies can be found in 85 percent of MG patients. These can cross the placenta and affect the fetus. About 10 to 20 percent of exposed neonates develop symptoms (Podciechowski and associates, 2005). Neonatal symptoms are most likely if the mother produces autoantibodies directed against embryonic rather than adult acetylcholine receptors (Vernet-der Garabedian and colleagues, 1994). Transient symptomatic myasthenia gravis in an affected neonate typically results in a feeble cry, poor suckling, and respiratory distress. All of these can be corrected by parenteral neostigmine or small doses of edrophonium, and symptoms usually resolve within 2 to 6 weeks.

Neuropathies

Peripheral neuropathy is a general term used to describe disorders of peripheral nerve(s) of any cause. Because neuropathy can result from a variety of causes, its discovery should prompt a search for an etiology. *Polyneuropathies* can be axonal or demyelinating as well as acute, subacute, or chronic (Chaudhry, 2008). They are often associated with systemic diseases such as diabetes, with drug or environmental toxin exposure, or with genetic diseases. *Mononeuropathies* signify focal involvement of a single nerve trunk and imply local causation such as trauma, compression, or entrapment—an example is carpal-tunnel syndrome (England and Asbury, 2004).

Guillain-Barré Syndrome (GBS)

In 75 percent of cases, this acute demyelinating polyradiculoneuropathy has clinical or serological evidence of an acute infection. Commonly associated are *Campylobacter jejuni*, cytomegalovirus, and Epstein-Barr virus (Hauser and Asbury, 2008). Some cases follow surgical procedures or immunizations. The syndrome is thought to be immune-mediated from antibodies formed against infective agents. Demyelination causes sensory and motor conduction blockade, but is restored with remyelination.

Clinical features include areflexic paralysis with mild sensory disturbances and at times, autonomic dysfunction. The full syndrome develops after 1 to 3 weeks. Management is supportive, but in the worsening phase, patients should be hospitalized because approximately 25 percent need ventilatory assistance. If begun within 1 to 2 weeks of motor symptoms, intravenous high-dose immunoglobulin or plasmapheresis is beneficial but does not decrease mortality rates (Hughes and colleagues, 2007). Almost 85 percent of patients recover fully, but the remainder are disabled or have one or more late relapses.

Pregnancy. The incidence of Guillain-Barré syndrome is not increased antepartum. Although it is said to be increased threefold postpartum, data are sparse (Cheng and co-workers, 1998). When GBS develops during pregnancy, its clinical course does not seem to be changed. After an insidious onset, paresis and paralysis most often continue to ascend, and respiratory insufficiency can then become a common and serious problem. Hurley and colleagues (1991) reported that a third of affected pregnant women ultimately required ventilatory support, and the overall mortality rate was 13 percent. Treatment of acute GBS in pregnancy is with either high-dose immunoglobulin or plasmapheresis (Chan, 2004; Kuller, 1995; Rockel, 1994, and all their co-workers).

Bell Palsy

This acute idiopathic peripheral facial paralysis of unknown etiology is relatively common, especially in women of reproductive age. Reactivation of herpes-virus infection may cause it, and there is some evidence to link neural damage with acute HIV-1 retroviral infections (Serrano and associates, 2007). Women are affected two to four times more often than men of the same age, and pregnant women are affected three to four times more often than nonpregnant women (Cohen and colleagues, 2000). The onset is usually abrupt and painful, with maximum weakness within 48 hours. In some cases, hyperacusis and loss of taste accompany varying degrees of facial muscle paralysis (Beal and Hauser, 2008).

Increased extracellular fluid, viral inflammation, and the relative immune suppression of pregnancy are thought to be predisposing factors. Data from five Canadian centers suggest that women who developed Bell palsy had a fivefold increase incidence of gestational hypertension compared with their general obstetrical population (Shmorgun and colleagues, 2002).

Sullivan and colleagues (2007) reported a randomized trial of nearly 500 nonpregnant patients enrolled within 72 hours of symptom onset. Those given prednisolone had better outcomes than those given acyclovir or placebo. At 3 months, 83 percent given steroids had recovery of facial function, compared with only 64 percent of those not given prednisolone. At 9 months, these were 95 versus 82 percent, respectively. The addition of acyclovir to prednisolone did not improve outcomes. Importantly, supportive care includes facial muscle massage, prevention of injury to the constantly exposed cornea, and reassurance.

Effects of Pregnancy. It is uncertain if pregnancy alters the prognosis for spontaneous recovery from facial palsy. Gillman and colleagues (2002) found that only half of pregnant women recovered to a satisfactory level after 1 year—this compares with about 80 percent of nonpregnant women and men. Bilateral palsies, recurrence in a subsequent pregnancy, greater percentage of nerve function loss, and a faster rate of loss are prognostic markers for incomplete recovery (Cohen and associates, 2000; Gilden, 2004). Electroneurography may also be helpful in determining prognosis. As discussed, corticosteroid therapy given early in the course of the disease significantly improves outcomes. Supportive treatment is given, and measures taken to prevent corneal injury.

Carpal Tunnel Syndrome

This syndrome results from pressure on the median nerve. There are a variety of associated conditions, and pregnancy is a common one (Smith and colleagues, 2008b). Symptoms include burning, numbness, or tingling in the inner half of one or both hands, and wrist pain and numbness extending into the forearm and sometimes into the shoulder (Katz and Simmons, 2002). Symptoms are bilateral in 80 percent of pregnant women, and 10 percent have signs of severe denervation (Seror, 1998). Carpal tunnel syndrome should be distinguished from *De Quervain tendonitis* caused by swelling of the conjoined tendons and sheaths near the distal radius. Nerve conduction studies may be helpful in distinguishing these two.

Pregnancy. The incidence in pregnancy varies greatly and is reported to range from 1 to 17 percent (Bahrami, 2005; Finsen and Zeitlmann, 2006; Stolp-Smith, 1998, and all their co-workers). In a multicenter Italian study, the incidence of the syndrome diagnosed clinically during the third trimester was an astounding 63 percent. In more than half of these, diagnosis was confirmed by neurophysiological evaluation (Pazzaglia and colleagues, 2005). Importantly, one year later, half of affected women still had some symptoms. This high incidence has not been observed by others, and it is far less common in our large services at Parkland and the University of Alabama at Birmingham Hospitals.

Carpal tunnel syndrome is usually self-limited, and in most cases, symptomatic treatment is sufficient. A splint applied to a slightly flexed wrist and worn during sleep relieves pressure to provide relief for most women. Occasionally, surgical decompression and corticosteroid injections are necessary (Dammers and associates, 1999; Gerritsen and co-workers, 2002).

Spinal Cord Injury

Of the 11,000 spinal cord injuries each year, at least 50 percent are in patients of reproductive age, and 18 percent of these are women (American College of Obstetricians and Gynecologists, 2002b). Management guidelines are available for impaired sexual functioning (Elliott, 2006; Rees and colleagues, 2007). In a survey of 472 reproductive-aged women with such injuries, Jackson and Wadley (1999) found that two thirds resumed intercourse after the injury, and almost 14 percent became pregnant. Although fertility in women is probably not affected, pregnancy rates are only 50 percent in partners of injured men (De Forge and co-workers, 2005).

Women with spinal cord injury have increased frequencies of preterm and low-birthweight infants, and they experience more pregnancy complications compared with unaffected women. The majority have either asymptomatic bacteriuria or symptomatic urinary infection. Serum creatinine levels are used to detect renal damage from repeated infection. Significant bowel dysfunction and constipation develop in more than half of women. Anemia and pressure necrosis skin lesions are also common. There are two serious and life-threatening complications that can develop:

1. If the spine is transected above T10, the cough reflex is impaired, and respiratory function may be compromised. Pneumonitis triggered by covert aspiration can be serious. Pulmonary function tests may be indicated, and some women with high lesions may need ventilatory support in late pregnancy or in labor.
2. In women with lesions above T5–T6, *autonomic dysreflexia* can develop. With this complication, stimuli from structures innervated below the level of the lesion—usually the bowel, bladder, or uterus—lead to massive disordered sympathetic stimulation. Vasoconstriction and sudden catecholamine release can cause severe hypertension and a range of symptoms including a throbbing headache, facial flushing, sweating, bradycardia, tachycardia, arrhythmia, and respiratory distress. Dysreflexia can be precipitated by a variety of stimuli, including urethral, bladder, rectal, or cervical distension; catheterization; cervical dilatation; uterine contractions; or manipulation of pelvic structures (American College of Obstetricians and Gynecologists, 2002b). In a report by Westgren and colleagues (1993), 12 of 15 women at risk for dysreflexia suffered at least one episode during pregnancy.

Uterine contractions are not affected by cord lesions, and labor is usually easy, even precipitous, and comparatively painless. If the lesion is below T12, uterine contractions are felt normally. For lesions above T12, the risk of delivery at home can be minimized by teaching women to palpate for uterine contractions. Up to 20 percent of women deliver preterm (Westgren and coworkers, 1993). Because of this, some investigators recommend tocodynamometry and weekly cervical examinations beginning at approximately 28 weeks. Hughes and associates (1991) recommend elective hospitalization between 36 and 37 weeks until delivery.

Spinal or epidural analgesia extending to T10 prevents autonomic dysreflexia and should be instituted at the start of labor. If severe symptoms begin before epidural placement, the first step is to stop whatever stimulus provoked the episode. Then, an antihypertensive agent or a peripheral vasodilator should be given. Vaginal delivery is preferred with epidural or spinal analgesia to minimize autonomic dysreflexia (Kuczkowski, 2006). Prolonged second-stage labor may be expedited with forceps or vacuum extraction with adequate conduction analgesia.

Shunts for Maternal Hydrocephalus

Pregnancies in women with ventriculoperitoneal, ventriculoatrial, or ventriculopleural shunts for hydrocephalus usually have satisfactory outcomes (Landwehr and colleagues, 1994). Partial shunt obstruction is common, typically late in pregnancy. Wisoff and associates (1991) reported neurological complications in 13 of 17 such pregnancies—these included headaches in 60 percent, nausea and vomiting in 35 percent, lethargy in 30 percent, and ataxia or gaze paresis, each in 20 percent. Most responded to conservative management. If CT scanning discloses acute hydrocephaly, the shunt can be tapped or pumped several times daily. In some cases, surgical revision is necessary.

More recently *endoscopic third ventriculostomy* has been used for hydrocephalus in children as well as adults (de Ribaupierre and associates, 2007). In the report by Riffaud and co-workers (2006), five pregnant women underwent successful ventriculostomy placement for either obstructive hydrocephalus or a malfunctioning ventriculopheritoneal shunt.

Vaginal delivery is preferred in women with shunts, and unless there is a meningomyelocele, conduction analgesia is permitted. Antimicrobial prophylaxis is indicated if the peritoneal cavity is entered for cesarean delivery or tubal sterilization.

Maternal Brain Death

There are now at least six case reports describing *maternal brain death with somatic support*. Life-support systems and parenteral alimentation were used 1 to 15 weeks to gain fetal maturity (Hussein and colleagues, 2006; Souza and associates, 2006). Aggressive tocolysis and antimicrobial therapy were used by some. Chiossi and co-workers (2006) reviewed the clinical course of 17 women with *persistent vegetative state* given various levels of support during pregnancy. At least five died after delivery, and most of the remainder continue to be in the vegetative state. The ethical, financial, and legal implications, both civil and criminal, that arise from attempting or not attempting such care are profound (Farragher and Laffey, 2005; Feldman and colleagues, 2000). Perimortem cesarean delivery is discussed in Chapter 42 (p. 942).

Benign Intracranial Hypertension—Pseudotumor Cerebri

This condition is characterized by increased intracranial pressure without hydrocephalus, possibly as the result of either overproduction or underabsorption of cerebrospinal fluid. Symptoms include headache in at least 90 percent of cases and visual disturbances—loss of a visual field or central visual acuity—in 70 percent (Evans and Friedman, 2000). Other complaints are stiff neck, back pain, pulsatile tinnitus, facial palsy, ataxia, or paresthesias. The syndrome is commonly found in young women, and it is prevalent in those who are obese, who recently gained weight, or both (Daniels and associates, 2007). Along with symptoms, other criteria for diagnosis include elevated intracranial pressure—$>$ 200 mm H_2O or $>$ 250 mm H_2O if obese—and normal composition of cerebrospinal fluid (CSF), normal cranial CT or MR imaging findings, and no evidence for systemic disease (International Headache Society, 2004).

Benign intracranial hypertension is usually self-limited. Visual defects can be prevented by lowering the CSF pressure. Drugs given to lower pressure include acetazolamide, furosemide, topiramate, or corticosteroids such as dexamethasone. In some cases, lumboperitoneal shunting of spinal fluid or optic nerve sheath decompression is necessary.

Effects of Pregnancy

Although once taught, the incidence of benign intracranial hypertension is not increased during pregnancy. The onset of symptoms, however, may first appear in pregnancy, and women previously diagnosed may become symptomatic. Symptoms usually develop by midpregnancy, tend to be self-limited, and usually resolve postpartum.

Pregnancy does not alter treatment. Some recommend serial visual field testing because visual loss can become permanent. In 16 pregnant women, Huna-Baron and Kupersmith (2002) reported that visual field loss developed in four, and it was permanent in one. Visual field loss is often coincident with the development of papilledema. Acetazolamide is given as described above, and Lee and associates (2005) reported successful treatment of 12 pregnant women. Although outmoded for treatment of nonpregnant individuals, repeated lumbar punctures are generally successful in providing temporary relief throughout pregnancy. Surgical options are lumboperitoneal shunting, endoscopic third ventriculostomy, or optic nerve sheath fenestration (Thambisetty and co-workers, 2007).

Pregnancy complications are likely due to the associated obesity, not to intracranial hypertension. In their review of 54 pregnancies, Katz and associates (1989) reported no excessive adverse perinatal outcomes. The route of delivery is decided by obstetrical indications. Conduction analgesia is permitted, and Aly and Lawther (2007) described a woman with an intrathecal catheter placed to control intracranial hypertension as well as to provide labor analgesia.

Chorea Gravidarum

Involuntary writhing of the limbs or facial muscles—chorea—may develop during pregnancy. In the past, most cases were linked to rheumatic fever in association with group A streptococcal infection (Brockington, 2006). Currently, pregnancy-related chorea is rare (Palanivelu, 2007). According to Branch (1990), chorea in pregnancy is usually caused by collagen-vascular disease, especially if there are antiphospholipid antibodies (see Chap. 54, p. 1151).

PSYCHIATRIC DISORDERS

Pregnancy and the puerperium are at times sufficiently stressful to provoke mental illness. Such illness may represent recurrence or exacerbation of a preexisting psychiatric disorder, or may signal the onset of a new disorder. In a Swedish population-based study, Andersson and associates (2003) reported a 14-percent point prevalence of psychiatric disorders during pregnancy. Unfortunately, they also found that only 5.5 percent of this fraction had some form of treatment. Importantly, Borri and co-workers (2008) found that many disorders preceded pregnancy and were detected by screening at 12 weeks.

In both the United Kingdom and Australia, where late maternal deaths—those between 43 and 365 days postpartum—are considered, psychiatric illness is a leading cause of mortality (Austin and colleagues, 2007). Suicide by violent means was responsible for 65 percent of these deaths. In a 10-year review of Washington state hospitalizations, Comtois and associates (2008) studied 355 women with a postpartum suicide attempt. In a case-control analysis, significantly increased risk factors included prior hospitalization for a psychiatric diagnosis—27 fold, for substance abuse—sixfold, and both together—11 fold. All these rates were further increased if there were multiple hospitalizations.

Adjustment to Pregnancy

Biochemical factors—including effects of hormones—and life stressors can markedly influence mental illness. It is thus intuitive that pregnancy would affect some coexisting mental disorders. Women respond in a variety of ways to stressors of pregnancy, and some express persistent concerns about fetal health,

child care, lifestyle changes, or fear of childbirth pain. Anxiety and functional impairment are common (Morewitz, 2003; Vythilingum, 2008). But, according to Littleton and co-workers (2007), anxiety symptoms in pregnancy are associated with psychosocial variables similar to those for nonpregnant women. The level of perceived stress is significantly higher for women whose fetus is at high risk for a malformation, for those with preterm labor or delivery, and for those with other medical complications (Alder and associates, 2007; Ross and McLean, 2006). For example, Hippman and co-workers (2009) screened 81 women at increased risk for a fetus with aneuploidy. Half of these had a positive screening score compared with only 2.4 percent of normal pregnant controls. A number of steps can be taken to diminish psychological stress in the event of a poor obstetrical outcome. For example, following a stillbirth, Gold and colleagues (2007) encourage parental contact with the newborn and provision of photos and other memorabilia of the infant.

The Puerperium

Because psychological stress often increases postpartum, there is increased risk for mental illness. For example, approximately 15 percent of women develop a nonpsychotic postpartum depressive disorder within 6 months of delivery (Tam and Chung, 2007). Others have a severe, psychotic illness following delivery that usually is manic-depressive (Wisner and associates, 2002). This likely is more common in women with obstetrical complications such as severe preeclampsia or fetal-growth restriction, especially if associated with early delivery (Rep and co-workers, 2007).

Maternity Blues

Also called *postpartum blues*, this is a transient state of heightened emotional reactivity experienced by half of women within approximately the first week after parturition (Miller, 2002). The predominant mood is happiness, but they are more emotionally labile with insomnia, weepiness, depression, anxiety, poor concentration, irritability, and affective lability. They may be transiently tearful for several hours and then recover completely, only to be tearful again the next day. Symptoms are mild and usually last only between a few hours to a few days. Supportive treatment is indicated, and sufferers can be reassured that the dysphoria is transient and most likely due to biochemical changes. They should be monitored for development of depression and other severe psychiatric disturbances as discussed above.

Prenatal Evaluation

Screening for mental illness is done at the first prenatal visit. Factors include a search for any psychiatric disorders, including hospitalizations, outpatient care, prior or current use of psychoactive medications, and current symptoms. Risk factors should be evaluated. For example, a prior personal or family history of depression is a significant risk for depression. Women with a history of sexual, physical, or verbal abuse; substance abuse; and personality disorders are also at greater risk for depression (Akman and colleagues, 2007; Tam and Chung, 2007). And smoking and nicotine dependence have been associated with an increase in *all* mental disorders in pregnancy (Goodwin and co-workers, 2007). Finally, because eating disorders may be exacerbated by pregnancy, affected women should be followed closely.

Treatment Considerations

A large number of psychotropic medications may be used for management of the myriad mental disorders encountered in pregnancy. Their application is discussed with respective disorders. Women taking psychotropic medication should be informed of likely side effects. Dell and O'Brien (2003) advocate a risk-benefit model of drug selection that factors the concerns of both mother and fetus. Many of these drugs are discussed in more detail throughout Chapter 14 as well as by the American College of Obstetricians and Gynecologists (2007).

Pregnancy Outcomes

There are only a few reports of psychiatric disorders and pregnancy outcomes. In a population-based cohort of more than 500,000 California births, Kelly and colleagues (2002) assessed the perinatal effects of a psychiatric diagnosis that included all *ICD-9-CM* diagnostic codes. Women with these diagnoses had up to a threefold increased incidence of very-low- or low-birthweight neonates or preterm delivery. Conversely, Littleton and associates (2007) reviewed 50 studies and concluded that anxiety symptoms had no adverse effect on outcomes.

Classification of Mental Disorders

The *Diagnostic and Statistical Manual-IV-TR* is the most recent updated version by the American Psychiatric Association (2000b). Its purpose is to assist in the classification of mental disorders, and it specifies criteria for each diagnosis. Shown in Table 55-4 are 12-month prevalences for adults.

Major Mood Disorders

These include major depression—a unipolar disorder—and manic-depression—a bipolar disorder with both manic and depressive episodes. It also includes dysthymia, which is chronic, mild depression. Major mood disorders as a group contribute to two thirds of all suicides.

Major Depression

This is the most common mood disorder, and the National Mental Health Association (2004) estimates that each year 12 million women are affected. The lifetime incidence is 12 percent, but only half ever seek care. The diagnosis is arrived at by identifying symptoms listed in Table 55-5.

Major depression is multifactorial and prompted by genetic and environmental factors. First-degree relatives have a 25-percent risk, and female relatives are at even higher risk. Families of affected individuals often have members with alcohol abuse and anxiety disorders. Provocative conditions leading to depression include life events that prompt grief reactions, substance abuse, use of certain medications, and other medical disorders. Although life events can trigger depression, genes influence the liability to life events, making the distinction between genetic and environmental factors difficult.

TABLE 55-4. The 12-Month Prevalence of Mental Disorders in Adults in the United States

Disorder[a]	1-Year Prevalence (Percent)	Adults Affected[b]	Comments
All disorders	26.2	58 million	1 in 4 adults affected annually
Mood disorders	9.5	21 million	Median onset age 30 years
Major depression—6.7%		15 million	Leading cause of disability in the United States
Dysthymia—1.5%		3.3 million	Chronic, mild depression
Bipolar disorder—2.6%		5.7 million	
Suicide		32,400	90% have mental disorder; depression most common
Schizophrenia	1.1	18 million	Men = women; onset women 20s or early 30s
Anxiety disorders	18	40 million	Frequent co-occurrence with depression or substance abuse
Panic—2.7%			
Obsessive-compulsive—1%			
Posttraumatic stress—3.5%			
Generalized anxiety—3.1%			
Social phobias—6.8%			
Eating disorders			
Anorexia nervosa	Lifetime: 0.5–3.7		Females = 85–95%; mortality rate 0.56% per year
Bulimia nervosa	Lifetime: 1.1–5		
Binge eating	6-month: 2–5		

[a]Based on *Diagnostic and Statistical Manual-IV-R (DSM-IV-R)* of the American Psychiatric Association (2000b).
[b]Based on 2004 census data.
From the National Institute of Mental Health (2006).

Pregnancy. It is unquestionable that pregnancy is a major life stressor that can precipitate or exacerbate depressive tendencies. In addition, there are likely a variety of pregnancy-induced effects. Hormones certainly affect mood as evidenced by premenstrual syndrome and menopausal depression. Estrogen modulates serotonergic function, and women who experience postpartum depression often have higher predelivery serum estrogen and progesterone levels and experience a greater decline postpartum (Ahokas and co-workers, 1999).

TABLE 55-5. Symptoms of Depressive Illness[a]

Persistent sad, anxious, or "empty" feelings
Feelings of hopelessness and/or pessimism
Feelings of guilt, worthlessness, and/or helplessness
Irritability, restlessness
Loss of interest in activities or hobbies once pleasurable, including sex
Fatigue and decreased energy
Difficulty concentrating, remembering detail, and making decisions
Insomnia, early-morning wakefulness, or excessive sleeping
Overeating or appetite loss
Thoughts of suicide, suicide attempts
Persistent aches or pains, headaches, cramps, or digestive problems that do not ease even with treatment

[a]Not all patients experience the same symptoms and their severity, frequency, and duration will vary among individuals.
From the National Institute of Mental Health (2007).

Dennis and associates (2007) reviewed the Cochrane Database and reported the prevalence of antenatal depression to average 10.7 percent. And although Gavin and co-workers (2005) found it to range from 6 to 12 percent in their systematic review, others have reported the incidence to be as high as 30 percent (Lee and colleagues, 2007; Westdahl and associates, 2007). The higher estimates may be closer, as Cooper and associates (2007) reported that 13 percent of pregnant women in the Tennessee Medicaid program were prescribed antidepressants. Conversely, Wichman and colleagues (2009) reported that only 3.2 percent of more than 25,000 prenatal patients at the Mayo Clinic took selective serotonin-reuptake inhibitors (SSRIs) during pregnancy.

Postpartum depression—major or minor—develops in 10 to 20 percent of parturients (Centers for Disease Control and Prevention, 2008; National Mental Health Association, 2004). These incidences are slightly higher than the usual 6-month prevalence for depression among nonpregnant women. In addition to antenatal depression, postpartum depression has been associated with young maternal age, unmarried status, smoking or drinking, substance abuse, hyperemesis gravidarum, preterm birth, and high utilization of sick leave during pregnancy (Josefsson, 2002; Lee, 2007; Marcus, 2009, and all their colleagues).

Depression is frequently recurrent. At least 60 percent of women taking antidepressant medication before pregnancy

have symptoms during pregnancy. For those who discontinue treatment, almost 70 percent have a relapse compared with 25 percent who continue therapy. Up to 70 percent of women with previous postpartum depression have a subsequent episode. Women with both a previous puerperal depression episode and a current episode of "maternity blues" described on page 1176 are at inordinately high risk for major depression. Indeed, the need for help for postpartum depression was the fourth most common challenge identified at 2 to 9 months postpartum identified by the Pregnancy Risk Assessment Monitoring System—PRAMS (Kanotra and colleagues, 2007).

Without treatment, the natural course of depression is one of gradual improvement in the 6 months after delivery (Fleming and colleagues, 1992). As the duration of depression increases, however, so do the number of sequelae and their severity. In addition, maternal depression during the first weeks and months after delivery can lead to insecure attachment and later behavioral problems in the child.

Treatment. Antidepressant medications, along with some form of psychotherapy, are indicated for severe depression during pregnancy or the puerperium (American College of Obstetricians and Gynecologists, 2007). An SSRI should be tried initially (Table 55-6). If depressive symptoms improve during a 6-week trial, the medication should be continued for a minimum of 6 months to prevent relapse (Wisner and associates, 2002). If the response is suboptimal or a relapse occurs, psychiatric referral is considered.

And again, recurrence some time after medication is stopped is common and develops in 50 to 85 percent of women with an initial postpartum depression. Women with a history of more than one depressive episode are at greater risk (American Psychiatric Association, 2000a). Surveillance should also include monitoring for thoughts of suicide or infanticide, emergence of psychosis, and response to therapy. For some women, the course of illness is severe enough to warrant hospitalization.

Fetal Effects of Therapy. Some known and possible fetal and neonatal effects are listed in Table 55-6. These were reviewed recently by the American College of Obstetricians and Gynecologists (2007) and Way (2007) and are detailed in Chapter 14 (p. 323). Although some psychotropic medications pass into breast milk, in most cases, the levels are very low or undetectable. The possible exception is lithium (Buhimschi and Weiner, 2009). Importantly, there have been no reports of adverse events in breast-fed infants of these women.

Electroconvulsive Therapy. Treatment of depression with electroconvulsive therapy (ECT) during pregnancy is occasionally necessary for women with major mood disorders unresponsive to pharmacological therapy. With proper preparation, the risks to both mother and fetus appear to be reasonable (Pinette

TABLE 55-6. Some Drugs Used for Treatment of Major Mental Disorders in Pregnancy

Indication of Class	Examples	Comments
Antidepressants		
Selective serotonin-reuptake inhibitors[a]	Citalopram, fluoxetine, paroxetine, sertraline	*Possible* link with heart defects; neonatal withdrawal syndrome; *possible* persistent pulmonary hypertension[a]; paroxetine use avoided by some
Others	Buproprion, duloxetine, nefazodone, venlafaxine	
Tricyclics	Amitryptyline, desipramine, doxepin, imipramine, nortryptyline	Not commonly used currently; no evidence of teratogenicity
Antipsychotics		
Typical	Chlorpromazine, fluphenazine, haloperidol, thiothixene	
Atypical	Aripiprazole, clozapine, olanzapine, risperidone, ziprasidone	
Bipolar Disorders		
Lithium	Lithium carbonate	Treatment of manic episodes; definite teratogen—heart defects, *viz.*, Ebstein anomaly; little data after 12 weeks
Antipsychotics	See above	

[a] See Chapter 14 (p. 323).
Data from American College of Obstetricians and Gynecologists (2007); Briggs and colleagues (2005); Buhimschi and Weiner (2009); Physicians' Desk Reference (2008).

and co-workers, 2007). That said, adverse maternal and perinatal outcomes have been described. For example, Balki and associates (2006) reported a pregnancy in which fetal brain damage likely was caused by sustained maternal hypotension associated with treatment of status epilepticus stimulated by ECT.

Women undergoing ECT should be fasting for at least 6 hours. They are given a rapid-acting antacid before the procedure, and their airway protected to decrease the likelihood of aspiration. A wedge should be placed under one hip to prevent sudden maternal hypotension from aortocaval compression. Other important preparatory steps include cervical assessment, discontinuation of nonessential anticholinergic medication, uterine and fetal heart rate monitoring, and intravenous hydration. During the procedure, excessive hyperventilation should be avoided. In most cases, maternal and fetal heart rate and maternal blood pressure and oxygen saturation remain normal throughout the procedure.

There have been at least two reviews of ECT outcomes in pregnancy. In the earlier one, Miller (1994) found 300 cases and reported complications in 10 percent. These included fetal arrhythmias, vaginal bleeding, abdominal pain, and self-limited contractions. Women not adequately prepared had increased risks for aspiration, aortocaval compression, and respiratory alkalosis. In the recent review, Anderson and Reti (2009) found 339 cases, undoubtedly with some homology with the earlier study. In most cases, ECT was done to treat depression, and it was 78-percent effective in this regard. They reported a 5-percent maternal ECT-related complication rate and a 3-percent associated perinatal complication rate that included two fetal deaths. For all of these reasons, we agree with Richards (2007) that ECT in pregnancy is not "low risk" and that it should be reserved for women whose depression is recalcitrant to intensive pharmacotherapy.

Bipolar Disorder

Manic-depressive illness has a strong genetic component and has been linked to possible mutations on chromosomes 16 and 8 (Jones and associates, 2007). The risk that monozygotic twins are both affected is 40 to 70 percent, and the risk for first-degree relatives is 5 to 10 percent (Muller-Oerlinghausen and colleagues, 2002). Periods of depression last at least 2 weeks. At other times, there are manic episodes-distinct periods during which there is an abnormally raised, expansive, or irritable mood. Potential organic causes of mania include substance abuse, hyperthyroidism, and central nervous system tumors. Up to 20 percent of patients with manic-depression commit suicide. Treatment is with drugs listed in Table 55-6, with special caution for lithium during fetal organogenesis.

Postpartum Psychosis. This severe mental disorder is usually a bipolar disorder, but it may be due to major depression (American Psychiatric Association, 2000b). It is more common in primiparas, especially those with obstetrical complications (Blackmore and colleagues, 2006). In most cases, it manifests within 2 weeks of delivery. In their experiences with 101 cases, Heron and associates (2007, 2008) reported that a fourth were symptomatic on the first day and half by the third day postpartum. Manic symptoms—excited, elated, "high"; not needing sleep or unable to sleep; feeling active or energetic; and "chatty"—were common early. Affected women have signs of confusion and disorientation but may also have episodes of lucidity. Because women with underlying disease have a 10- to 15-fold risk for recurrence postpartum, close monitoring is imperative. Postpartum psychosis has a 50-percent recurrence risk in the next pregnancy. In most instances, these women ultimately develop relapsing, chronic psychotic manic-depression.

The clinical course of bipolar illness with postpartum psychosis is comparable with that for nonpregnant women. They usually require hospitalization, pharmacological treatment, and long-term psychiatric care. Psychotic women may have delusions leading to thoughts of self-harm or harm to their infants. Unlike women with nonpsychotic depression, these women commit infanticide, albeit uncommonly (Kim and associates, 2008).

Schizophrenia

This major form of mental illness affects 1.1 percent of adults (Table 55-4). Four major subtypes of schizophrenia are recognized: catatonic, disorganized, paranoid, and undifferentiated. The hallmarks of paranoid schizophrenia are delusions, hallucinations, flat or blunted affect, and confused or impoverished speech. Brain scanning techniques such as positron emission tomography and functional magnetic resonance imaging have shown that schizophrenia is a degenerative brain disorder. Subtle anatomical abnormalities are present early in life and worsen with time.

The disorder has a major genetic component with 50-percent concordance in monozygotic twins. If one parent has schizophrenia, the risk to offspring is 5 to 10 percent. Some data, including a strong association between schizophrenia and the velocardiofacial syndrome, suggest that associated genes are located on chromosome 22q11 (Murphy, 2002). Other putative risk factors for subsequent schizophrenia in a fetus include maternal iron-deficiency anemia, diabetes, and acute maternal stress (Insel and colleagues, 2008; Malaspina and associates, 2008; Van Lieshout and Voruganti, 2008). These remain unproven as does the association with maternal influenza A infection, which is discussed further in Chapter 58 (p. 1212).

Signs of illness begin approximately at age 20 years, and commonly, work and psychosocial functioning deteriorate over time. Because women have a slightly later onset than men and are less susceptible to autism and other neurodevelopmental abnormalities, many investigators theorize that estrogen has a protective effect. Affected women may marry and become pregnant before symptoms manifest. With appropriate treatment, patients may experience a decrease or cessation of symptoms. Within 5 years from the first signs of illness, 60 percent have social recovery, 50 percent are employed, 30 percent are mentally handicapped, and 10 percent require continued hospitalization (American Psychiatric Association, 2000b).

Patients with *schizoaffective disorder* have a chronic deteriorating psychotic disorder similar to schizophrenia but combined with prominent mood symptoms. Although the psychosis rarely abates, the mood symptoms often improve with therapy.

Pregnancy

There has been an increase in relative fertility in schizophrenic women (Solari and co-workers, 2009). Adverse maternal

outcomes do not appear to be increased in most studies. There is a link, however, to increased adverse perinatal outcomes in Swedish studies to include low birthweight, fetal-growth restriction, and preterm delivery (Bennedsen and colleagues, 1999). In the Australian study by Jablensky and associates (2005) of more than 3000 pregnancies in schizophrenic women, placental abruption was increased threefold and "fetal distress"—vaguely defined, was increased 1.4-fold.

Treatment. Because schizophrenia has a high recurrence if medications are discontinued, it is advisable to continue therapy during pregnancy. After 40 years of use, there is no evidence that conventional or "typical" antipsychotic drugs cause adverse fetal or maternal sequelae (McKenna and colleagues, 2005; Yaeger and associates, 2006). Because less is known about "atypical" antipsychotics, the American College of Obstetricians and Gynecologists (2007) recommends against their *routine* use in pregnant and breast feeding women.

Anxiety Disorders

These relatively common disorders include panic attack, panic disorder, social anxiety disorder, specific phobia, obsessive-compulsive disorder, posttraumatic stress disorder, and generalized anxiety disorder. All are characterized by irrational fear, tension, and worry, which are accompanied by physiological changes such as trembling, nausea, hot or cold flashes, dizziness, dyspnea, insomnia, and frequent urination (Schneier, 2006). They are treated with psychotherapy and medication, including selective serotonin-reuptake inhibitors, tricyclic antidepressants, monoamine oxide inhibitors, and others.

Pregnancy

Despite their relative high prevalence in childbearing-aged women as shown in Table 55-4, little specific attention has been directed to anxiety disorders in pregnancy. Older studies indicate increased risks for adverse pregnancy outcomes with some of these disorders (American College of Obstetricians and Gynecologists, 2007). From their review, Ross and McLean (2006) concluded that some of the anxiety disorders may have important maternal-fetal implications, but that there are limited data to guide antenatal treatment. Conversely, Littleton and associates (2007) found no excessive adverse pregnancy outcomes with "anxiety symptoms." One important exception is their link with postpartum depression (Vythilingum, 2008).

Eating Disorders

These severe disturbances in eating behavior largely affect adolescent females and young adults with a lifetime prevalence of 2 to 3 percent each (Table 55-4). They include *anorexia nervosa*, in which the patient refuses to maintain minimally normal body weight. With *bulimia nervosa,* there usually is binge eating followed by purging or by excessive fasting to maintain normal body weight (Zerbe and Rosenberg, 2008). Bulik and co-workers (2009) studied pregnancy outcomes in almost 36,000 Norwegian women screened for eating disorders. About 0.1 percent—1 in 1025—had anorexia nervosa; 0.85 percent—1 in 120—had bulimia nervosa; and 5.1 percent reported a binge-eating disorder—a pregnancy prevalence similar to the 6-month prevalence for nonpregnant individuals (see Table 55-4). The last group had a higher risk for large-for-gestational age infants with a concomitantly increased cesarean delivery rate.

Pregnancy

A high miscarriage rate is characteristic of both eating disorders (Sollid and colleagues, 2004). As perhaps expected, anorexia is associated with low-birthweight infants, and it likely is related to small body mass (Micali and associates, 2007). According to Ekéus and associates (2006), women with a prior history of anorexia do well without special surveillance.

Personality Disorders

These disorders are characterized by the chronic use of certain coping mechanisms in an inappropriate, stereotyped, and maladaptive manner. They are rigid and unyielding personality traits. The American Psychiatric Association (2000b) recognizes three clusters of personality disorders:

1. Paranoid, schizoid, and schizotypal personality disorders, which are characterized by oddness or eccentricity
2. Histrionic, narcissistic, antisocial, and borderline disorders, which are all characterized by dramatic presentations along with self-centeredness and erratic behavior
3. Avoidant, dependent, compulsive, and passive-aggressive personalities, which are characterized by underlying fear and anxiety.

Genetic and environmental factors are important in the genesis of these disorders, whose prevalence may be as high as 20 percent. Although management is through psychotherapy, most affected individuals do not recognize their problem, and thus only 20 percent seek help.

Pregnancy

Problems during pregnancy are probably no different than in nonpregnant women. Management may be vexing with some of these disorders. Akman and colleagues (2007) reported that avoidant, dependent, and obsessive-compulsive disorders are associated with an excessive prevalence of postpartum major depression. Magnusson and associates (2007) found a link between some *personality traits*—not disorders—and excessive alcohol consumption, but not necessarily addiction or dependence.

CHAPTER 56

Dermatological Disorders

SKIN CHANGES IN PREGNANCY 1185
DERMATOSES OF PREGNANCY 1187
PREEXISTING SKIN DISEASE 1191

There are a number of normal pregnancy-induced skin changes that may be alarming to some women. There are also several pregnancy-specific dermatoses, and some are associated with adverse perinatal outcomes. And of course, any skin disease that affects women of childbearing age may be encountered in pregnancy.

SKIN CHANGES IN PREGNANCY

A number of factors are responsible for normal skin changes during pregnancy. These include that fetoplacental hormone production or alteration of clearance may increase plasma availability of estrogens, progesterone, and a variety of androgens. There is accumulating evidence that sex steroids have modulating influences on some skin diseases (Kanda and Watanabe, 2005). There are also profound changes in the availability or concentrations of some adrenal steroids, including cortisol, aldosterone, and deoxycorticosterone. Moreover, presumably as a result of enlargement of the intermediate lobe of the pituitary gland, plasma levels of melanocyte-stimulating hormone (MSH) become remarkably elevated by 8 weeks' gestation. Production of proopiomelanocortin has been demonstrated in placental extracts, and this ultimately is a source of α- and β-MSH. Neurotropins and neuropeptides, some produced by trophoblastic cells, may also play a role in skin and hair changes (Botchkarev and associates, 2006; Imperatore and colleagues, 2006).

A synopsis of these changes is shown in Table 56-1. They are also discussed in more detail in Chapter 5 (p. 111). Nguyen Huu and associates (2009) found that *fetal microchimerism* may also involve the skin. Thus, endothelial-type fetal cells become grafted in maternal skin cells discussed with nevi. This phenomenon has been associated with maternal autoimmune diseases such as lupus, sclerosis, Hashimoto thyroiditis, and other conditions. Its mechanisms are considered further in Chapters 3 (p. 58), 53 (p. 1127) and 54 (p. 1146).

Pigmentation

Some degree of skin darkening from melanin deposition into epidermal and dermal macrophages develops in 90 percent of pregnant women. Pigmentation is more pronounced in brunettes and in women with dark complexions, especially those of Hispanic descent (Aronson and Bass, 2000). Its exact cause is not known, but it is doubtful that elevated serum levels of MSH are responsible. Estrogens play a role in melanogenesis and may be the inciting factor. Melanocytes also respond directly to corticotropin-releasing hormone (Kauser and colleagues, 2006).

Hyperpigmentation is evident beginning early in pregnancy and is more pronounced in naturally hyperpigmented areas such as the areolae, perineum, and umbilicus. Areas prone to friction, such as the axillae and inner thighs, also may become darkened. Recent scars may be involved. When the *linea alba* becomes pigmented, it is called the *linea nigra.* Pigmentation of the face, referred to as the mask of pregnancy, is also called *chloasma* or *melasma.* This is seen in about half of pregnant women. Ultraviolet (UV) light exacerbates melasma by stimulating melanogenesis. Thus, the severity of pigmentation may be mitigated by avoiding excessive sun exposure and by using sunscreens (Lakhdar and co-workers, 2007).

Although hyperpigmentation usually regresses postpartum, dermal melanosis may persist up to 10 years in a third of affected women. Oral contraceptives may aggravate melasma and should be avoided in susceptible women. Sunscreen use should be continued. If particularly disfiguring, hyperpigmentation can be treated with topical application of hydroxyquinone, tretinoin gel or cream, or azelaic acid cream (Muallem and Rubeiz, 2006).

TABLE 56-1. Some Pregnancy-Induced Skin Changes

Structure	Involved Areas
Skin	Hyperpigmentation pronounced in normally hyperpigmented areas
	Chloasma (melasma) common
	Striae gravidarum
	Linea nigra
	Acne—may improve
Connective tissue	Striae gravidarum
	Skin tags—common in neck area
Nevi	Some darken
	Only 3 percent enlarge
Hair	Scalp hair thickens
	Hirsutism—some degree in most women
	Telogen effluvium-postpartum hair loss
	Nails become soft and brittle
Vascular changes	Palmar erythema
	Spider and capillary hemangiomas
Oral cavity	Gingivitis
	Epulis
	Pyogenic granuloma

Data from Muallem and Rubiez (2006), Nussbaum and Benedetto (2006), Salter and Kimball (2006), and Torgerson and colleagues (2006).

Striae Gravidarum

These are linear lesions that frequently appear during pregnancy and are commonly found on the abdomen and breasts. They are at least partially tension related, but there are other factors (Osman and associates, 2007). Histologically, these lesions show a decrease and reorganization of the dermal elastin fiber network (Watson and associates, 1998). During pregnancy they are reddish purple, but over time lose pigmentation and overlying skin becomes atrophic (Fig. 56-1). These "stretch marks" are undesirable to most women, but unfortunately they are unpreventable. Treatment is also problematic, but some lesions respond to laser and a variety of topical preparations (Salter and Kimball, 2006).

FIGURE 56-1 Striae gravidarum of the axilla and upper arm. (Reprinted from *Clinics in Dermatology*, Vol. 24, No. 2, SA Salter and AB Kimball, Striae gravidarum, pp. 97–100, Copyright 2006, with permission from Elsevier.)

Nevi

All persons have some form of benign melanocytic nevi. Pennoyer and colleagues (1997) found that only 6 percent of 129 nevi changed in diameter over pregnancy—3 percent increased by 1 mm, and 3 percent *decreased* by 1 mm. And although a small minority of nevi develop enlarged melanocytes and increased melanin deposition during pregnancy, there is no evidence for malignant transformation (Driscoll and Grant-Kels, 2006, 2009). Because it is uncommon during pregnancy for nevi to enlarge or become darker as shown in Figure 56-2, it is reasonable to be concerned if either occurs (MacKelfresh and associates, 2005). As discussed previously, Nguyen Huu and coworkers (2009) found engrafted endothelial-type fetal cells in 12 percent of nevi from pregnant women. Moreover, these cells were identified in 63 percent of malignant melanomas from pregnant women (see Chap. 57, p. 1199).

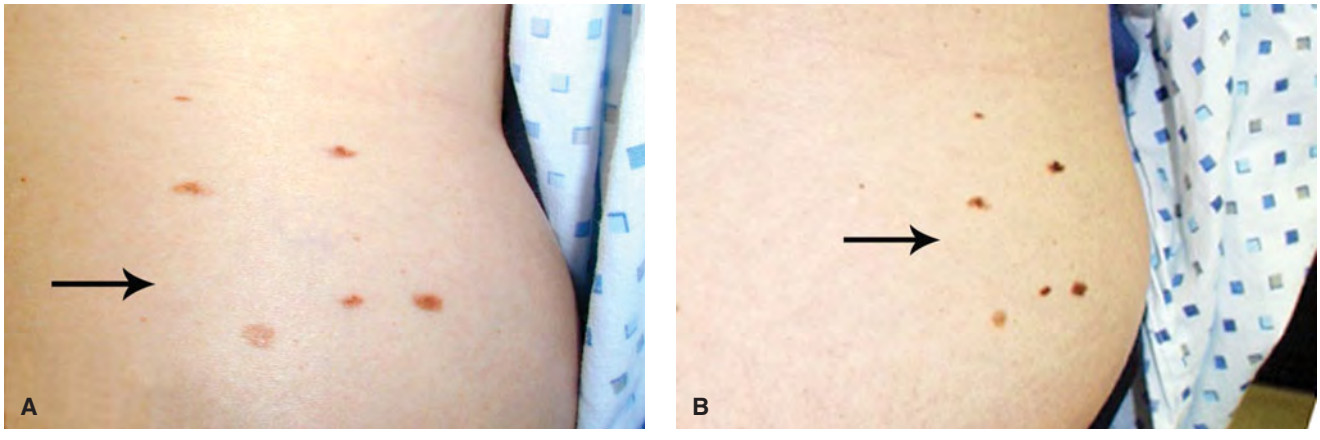

FIGURE 56-2 Melanocytic nevi before pregnancy **A.** and during pregnancy **B.** Note the darkening of all the nevi in the photograph on the right taken during pregnancy. Each arrow is placed proportionally between the six nevi in each image. (From MacKelfresh and co-workers, 2005, with permission.)

FIGURE 56-3 Telogen effluvium in a postpartum woman. (Reprinted from *Clinics in Dermatology*, Vol. 24, No. 2, R Nussbaum and AV Benedetto, Cosmetic aspects of pregnancy, pp. 133–141, Copyright 2006, with permission from Elsevier.)

Hair

During pregnancy, the *anagen*—hair-growth phase, is increased relative to the *telogen*—resting hair phase (Randall, 1994). Estrogens prolong anagen, and androgens cause enlargement of follicles in responsive areas such as the face (Paus and Cotsarelis, 1999). When these effects dissipate postpartum, hair shedding develops—*telogen effluvium* (**Fig. 56-3**). This rather abrupt hair loss begins approximately 1 to 4 months postpartum. It may sometimes be characterized by alarming amounts of hair shedding with brushing or washing. Fortunately, the process is self-limited, and women may be reassured that normal hair growth is usually restored in 6 to 12 months.

Because hair growth is modulated by estrogens, androgens, thyroid hormones, glucocorticoids, and prolactin, it is not surprising that mild *hirsutism* is common during pregnancy. This may be most noticeable on the face, and women who are predisposed genetically to coarse hair growth are more severely affected. Hirsutism typically regresses within several months after delivery. Severe hirsutism with other evidence of masculinization should prompt consideration for another androgen source such as adrenal tumors (see Chap. 53, p. 1138) or pregnancy luteomas and theca-lutein cysts (see Chap. 5, p. 110). A few cases of women with recurrent and regressing severe hyperandrogenism during pregnancy have been reported (Holt and co-workers, 2005).

Nail Changes

Fingernails may become soft and brittle, but treatment is not necessary. Occasionally in darker-skinned individuals, a brown pigment stripe extends the length of the nail. Termed *melanonychia*, it usually regresses postpartum (Muallem and Rubeiz, 2006).

Vascular Changes

Augmented cutaneous blood flow in pregnancy is due to a marked decrease in peripheral vascular resistance (Spetz, 1964). Pregnancy incites estrogen-induced changes in small blood vessels, and they are widely dilated in the superficial dermis (Henry and associates, 2006). *Spider hemangiomas* are found in most white women during pregnancy, but in only 10 percent of black women. Most of these vascular lesions regress postpartum. *Palmar erythema* is noticed in two thirds of white women and a third of black women. *Capillary hemangiomas* or *glomus tumors*, especially of the head and neck, are seen in up to a third of women during pregnancy.

One vascular condition that may be distressing is *pregnancy gingivitis* caused by growth of the mucosal capillaries and fibroblasts. This swelling—e*pulis of pregnancy*—is common in the gum region and usually is controlled by proper dental hygiene. It is uncertain if this exacerbates periodontal infection that is associated with adverse pregnancy outcomes (Boggess and associates, 2008). These lesions may appear on any mucosal or cutaneous surface and are termed *pyogenic granuloma or granuloma gravidarum.* Radar and co-workers (2008) described five cases in which the hand was involved. Lesions are erythematous and friable, and although treatment is usually unnecessary, large granulomas may require excision. If this is done, however, recurrences are common (Torgerson and colleagues, 2006).

DERMATOSES OF PREGNANCY

A number of dermatological conditions either are identified as unique to pregnancy or are encountered more often during gestation. Their terminology can be confusing because of differing usage in the United States and Europe and other countries. Shornick (1998) concluded that only three conditions are universally accepted as unique to pregnancy: *pruritus gravidarum* caused by cholestasis; *pruritic urticarial papules* and *plaques of pregnancy;* and *herpes gestationis.* Their gross appearance may be similar to each other or to unrelated skin disorders. Shown in **Table 56-2** is one classification scheme with various international differences in nomenclature.

This classification does not include atopic eczema, recently described by Ambros-Rudolph and co-workers (2006) to comprise half of symptomatic skin disorders seen in their clinics. Fortunately, inflammatory skin diseases such as atopic dermatitis and psoriasis have no significant effects on pregnancy outcome (Seeger and associates, 2007).

Pruritus

Complaints of itching during pregnancy are common, and its cited incidence varies directly with the vigilance for which it is sought. In almost 3200 women carefully studied by Roger and colleagues (1994), 1.6 percent had significant pruritus at some time during pregnancy.

Pruritus Gravidarum

This common pregnancy-related skin condition is not primarily a dermatological disorder. It is considered to be a mild variant of *intrahepatic cholestasis of pregnancy* (see Chap. 50, p. 1063). Contributing factors include pregnancy hormones, genetics, dyslipidemia, and environmental factors (Dann and colleagues, 2006; Rutherford and Pratt, 2006). In the population-based

TABLE 56-2. Dermatoses Unique to Pregnancy

Disorder	Frequency	Clinical Characteristics	Histopathology	Effects on Pregnancy	Treatment	Comments
Pruritus gravidarum (also cholestasis of pregnancy)	Common (1–2%)	Onset third trimester; intense pruritus; generalized; excoriations common	Nonspecific; no primary lesions, but excoriations common	Perinatal morbidity increased	Antipruritics, cholestyramine, ursodeoxycholic acid	Mild form of cholestatic jaundice; recurs in subsequent pregnancies (see Chap. 50, p. 1063)
Pruritic urticarial papules and plaques of pregnancy (PUPPP) In Europe: polymorphic eruption of pregnancy (PEP)	Common (0.25–1%)	Onset usually third trimester; intense pruritus; patchy or generalized on abdomen, thighs, arms, buttocks; erythematous papules, urticarial papules, plaques	Lymphocytic perivascular infiltrate; negative immunofluorescence	No adverse effects	Antipruritics, emollients, topical steroids, oral steroids if severe	More common in white women, nulliparas, and those with twins; seldom recurs
Prurigo of pregnancy (also prurigo gestationis, papular dermatitis)	Uncommon (1:300–1:2400)	Onset late second or third trimester; localized or generalized; usually forearms and trunk; 1–5 mm commonly excoriated pruritic papules	Lymphocytic perivascular infiltrate; parakeratosis acanthosis; negative immunofluorescence	Probably unaffected	Antipruritics, topical steroids, oral steroids if severe	Prurigo gestationis localized to forearms and trunk; papular dermatitis is generalized; does not recur
Pruritic folliculitis of pregnancy (PFP) (also impetigo herpetiformis)	Rare	Onset third trimester; local, then generalized; erythema with marginal sterile pustules; mucous membranes involved; systemic symptoms	Microabscesses; spongiform pustules of Kogoj; neutrophils	Maternal sepsis common	Antibiotics, oral steroids	Possibly pustular psoriasis; persists weeks to months postpartum; usually does not recur
Herpes gestationis In Europe: pemphigoid gestationis, bullous pemphigoid of pregnancy	Rare (1:10,000)	Onset after midpregnancy, 1–2 weeks postpartum; severe pruritus; abdomen, extremities, or generalized; urticarial papules and plaques, erythema, vesicles, and bullae	Edema; infiltrate of lymphocytes, histiocytes, and eosinophils; C_3 and IgG deposition at basement membrane	Possibly increased preterm birth; transient neonatal lesions (5–10%)	Antipruritics, topical steroids, oral steroids if severe	Autoimmune HLA-related; may occur with trophoblastic disease; exacerbations and remissions common with pregnancy and postpartum; recurrence common; neonatal skin lesions in 10%

study by Sheiner and colleagues (2006), it was found in 0.2 percent of nearly 160,000 deliveries. With cholestasis, bile salt serum levels increase in most women, and they are deposited in the dermis to cause pruritus. Not all women, however, have elevated bile salt levels (Yoong and co-workers, 2008). Skin lesions develop from scratching and excoriation. Treatment of pruritis follows that for cholestasis of pregnancy.

Pruritic Urticarial Papules and Plaques of Pregnancy

This is the most common pruritic pregnancy-specific dermatosis. It is called *PUPPP* in the United States and referred to as *polymorphic eruption of pregnancy (PEP)* in much of Europe. Almost half of the 3200 reported women by Roger and co-workers (1994) with pruritus had this dermatosis. The incidence is approximately 1 in 200 pregnancies, but increases to 8 in 200 for multifetal gestations (Kroumpouzos and Cohen, 2003). PUPPP is more common in white and nulliparous women and is characterized by an intensely pruritic cutaneous eruption that usually appears late in pregnancy (see Table 56-2). It is more common with a male fetus (Regnier and colleagues, 2008). Shown in **Figure 56-4** are the erythematous urticarial papules and plaques that involve the abdomen and proximal thighs in 97 percent of affected women (Rudolph and colleagues, 2005). Half of these women will develop erythema, vesicles, and targetoid lesions with eczema. Although rare, the face, palms, and soles may be affected (High and co-workers, 2005). There is no evidence that perinatal morbidity is increased with PUPPP (Kroumpouzos and Cohen, 2003; Rudolph and associates, 2005). It seldom recurs in subsequent pregnancies.

Pathophysiology

The etiopathogenesis is unknown. Histologically, there is a mild, nonspecific lymphohistiocytic perivasculitis with an eosinophilic component. There is no immunoglobulin or complement dermal deposition, and absence of a linear band of C_3 in the basement membrane differentiates it from herpes gestationis (Rudolph and co-workers, 2005). It has been hypothesized that this disorder may be stimulated by fetal cells that have invaded maternal skin (Aractingi and associates, 1998). This intriguing possibility has been linked with nevi and malignant melanoma and reviewed by Gilliam (2006). Also as discussed, similar mechanisms are proposed for lupus and systemic sclerosis (see Chap. 54, p. 1146) and postpartum thyroiditis (see Chap. 53, p. 1027).

FIGURE 56-4 Pruritic urticarial papules and plaques of pregnancy (PUPPP).

Treatment

Most women respond to treatment with oral antihistamines, skin emollients, and topical corticosteroids. About 10 percent require systemic corticosteroids to relieve severe itching (Rudolph and colleagues, 2005; Scheinfeld, 2008). In most cases, the rash disappears quickly either before or within several days following delivery. Symptoms persist for 2 to 4 weeks postpartum in 15 to 20 percent (Vaughan Jones and co-workers, 1999). Up to 15 percent of cases will begin postpartum (Buccolo and Viera, 2005).

Prurigo of Pregnancy

This likely refers to a group of disorders previously described by a multitude of names (Dahdah and Kibbi, 2006). According to Shornick (1998), it includes *prurigo gestationis* and *papular dermatitis* as likely variants of the same disease and not pregnancy specific (see Table 56-2). They appear to share a strong component of atopic eczema.

Prurigo gestationis is the milder and more common variant, characterized by small, pruritic, rapidly excoriated lesions on the forearms and trunk. The bitelike papules may resemble scabies or other insect bites. Pruritis is usually controlled with oral antihistamines and topical corticosteroid creams. The course is protracted and lesions typically appear at 25 to 30 weeks and may persist for 3 months after delivery. Perinatal outcome does not appear to be adversely affected. Recurrence in subsequent pregnancy is common.

Pruritic Folliculitis of Pregnancy

This rare pustular eruption—also called *impetigo herpetiformis*—is seen in late pregnancy. It is uncertain if it is unique to pregnancy, or if it is a form of pustular psoriasis coincidental to pregnancy. Less than 50 cases have been reported (Green and co-workers, 2009; Kroumpouzos and Cohen, 2003). The hallmark lesions of pruritic folliculitis are sterile pustules that form around the margin of erythematous patches that characteristically begin at flexures and extend peripherally. Mucous membranes are usually involved. The characteristic histological lesion is a spongelike epidermal cavity filled with neutrophils—the *spongiform pustule of Kogoj.*

Pruritus is not severe, but constitutional symptoms are common. In addition to nausea, vomiting, diarrhea, chills, and fever, hypoalbuminemia and hypocalcemia are common. Although the pustules are initially sterile, they may become infected after rupture, and sepsis is a serious concern. Treatment is with systemic corticosteroids along with antimicrobials for secondary infection. Infliximab has also been used (Sheth and colleagues, 2009). The disease may persist for several weeks to months after delivery.

FIGURE 56-5 Herpes gestationis. (Courtesy of Dr. Amit Pandya.)

Herpes Gestationis

This uncommon noninfectious skin disorder shares an etymological but not biological connection with herpes viral infection. In Europe, it is also called *pemphigoid gestationis* (see Table 56-2). It is a rarely encountered autoimmune blistering skin eruption with a cited incidence of 1 in 10,000 to 50,000 pregnancies. It can also occur with trophoblastic disease.

It is characterized by an extremely pruritic widespread eruption that most commonly begins in the last trimester (Ambros-Rudolph and colleagues, 2006; Hon and co-workers, 2008). Lesions vary from erythematous and edematous papules to large, tense vesicles and bullae (**Figs. 56-5** and **56-6**). Before bullae form, these lesions may resemble PUPPP as described previously. Common sites of involvement are the abdomen and periumbilical area—70 percent, and the extremities—95 percent (Ambros-Rudolph and associates, 2006). Exacerbations and remissions throughout pregnancy are common, and up to 75 percent of women suffer intrapartum flares (Shornick, 1998). In subsequent pregnancies, the disease invariably recurs, and it usually does so earlier and is more severe (Al-Fouzan and colleagues, 2006).

There is an inherited predisposition, and more than half of affected women have HLA-DR3 and HLA-DR4 antigens compared with only 3 percent of unaffected women (Al-Fouzan and colleagues, 2006). Maternal HLA-DR antigens are also associated with other autoimmune disorders to include Addison disease, type 1 diabetes, systemic lupus erythematosus, Graves disease, and Hashimoto thyroiditis. And Shornick and Black (1992) reported that 10 percent of 75 women with herpes gestationis also had Graves disease.

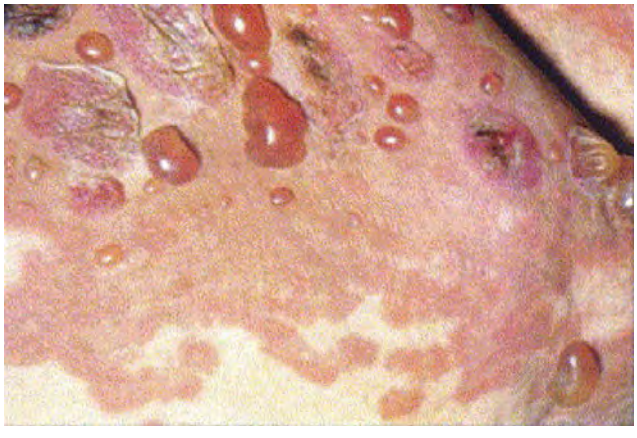

FIGURE 56-6 Herpes gestationis with large, tense generalized bullous eruptions. (From Al-Fouzan and co-workers, 2006, with permission.)

Etiopathogenesis

Herpes gestationis is characterized by development of an immunoglobulin G_1 antibody to the epidermal basement membrane. It is a thermostable immunoglobulin G (IgG) that reacts with the bullous pemphigoid 180-kDa (BP180) epidermal antigen (Patton and associates, 2006). BP180 is a glycoprotein integral to adhesion structures that anchor basal cells to their basement membrane (Shimanovich and colleagues, 2002). The antibody is also called *herpes gestationis serum factor,* and it both reacts with amnionic tissue and is passively transferred to the fetus.

The classical histological finding is subepidermal edema with perivascular infiltrates of lymphocytes, histocytes, and eosinophils. With immunofluorescent techniques, C_3 complement and sometimes IgG are deposited along the basement membrane zone between the epidermis and the dermis (**Fig. 56-7**).

Treatment

Pruritus with this condition may be severe. Topical corticosteroids and oral antihistamines are usually not effective. Orally administered prednisone, 0.5 to 1 mg/kg daily, brings relief promptly in most women and also inhibits formation of new lesions. Cyclosporine as well as plasmapheresis and high-dose intravenous immunoglobulin therapy have been used in intractable cases (Al-Fouzan and colleagues, 2006; Kroumpouzos and Cohen, 2003). Some women develop chronic disease that

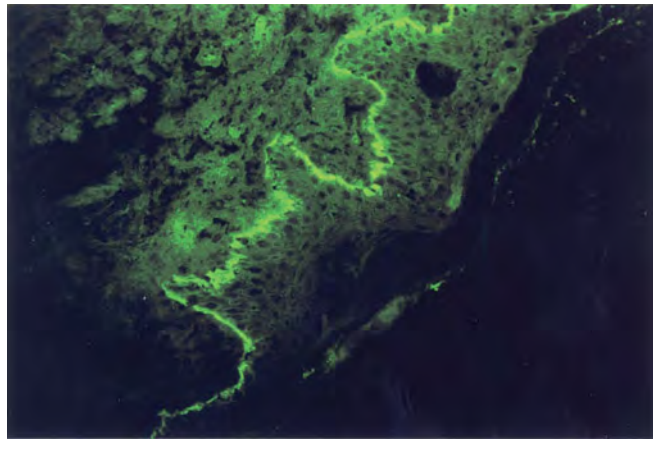

FIGURE 56-7 Herpes gestationis. Direct immunofluorescent stain of a punch biopsy of a skin vesicle in a postpartum women shows a linear pattern of C_3 staining on the basement membrane (original ×200). (Reprinted from Erickson NI, Ellis RL: Neonatal rash due to herpes gestationis. *N Engl J Med* 347(9):660, with permission. Copyright © 2002 Massachusetts Medical Society. All rights reserved.)

may be identical to bullous pemphigoid (Amato and associates, 2003).

Effect on Pregnancy

Observations from small studies have been inconclusive but suggest an association with preterm birth, stillbirths, and fetal-growth restriction (Aronson and Bass, 2000). In a recent study from Oxford, Chi and colleagues (2009) retrospectively analyzed perinatal outcomes in 63 pregnancies. They found significantly increased risks of preterm birth and low birthweight with the presence of blisters and with disease onset in the first and second trimesters. These findings lend credence to recommendations for antepartum surveillance. Up to 10 percent of neonates develop lesions similar to those of the mother (Erickson and Ellis, 2002). These lesions typically clear spontaneously within a few weeks. Chiaverini and associates (2006) described four neonates with bullous pemphigoid, but their mothers had neither skin lesions nor anti-BP180 antibodies.

PREEXISTING SKIN DISEASE

A number of chronic dermatological disorders may complicate pregnancy. These may antedate pregnancy or manifest for the first time during pregnancy. Like other chronic inflammatory disorders, their course may vary during pregnancy (Oumeish and Al-Fouzan, 2006).

Acne is unpredictably affected by pregnancy, but may improve. For nonpregnant women, treatment may include some of the highly teratogenic congeners of retinoic acid (see Chap. 14, p. 324). **Isotretinoin, etretinate, and tretinoin are strictly contradicted in pregnancy.** For severe acne, topically applied *benzoyl peroxide* appears to be safe. *Topical tretinoin* is absorbed poorly and thought to pose no significant teratogenic risk (Briggs and colleagues, 2005; Leachman and Reed, 2006).

From their review, Oumeish and Al-Fouzan (2006) reported that *psoriasis* improves in approximately 40 percent of women during pregnancy, it is unchanged in another 40 percent, and it worsens in another 20 percent. Raychaudhuri and associates (2003) theorize that improvement may be due to downregulated proinflammatory Th-1 cytokines. Ben-David and colleagues (2008) performed a case-control study of 145 pregnancies complicated by psoriasis. Perinatal outcomes were generally not different from affected women compared with 860 normal controls. There was, however, a significant two- to fourfold increase in recurrent miscarriage—OR 2.1; in chronic hypertension—OR 2.9; and cesarean delivery—OR 4.1. There are a number of regimens used in nonpregnant individuals that are contraindicated during pregnancy. Topical corticosteroids are recommended for localized disease (Tauscher and co-workers, 2002). If there is no response, then stepwise therapy is given with topical calcipotriene, anthralin, and then tacrolimus. For generalized mild disease, they recommended UVB phototherapy. Vun and colleagues (2006) reported the successful use of narrowband UVB phototherapy for pustular psoriasis in a pregnant woman. If there is no response, psoralens are given with UVB phototherapy, followed by oral cyclosporine, if unsuccessful. Topical or oral corticosteroids may also be given for moderate or severe disease. Coal tar derivatives and some systemic immunosuppressives such as methotrexate are avoided. Recently, mycophenolate mofetil is again being used for psoriasis (Orvis and co-workers, 2009). As discussed in Chapter 14 (p. 322), the drug is teratogenic and should be avoided.

Hidradenitis suppurativa is a chronic, progressive, inflammatory and suppurative skin disorder. It is characterized by apocrine gland plugging that leads to anhidrosis and bacterial infection. The disease is hormonally responsive and thus not seen until puberty. It has been said to improve with pregnancy, but in our experiences, it is not appreciably changed. Treatment is control of acute infections with either systemic antimicrobials or clindamycin ointment. Milder inflammatory changes and maintenance are treated with oral antimicrobial agents, and more recently, with anti-inflammatory polyclonal antibodies (Alikhan and associates, 2009). Some women will require surgical drainage and debridement during pregnancy. Radical surgical resection may be necessary to control and prevent recurrences, but this can usually be done after pregnancy (Buimer and colleagues, 2009).

If *pemphigus* appears for the first time during pregnancy, it may be confused with herpes gestationis (Vaughan Jones and Black, 1999). Even with corticosteroid therapy, the mortality rate is 10 percent from sepsis caused by infection of denuded skin. Lesions of *neurofibromatosis* may increase in size and number as a result of pregnancy. According to Perez-Maldonado and Kurban (2006), both *porphyria cutanea tarda* and *acrodermatitis enteropathica* characteristically exacerbate during pregnancy.

Erythema nodosum is a cutaneous reaction associated with a number of disorders. These include sarcoidosis, drugs, connective-tissue disorders, inflammatory bowel disease, infections, and malignancies. Although pregnancy itself is reported by Requena and Sánchez (2007) to be a cause, in our experiences, this is rare.

OTHER TUMORS 1206

Cancer during pregnancy is uncommon but not rare. Reported rates for most cancers vary widely, reflecting not only differences in populations, but also differing methods of ascertainment and inconsistency of reporting. In a review of more than 4.8 million deliveries in California during a 9-year period, Smith and colleagues (2003) found the incidence of malignant neoplasms during pregnancy or in the subsequent 12 months to be 0.94 per 1000 live births. About a third were diagnosed in the prenatal period and the others within 12 months of delivery. Shown in Table 57-1 are some of the more common cancers associated with pregnancy. Breast, thyroid, and cervical cancers; lymphoma; and melanoma account for at least 85 percent of these malignancies. Although management of the pregnant woman with cancer is problematic, a basic tenet should be followed: she should not be penalized because she is pregnant. That said, treatment must be individualized and include consideration of the type and stage of cancer, her desire to continue the pregnancy, and risks of modifying or delaying treatment.

PRINCIPLES OF CANCER THERAPY DURING PREGNANCY

Surgery

Surgical intervention for cancer may be indicated for diagnostic, staging, or therapeutic purposes. Most procedures that do not interfere with the reproductive tract are well tolerated by both mother and fetus (see Chap. 41, p. 913). Although many operative procedures have classically been deferred until after 12 to 14 weeks to minimize abortion risks, this probably is not necessary. Specifically, visualizing a live, normal-appearing fetus with sonography between 9 and 11 weeks forecasts a 95-percent chance that pregnancy will reach viability. We are of the opinion that surgery should be performed regardless of gestational age if maternal well-being is imperiled.

Radiation Therapy

Most diagnostic radiographic procedures have very low x-ray exposure and should not be delayed if they would directly affect therapy (American College of Obstetricians and Gynecologists, 2004). Radiation dosimetry of many procedures is discussed in Chapter 41 (p. 915). Conversely, therapeutic radiation often results in significant fetal exposure. The amount depends on the dose, tumor location, and field size. Although the most susceptible period is during organogenesis, there is no gestational age considered safe for therapeutic radiation exposure. Adverse effects include cell death, carcinogenesis, and genetic effects on future generations (Brent, 1989, 1999; Hall, 1991). Characteristic adverse fetal effects are microcephaly and mental retardation. In some cases, even late exposure can cause fetal-growth restriction and brain damage.

These dangers raise very practical issues. For example, therapeutic radiation doses to the maternal abdomen are contraindicated because of a high risk of fetal death or damage, unless of

TABLE 57-1. Incidence of Malignant Tumors Associated with Pregnancy in 4.85 Million Women

		Incidence Per 100,000		
Cancer	No.	Pregnancy	Postpartum[a]	Incidence Per Pregnancy[b]
Any	4539	34.0	59.6	1:1100
Breast	935	5.5	13.8	1:5000
Thyroid	699	3.6	10.8	1:7000
Cervix	580	4.6	7.4	1:8500
Lymphoma	425	4.1	4.6	1:12,000
Melanoma	424	3.2	5.5	1:12,000
Ovary	253	3.6	1.7	1:19,000
Gastrointestinal	225	1.2	3.5	1:21,500
Leukemia	206	2.4	1.8	1:23,500
Nervous System	175	1.5	2.2	1:28,000

Data from the California Cancer Registry (Smith and colleagues, 2003).

course abortion induction is one of its purposes. In some cases, such as head and neck cancers, radiotherapy to supradiaphragmatic areas can be given relatively safely with abdominal shielding. In others, such as breast cancer, significant scatter doses can accrue to the fetus.

Chemotherapy

Chemotherapy is recommended for primary treatment or as adjunctive therapy along with surgery or radiation. Although chemotherapy often improves long-term maternal outcome, there is too often a reluctance to employ it during pregnancy. To be sure, fetal concerns include malformations, growth restriction, mental retardation, and the risk of future malignancies. But the risks for these effects are dependent primarily on gestational age at exposure. For example, most antineoplastic drugs are potentially harmful to the fetus if given during organogenesis. Indeed, embryonic exposure to cytotoxic drugs causes major malformations in 10 to 20 percent of cases (Muslin and colleagues, 2001).

After the first trimester, most antineoplastic drugs are without immediate obvious adverse sequelae (Avilés and Neri, 2001; Cardonick and Iacobucci, 2004). Long-term effects, however, have not been evaluated thoroughly (Gwyn, 2005; Partridge and Garber, 2000). Late mutagenic effects on offspring of women treated during pregnancy have been of concern. In one study, Li and associates (1979) found only two childhood malignancies in offspring of 146 women treated during 286 pregnancies. In another study, Avilés and Neri (2001) found no adverse sequelae in 84 children exposed to antineoplastic drugs in utero.

Regarding specific agents, from their reviews of *alkylating agents*, Glantz (1994) and Doll and colleagues (1988) concluded that these agents could be used after the first trimester. These observations also apparently apply to the two potent teratogens—*all-trans-retinoic acid* and *methotrexate*—both of which have few adverse effects after the first trimester (Briggs and co-workers, 2002).

Other Considerations

Chemotherapy is a contraindication to breast feeding. There is also concern with contact exposure of healthcare workers to chemotherapeutic agents. Selevan and colleagues (1985) and Stucker and co-workers (1990) reported a twofold increased risk of fetal loss in nurses exposed during the first trimester. They recommend caution during mixing and administration of antineoplastic drugs (see Chap. 14, p. 320).

Immunotherapy

Hybridized monoclonal antibodies directed against tumor-specific antigens are commonly used for treatment of an ever-increasing list of malignant neoplasms. A common example is *trastuzumab*, whose trade name is *Herceptin*. It is directed against human epidermal growth factor receptor type 2—*Her2/neu*—commonly found in breast cancers (Hudis, 2007). These drugs are described in more detail on page 1197 as well as with tumors for which they are used.

Fertility after Cancer Therapy

Subsequent fertility may be diminished after chemotherapy or radiotherapy in both men and women. In one example, treatment of advanced Hodgkin lymphoma with multiple-drug chemotherapy may result in azoospermia in men and in decreased follicular maturation, destruction, and ovarian fibrosis

in women (Waxman, 1985). Gershenson (1988) reviewed outcomes in women successfully treated for germ cell ovarian tumors and found that a third had total or partial ablation of ovarian function. Tangir and associates (2003) reviewed women who had ovarian germ cell malignancies treated with fertility-sparing surgery, followed in most cases by chemotherapy. More than 75 percent who attempted pregnancy were successful at least once. Falconer and Ferns (2002) presented similar findings. The likelihood of fertility effects is both age- and dose-related. Interestingly, the prepubertal ovary is more resistant to chemotherapy effects.

Recently, pretherapy harvesting and cryopreservation of ovarian tissue for posttherapy autologous transplantation has been described (Falcone and Bedaiwy, 2005). This is an expensive and still experimental approach to fertility preservation that has been used in women who are to undergo chemotherapy (Patrizio and colleagues, 2005). At least one live birth using this approach was reported (Donnez and co-workers, 2004). Current methods of fertility preservation and conception options have been reviewed by Jeruss and Woodruff (2009) and Maltaris and associates (2009).

Pregnancy in Cancer Survivors

The Childhood Cancer Survivor Study (CCSS) was established in 1994 to study long-term effects of therapy on cancer survivors. In a description of more than 10,000 surviving adults, Oeffinger and colleagues (2006) reported that relative to their siblings, survivors had a threefold risk of developing a number of chronic health conditions. Problems include second malignancies and heart failure, as well as cranial radiotherapy-related cognitive dysfunction, growth hormone deficiency, and obesity. Pregnancy outcomes from 1953 women in the CCSS cohort, who had a total of 4029 pregnancies, have also been reported (Green and colleagues, 2002; Robison and associates, 2005). In general, there were no increased adverse outcomes. Signorello and associates (2006) reported similar results. In a Scottish study, Clark and co-workers (2007) reported that 917 first pregnancies in cancer survivors had slightly higher rates of preterm birth and postpartum hemorrhage.

Finally, Larsen and colleagues (2004) reported that radiotherapy, but not chemotherapy, at a young age irreversibly reduces uterine volume of childhood cancer survivors. Similarly, Wo and Viswanathan (2009) in their review concluded that abdomino-pelvic radiation impairs subsequent reproductive function. Reassuringly, however, mothers who were treated in childhood with radiotherapy did not have significantly increased risks of delivering neonates with congenital malformations (Winther and co-workers, 2009).

BREAST CARCINOMA

Breast cancer is the most common malignancy of women of all age groups. However, there is encouraging evidence from the Centers for Disease Control and Prevention (2007) that its incidence is decreasing. Despite this, the American College of Obstetricians and Gynecologists (2003b) estimates that almost 1 of every 8 women will eventually be afflicted. It is also one of the more common malignancies encountered during pregnancy with an incidence that ranges from 1 in 5000 to 50,000 pregnancies (Smith and associates, 2003; Sorosky and Scott-Conner, 1998). As more women choose to delay childbearing until a later age, the frequency of associated breast cancer likely will increase (Woo and associates, 2003).

According to some studies, women with *BRCA1* and *BRCA2* breast cancer gene mutations, as well as those with a family history of breast cancer, are more likely to develop malignancy during pregnancy than those without mutations (Johannsson and co-workers, 1998; Shen and colleagues, 1999). Ultimately, however, parity may modify risk in women with *BRCA1* and *BRCA2* mutations. In this group, parous women older than 40 have a significantly reduced cancer risk (Andrieu and co-workers, 2006; Antoniou and colleagues, 2006). Women in this group undergoing induced abortions or those who breast feed do not have an increased risk of breast cancer (Beral and associates, 2004; Friedman and colleagues, 2006). Moreover, Jernström and associates (2004) found that breast feeding actually conveyed a protective effect against this cancer in those with *BRCA1* gene mutation, but not in those with *BRCA2* mutations. It is controversial whether diethylstilbestrol exposure in utero is associated with an increased risk (Larson and co-workers, 2006; Titus-Ernstoff and associates, 2006).

Pregnancy and Breast Cancer

The effects of pregnancy on the course of breast cancer and its prognosis are complex and not simply due to the massively increased levels of both estrogens and progestins. Certainly, some data suggest that higher estrogen levels cause excess breast cancer later in life and that progesterone may be protective (Ward and Bristow, 2002). There is intriguing evidence that higher serum levels of alpha-fetoprotein are associated with a decreased incidence of breast cancer (Melbye and colleagues, 2000). Even so, it appears that pregnancy interruption following diagnosis of pregnancy-associated cancer has no influence on its course or prognosis.

Most clinical reports maintain that when breast cancer is diagnosed during pregnancy, the regional lymph nodes are more likely to contain microscopic metastases. This is important, because the 5-year survival rate is primarily dependent on its stage at diagnosis and is comparable stage for stage with that in nonpregnant women (King and colleagues, 1985; Nugent and O'Connell, 1985; Zemlickis and associates, 1992). According to Jacob and Stringer (1990), about 30 percent of pregnant women with breast cancer have stage I disease, 30 percent have stage II, and 40 percent stages III or IV. As shown in Table 57-2, the aggregate of studies published after 1990 indicate that about 60 percent of pregnant women have concomitant axillary node involvement.

Other findings support that breast cancer is generally more advanced in pregnant women. Zemlickis and associates (1992) found that pregnant women had a two- to threefold increased risk of metastatic disease compared with nonpregnant women. Bonnier and associates (1997) found a much higher incidence of inflammatory cancer in 154 pregnant women compared with that of 308 age-matched nonpregnant controls—26 versus 9 percent.

[α] Compared with 80 percent reported before 1980.

There are usually slight delays in clinical assessment, diagnostic procedures, and treatment of pregnant women with breast tumors (Berry and colleagues, 1999). The mean delay was found to be only 1 or 2 months by Woo and associates (2003). The delay can partially be attributed to pregnancy-induced breast changes that obscure breast masses. These changes are even more magnified during lactation, when there is lobular hyperplasia and galactostasis. Concerns that excessive nodal involvement is related to delayed diagnosis seem unlikely considering the biology of breast cancer. Nettleton and colleagues (1996) used mathematical modeling to conclude that even a 6-month delay increases the chance of axillary metastasis by only 5 percent. There is no doubt that breast cancer is more aggressive in younger women. Whether it is more aggressive during pregnancy in these same women is debatable. Beadle and co-workers (2009) found no differences in overall survival rates in young women with pregnancy-associated breast cancer compared with similarly aged and staged women whose cancer was not diagnosed during pregnancy. These findings were in contrast to Rodriguez and colleagues (2008), who reported poorer overall survival rates in those with pregnancy-associated breast cancer compared with matched controls. Both studies conclude that later disease stages seem to be more prevalent in pregnant women, and thus, overall survival is adversely affected. In the Swedish Cancer Registry, Bladström and associates (2003) reported a 5-year survival rate of 52 percent if breast cancer was diagnosed in pregnant women compared with 80 percent if detected in nonpregnant women. After an extensive review, Schedin (2006) hypothesized that postpregnancy breast remodeling contributes to tumor cell dissemination.

Placental Metastases

Malignant breast cells are occasionally found on placental microscopic examination (Dunn and co-workers, 1999). These have been confined to the intervillous space, and fetal disease has not been reported (see Chap. 27, p. 581).

Diagnosis

The diagnostic approach in pregnant women with a breast tumor should not differ significantly from that for nonpregnant women. Any suspicious breast mass found during pregnancy should prompt an aggressive plan to determine its cause. The "triple test" for a solid breast mass consists of clinical examination, imaging, and needle biopsy. At the University of Alabama, sonography is the initial diagnostic study performed. An oval or elongated lesion with smooth borders and no shadowing is highly suggestive of a benign mass. Most masses in pregnancy have these reassuring features, and definitive diagnosis can often await the conclusion of pregnancy.

Some use mammography to evaluate a breast mass. Fetal radiation risk is negligible with appropriate shielding, and the exposure is only 0.004 cGy for the typical two-view mammogram (Nicklas and Baker, 2000). Because breast tissue is denser in pregnancy, mammography is associated with a false-negative rate of 35 to 40 percent (Woo and associates, 2003).

Finally, magnetic resonance (MR) imaging is more sensitive than mammography but has a higher false-positive rate in nonpregnant women (Leach and colleagues, 2005). Importantly, if a suspicious mass is present and imaging studies are nondiagnostic, or if there are worrisome clinical features, then biopsy is indicated. Although there are no large studies in pregnant women, core biopsy is recommended. Fine-needle aspiration for cytology has become less popular in the past few years because it has a higher insufficient tissue sample rate and findings with pregnancy-associated breast cancer are more difficult to interpret (Woo and associates, 2003).

Once malignancy is diagnosed, a chest radiograph and a limited metastatic search are performed. Although routine computed tomography (CT) scans of bone and liver are both sensitive and specific, they are usually avoided during pregnancy because of excessive radiation (Pelsang, 1998). Magnetic resonance imaging is a reasonable alternative to assess liver involvement because it is sensitive and has excellent contrast resolution.

Treatment

The best clinical approach is by a multidisciplinary team with obstetricians, surgeons, and medical oncologists. Breast conservation surgery for small tumors, with or without adjunctive chemo- or radiotherapy, is preferable in nonpregnant women (Fisher and colleagues, 2002; Veronesi and co-workers, 2002).

Surgical treatment may be definitive for breast carcinoma during pregnancy (Woo and colleagues, 2003). In the absence of metastatic disease, wide excision, modified radical mastectomy, or total mastectomy, each with axillary node staging can be performed (Rosenkranz and Lucci, 2006). During staging, sentinel lymph node biopsy appears safe to perform in pregnant women (Mondi and associates, 2007; Spanheimer and co-workers, 2009).

Chemotherapy is recommended for node-positive disease if delivery is not anticipated within several weeks. It is given for advanced disease, and termination should be considered if pregnancy is early (Shah and Saunders, 2001). Cyclophosphamide, doxorubicin, and 5-fluorouracil are currently recommended by most clinicians (García-Manero and associates, 2009). After the first trimester, methotrexate can be substituted for doxorubicin (Sorosky and Scott-Conner, 1998). Because survival is improved with chemotherapy in premenopausal women, it should be considered even if lymph nodes are cancer free.

Immunotherapy for breast cancers has become commonplace in the past decade. *Trastuzumab—Herceptin*—is a monoclonal antibody to the human epidermal growth factor receptor type 2 (HER2/neu), which is found in about a third of invasive breast cancers (Hudis, 2007). The drug is used in metastatic breast cancer and is being used more commonly as adjunct therapy for early disease in HER2-positive tumors. Experience with its use in pregnancy is limited, but it may be associated with oligohydramnios (Shrim and colleagues, 2008; Sekar and Stone, 2007).

In 22 women treated with modified radical mastectomy and followed in most by chemotherapy, Berry and colleagues (1999) reported minimal fetal risks. Moreover, Hahn and co-workers (2006) reported good short-term outcomes for the offspring of 57 women treated during pregnancy with multi-agent chemotherapy for breast cancer. Adjunctive radiotherapy is not recommended during pregnancy because abdominal scatter is considerable. Sorosky and Scott-Conner (1998) determined that when the maternal radiation dose is 5000 cGy, the fetus receives at least 100 to 150 cGy. Bradley and colleagues (2006) emphasize that fetal size and depth within the maternal abdomen (as opposed to uterine size) should be used to calculate fetal dose.

Pregnancy Following Breast Cancer

Some women are rendered infertile by chemotherapy, as discussed previously on page 1194. For those who can choose pregnancy, there is little evidence to suggest that pregnancy adversely affects survival in women who have undergone prior breast cancer treatment (Averette and colleagues, 1999). Dow and colleagues (1994) found no differences in rates of recurrence or distant metastasis in those with or without subsequent pregnancies. Reports by Kroman (1997) and Velentgas (1999) and their colleagues have since confirmed these findings.

No data suggest that lactation adversely affects the course of breast cancer. Successful lactation and breast feeding are possible after conservative surgery and radiation for breast cancer, even from the treated side (Higgins and Haffty, 1994). Recommendations for future pregnancies in women successfully treated for breast malignancy are based on several factors, including consideration of recurrence risk. It seems reasonable to advise a delay of 2 to 3 years, which is the most critical observation period. Women who conceive before this time, however, do not appear to have diminished survival (Ives and associates, 2006). Finally, it is reassuring that women who undertake pregnancy after a diagnosis of breast cancer have birth outcomes comparable with those without cancer (Langagergaard and colleagues, 2006).

LYMPHOID CELL MALIGNANCIES

Some of these present as leukemia involving bone marrow and blood, and others are solid tumors, that is, lymphomas. They may be of B- or T-cell origin.

Hodgkin Disease

This is the most common malignant lymphoma in women of childbearing age. It is *probably* B-cell derived and is distinguished from other lymphomas by Reed–Sternberg cells. It has a bimodal incidence peak at age 18 to 30 years and again after age 50. Prognosis is good, and survival is greater than 70 percent.

In more than 70 percent of Hodgkin disease cases, there is painless enlargement of lymph nodes above the diaphragm—the axillary, cervical, or submandibular chains. About a third have symptoms including fever, night sweats, malaise, weight loss, and pruritus. The World Health Organization 1999 classification, used for clinical and therapeutic applications, includes consideration of morphological, clinical, immunological, and genetic information. The most common finding is peripheral adenopathy, and neck and supraclavicular nodes are commonly involved. Diagnosis is by histological examination of involved nodes (Armitage and Longo, 2005).

Pregnancy and Hodgkin Disease

In a population-based review of approximately 4 million deliveries, Smith and associates (2003) reported this lymphoma to complicate only 1 per 34,000 live births. Our experiences are similar during the past 35 years at Parkland Hospital with more than 300,000 pregnancies.

Pregnant women with Hodgkin disease present special management considerations. A tenet of treatment is that careful staging is essential, and either local radiotherapy or systemic chemotherapy is indicated. The Ann Arbor staging system, shown in **Table 57-3**, was designed for Hodgkin lymphomas but is also used for other lymphomas. Although pregnancy limits the widespread application of some radiographic studies, at minimum, evaluation includes chest radiography, bone marrow biopsy, and abdominal imaging (Williams and Schilsky, 2001). Spiral CT can be used with the "pitch" set so that radiation dose approaches that of conventional scanning (see Chap. 41, p. 918). MR imaging is an excellent alternative for evaluating thoracic and abdominal para-aortic lymph nodes (**Fig. 57-1**). Radionuclide gallium scanning, which is being used more frequently in nonpregnant patients, emits only 0.75 to 1.0 cGy, and its use should be considered. Staging is essential when radiotherapy alone is chosen because the presence of abdominal disease significantly alters treatment.

Treatment is individualized depending on stage and pregnancy duration. In nonpregnant patients, initial chemotherapy is given with increasing frequency even in stage I disease-isolated

TABLE 57-3. Ann Arbor Staging System for Hodgkin Disease

Stage	Findings
I	Involvement in a single lymph node region or lymphoid site—e.g., spleen or thymus.
II	Involvement of two or more lymph node groups on the same side of the diaphragm—the mediastinum is a single site
III	Involvement of lymph nodes on both sides of diaphragm
IV	Extralymphatic involvement—e.g., liver or bone marrow.

Substage A = no symptoms; substage B = fever, sweats, or weight loss; substage E = extralymphatic involvement excluding liver and bone marrow.

lymph node involvement. Radiotherapy alone for stage I disease has a 90-percent cure rate. In pregnancy, radiotherapy is preferable for isolated neck adenopathy, but it is not recommended for areas that would result in significant radiation scatter to the fetus.

As discussed on page 1194, chemotherapy is best avoided during the first trimester. A course of chemotherapy to precede local disease radiation should be an individualized decision and is probably best done after 12 weeks. With obvious widespread disease, however, we recommend that chemotherapy be initiated regardless of gestational age. Postponement of therapy until fetal maturity is achieved seems justifiable only when the diagnosis is found late in pregnancy (Shulman and associates, 2008).

Pregnancy does not adversely affect the course or survival of women with Hodgkin lymphoma (Pavlidis, 2002). Moreover, adverse perinatal outcomes do not appear to be increased (Langagergaard and colleagues, 2008). Because aggressive radiation and chemotherapy are often necessary for cure, however, pregnancy termination is reasonable in the first half of pregnancy. Jacobs and associates (1981) reported that neither chemotherapy during the second and third trimesters nor irradiation to the mediastinum and neck adversely affected the fetus or neonate. In our experiences, pregnant women with Hodgkin disease are inordinately susceptible to infection and sepsis, and both radiotherapy and chemotherapy increase this susceptibility.

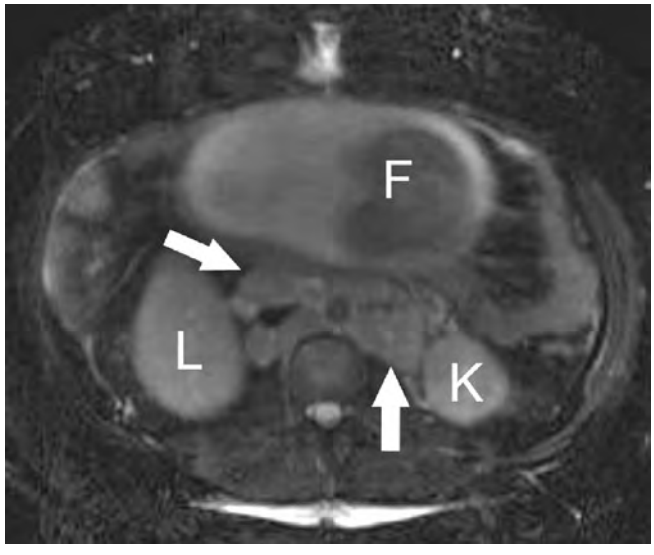

FIGURE 57-1 24-year-old woman diagnosed with Hodgkin lymphoma in the second trimester, undergoing noncontrast chest, abdomen, and pelvis MR imaging for staging. Axial T2 weighted MR image through the midabdomen demonstrates bilateral paraaortic adenopathy (*arrows*). Fetal abdomen (F), maternal inferior liver (L), maternal left kidney (K) are seen. (Used with permission of Dr. Desiree Morgan.)

Long-Term Prognosis

Horning and co-workers (1981) reported that 55 percent of women resumed normal menses after chemotherapy. There were no birth defects in 24 neonates subsequently born to these women. The risk of second cancers, especially leukemia, in treated individuals is about 20 percent within 15 years. Kaldor and associates (1990) reported that the risk of leukemia was increased almost ninefold following chemotherapy compared with that of radiotherapy given alone. Travis and co-workers (2003) presented surveillance data from 3817 female survivors who were treated for Hodgkin disease before age 30. Women treated with radiation had an overall 3.2-fold increased risk of breast cancer. When given chemotherapy alone, the risk was significantly decreased below baseline. Other complications of therapy for Hodgkin disease include myocardial damage and infarction, pulmonary fibrosis, hypothyroidism, and marrow suppression (Armitage and Longo, 2005).

Non-Hodgkin Lymphomas

Non-Hodgkin lymphoma, although usually B-cell tumors, can also be T-cell or natural killer-cell neoplasms. Their biology, classification, and treatment are complex (Armitage and Longo, 2005; Shulman and colleagues, 2008). For example, they are associated with viral infections including human immunodeficiency virus (HIV), Epstein-Barr virus (EBV), hepatitis C virus (HCV), and human herpes virus 8 (HHV8). These lymphomas tend to be more aggressive overall than Hodgkin lymphomas, and survival varies. The incidence of non-Hodgkin lymphomas has risen sharply, partly because 5 to 10 percent of HIV-infected persons develop a lymphoma.

Non-Hodgkin lymphomas are rare during pregnancy. In an earlier review, Ward and Weiss (1989) described only 75 cases associated with pregnancy. Avilés and colleagues (1990) reported their experiences with 16 pregnant women with non-Hodgkin lymphomas, half of whom were in the first trimester.

They were treated with cytotoxic drugs, and there were no fetal malformations. All but one of the offspring were healthy at 3 to 11 years. Half of the mothers who had remissions were alive 4 to 9 years later. In another study, Avilés and Neri (2001) described long-term surveillance of 55 children whose mothers had received chemotherapy for lymphomas during pregnancy. They found no congenital, neurological, or psychological abnormalities at 6 to 29 years. They observed that there were also no cancers, including leukemia.

Burkitt lymphoma is an aggressive B-cell tumor associated with Epstein-Barr virus (EBV) infection. Barnes and associates (1998) reviewed the outcome of 19 women whose pregnancies were complicated by this lymphoma: 17 died within a year. Pollack and colleagues (1993) described an HIV-infected woman with a B-cell lymphoma that metastasized to the placenta. Catlin and co-workers (1999) described a fascinating case in which a maternal T-cell/natural killer-cell lymphoma metastasized transplacentally and engrafted the fetus. Both mother and infant succumbed from the malignancy. Magloire and colleagues (2006) described the removal of a 15-cm Burkitt lymphoma of the ovary at 13 weeks' gestation in a woman with stage IV disease. She was delivered vaginally at term of a healthy neonate after being given six courses of multi-agent chemotherapy.

Management

Staging for non-Hodgkin lymphomas is performed according to the Ann Arbor system shown in Table 57-3. Radiotherapy typically is used for stage I disease, whereas chemotherapy and immunotherapy with rituximab is recommended for most stage II and all stage III and IV tumors. During pregnancy at least, if the peripheral nodes are involved, the disease is often widespread and staging laparotomy has limited benefit (Peleg and Ben-Ami, 1998).

Leukemias

There are, in general, two varieties of leukemia. These malignancies arise from lymphoid tissues—lymphoblastic or lymphocytic leukemias, or they arise from bone marrow—myeloid leukemias. They can be acute or chronic. Although adult leukemias are more prevalent after age 40, they still are among the most common malignancies of young women. For this reason, they are relatively common in pregnancy. Smith and colleagues (2003) reported an incidence of leukemia of 1:40,000 from the California Cancer Registry. Caligiuri and Mayer (1989) reviewed 350 reports of pregnancy complicated by leukemia. Of 72 women reported since 1975, 44 had acute myelogenous leukemia; 20 had acute lymphocytic leukemia; and 8 had one of the chronic leukemias.

Pregnancy and Leukemia

Before 1970, the maternal mortality rate was virtually 100 percent. However, with contemporary therapy, remission during pregnancy is common. *Induction chemotherapy* is aggressively pursued with a goal to attain complete remission. Thereafter, *postremission therapy* is mandatory to prevent a relapse which, if it occurs, is usually treated with stem-cell transplantation (Wetzler and colleagues, 2005). With some chronic leukemias it may be possible to delay therapy until after delivery (Fey and Surbeck, 2008). Combination chemotherapeutic regimes are complex and toxicity is common. The usual considerations for fetal exposure apply. More recently, monoclonal antibodies have been used to treat some leukemias. Ault and colleagues (2006) described 19 pregnancies conceived with either partner of the couple taking *imatinib*—*Gleevec*—for chronic myeloid leukemia. The fetal effects for this drug are unknown at this time.

There is no evidence that termination improves the prognosis. That said, abortion is a consideration in early pregnancy to avoid potential teratogenesis from chemotherapy. And because it may also simplify management of the acutely ill woman, it remains a consideration until fetal viability. Infection and hemorrhage are significant complications that should be anticipated in women with active disease. Puerperal infection is particularly problematic.

Greenlund and associates (2001) reviewed experiences with 17 women with acute leukemia during pregnancy. Of these, 13 had newly diagnosed acute myeloid leukemia, and the remission rate with induction chemotherapy was 70 percent. Importantly, three of four women who elected to delay chemotherapy until after delivery died within days of delivery and just after beginning such therapy. Survival has also improved for women with chronic myelogenous and chronic lymphocytic leukemias. Chronic hairy-cell leukemia has been reported in only six pregnancies (Stiles and colleagues, 1998).

Perinatal Outcome

There are few contemporaneous studies of leukemia treated during pregnancy. In an earlier review of 58 cases, Reynoso and colleagues (1987) reported that 75 percent were diagnosed during the second or third trimesters. Half were acute myelogenous leukemia, and they had a remission rate of 75 percent with chemotherapy. Only 40 percent of these pregnancies resulted in liveborn neonates. Caligiuri and Mayer (1989) reported preterm delivery in about half of women diagnosed during pregnancy. The stillbirth rate was also increased.

Leukemia cells may be seen in the placenta, however, these are usually in the intervillous space, and maternal-to-fetal transmission has never been authenticated (see Chap. 27, p. 581).

Fetal effects of chemotherapy are concerning. For example, treatment for acute promyelocytic leukemia may include all-trans-retinoic-acid (Carradice and associates, 2002; Celo and colleagues, 1994). Also known as tretinoin, this is a potent teratogen (see Chap. 14, p. 324). Although outcomes have been generally good, Siu and colleagues (2002) described transient dilated cardiomyopathy in a newborn exposed to tretinoin in the second trimester. Hansen and colleagues (2001) reported transient oligohydramnios in each of three cycles of intensive multi-agent chemotherapy for leukemia.

MALIGNANT MELANOMA

Melanomas are relatively common in women of childbearing age, and many of these malignancies are first recognized during pregnancy. Their general incidence has been increasing over the

past several decades (Katz and associates, 2002; MacKie and coworkers, 2002). The reported incidence of melanoma in pregnancy ranges widely from 0.03 to 2.8 per 1000 live births (Wong and Strassner, 1990; Smith and associates, 2003). Because many are treated on an outpatient basis, they are not entered into a tumor registry and are thus underreported (Salopek and colleagues, 1995).

Melanomas are most common in light-skinned Caucasians. More than 90 percent originate in the skin from pigment-producing melanocytes, usually arising from a preexisting nevus. Any suspicious "behavior" in a pigmented cutaneous lesion warrants a biopsy, including changes in contour, surface elevation, discoloration, itching, bleeding, or ulceration.

Staging of Melanomas

Staging is by clinical findings: In stage I, there are no palpable lymph nodes; in stage II, lymph nodes are palpable; in stage III, there are distant metastases. Tumor thickness is the single most important predictor of survival in stage I patients. The *Clark classification* is most widely used and includes five levels of involvement by depth into the epidermis, dermis, and subcutaneous fat. Alternatively, the *Breslow scale* measures tumor thickness and size, in addition to depth of invasion.

Pregnancy and Melanoma

There is probably little interaction between pregnancy and melanomas (Lens and Bataille, 2008). Previously, it had been widely held that the prognosis was worse during pregnancy and that future pregnancies increased the recurrence risk. This was disputed by Holly (1986) in his review of 11 studies. He concluded that there were no adverse effects on survival if melanoma was diagnosed during pregnancy or if pregnancy developed in a woman with a preexisting melanoma. These findings are supported by the later observations of Lens and colleagues (2004). Somewhat related, Lea and associates (2006) reported that a change in nevi during pregnancy was a risk factor for melanoma.

Overall, prognosis is determined by the stage, and women with deep cutaneous invasion or regional node involvement have a much poorer prognosis. MacKie (1999) from the World Health Organization Melanoma Programme reported that women diagnosed during pregnancy had significantly greater tumor thickness. These women have a correspondingly higher mortality rate compared with women whose melanoma was diagnosed before or after pregnancy (Fig. 57-2). Survival is equivalent, however, stage-for-stage, between pregnant and nonpregnant women (Kjems and Krag, 1993). Finally, therapeutic abortion does not appear to improve survival (Dipaola and colleagues, 1997).

Treatment

Primary surgical treatment for melanoma is determined by the stage of the disease and includes wide local resection, sometimes with extensive regional lymph node dissection. Schwartz and associates (2003) have recommended sentinel lymph node mapping and biopsy using ^{99m}Tc-sulfur colloid, which has a fetal dose of less than 100 mGy (see Chap. 41, p. 920). Cascinelli and co-workers (1998) reported that routine regional node dissection improved survival in nonpregnant patients with microscopic metastases. Although prophylactic chemotherapy or immunotherapy is usually avoided during pregnancy, chemotherapy should be given if indicated by tumor stage and maternal prognosis. In most cases of distant metastatic melanoma, treatment is at best palliative.

Sixty percent of recurrences manifest by 2 years, and 90 percent by 5 years. Thus, most recommend that pregnancy be avoided for 3 to 5 years after initial treatment. Subsequent pregnancies in woman with localized melanoma do not appear to have an adverse effect on survival (Driscoll and Grant-Kels, 2009). Importantly, there do not appear to be adverse effects from oral contraceptive use in these women (Katz and associates, 2002; Schwartz and colleagues, 2003).

Placental Metastases

Metastasis of any tumor type to the placenta or fetus is uncommon. As discussed in Chapter 27 (p. 581), a third of such cases are from malignant melanoma. In an extensive review, Alexander

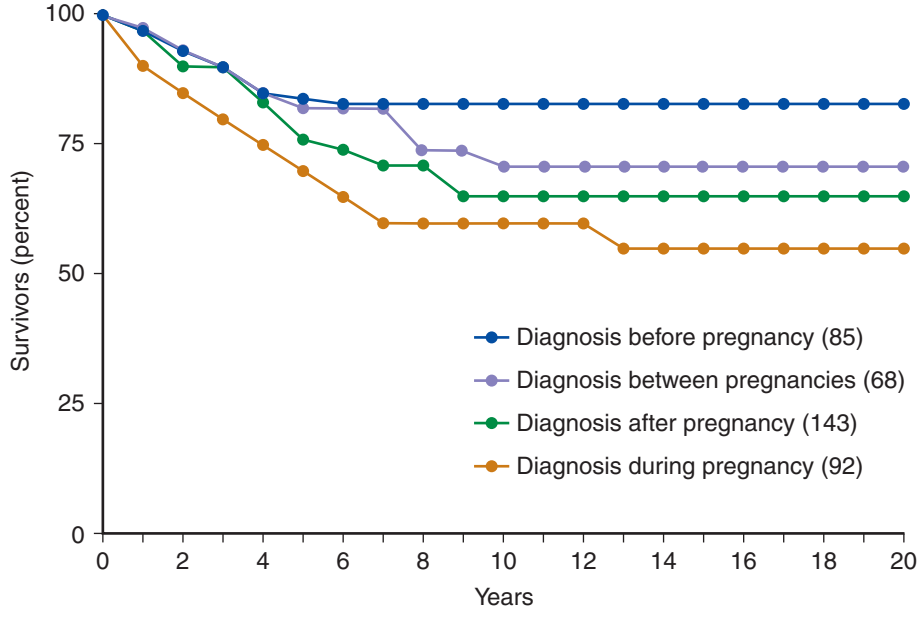

FIGURE 57-2 Disease-free survival in 388 women with malignant melanoma enrolled in the World Health Organization Melanoma Programme. Decreased survival in women diagnosed during pregnancy is due to increased thickness of tumors. (Modified from *The Lancet*, Vol. 337, No. 8742, RM MacKie, R Bufalino, A Morabito, et al., Lack of effect of pregnancy on outcome of melanoma, pp. 653–655, Copyright 1991, with permission from Elsevier.)

and colleagues (2003) found that placental metastasis had been reported in 27 cases of melanoma. Five of the six infants who were affected died of metastatic tumor. Trumble and colleagues (2005) reported transplacental melanoma metastasis to the fetal posterior cranial fossa which manifested at 7 months of age and ultimately proved fatal.

REPRODUCTIVE TRACT NEOPLASIA

Combined together, genital tract cancers are the most common malignancies encountered during pregnancy. Cervical cancer comprises almost 70 percent of these as shown in **Figure 57-3**. Advent of the quadrivalent HPV-6/11/16/18 vaccine—*Gardasil*—should decrease the incidence of high-grade dysplasia and thence cervical carcinoma (American College of Obstetricians and Gynecologists, 2006; FUTURE II study group, 2007). In addition, neonatal respiratory papillomatosis should also decrease (Paavonen, 2008).

Cervical Neoplasia

The effects of pregnancy and delivery on premalignant and malignant epithelial cervical lesions are not understood completely. It is well known that certain types of human papillomavirus (HPV) are associated with high-grade intraepithelial lesions and invasive cancer. Fife and colleagues (1996) found an increased incidence of high-cancer-risk viruses—HPV types 16, 18, 31, 35, 45, 51, 52 and 56—when they compared pregnant with nonpregnant women. Pregnancy provides an opportune time to screen for premalignant and malignant cervical disease, especially in women who do not seek or have access to routine healthcare (American College of Obstetricians and Gynecologists, 2002; Hunter and associates, 2008).

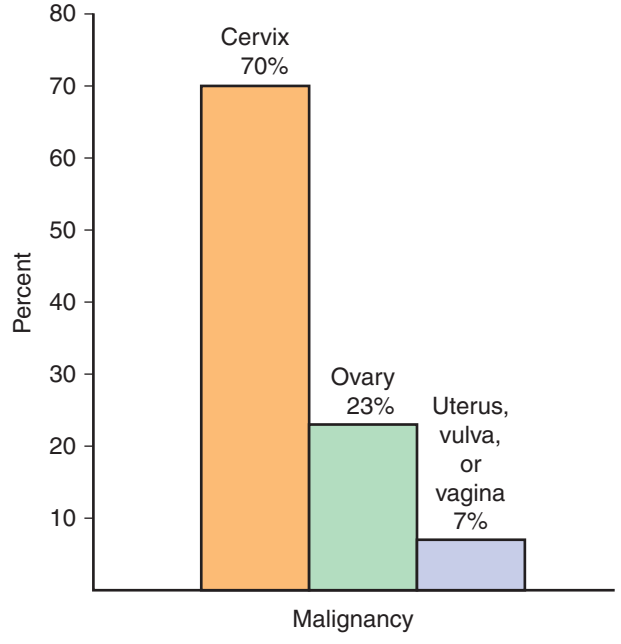

FIGURE 57-3 Frequency of reproductive-tract malignancies in 844 pregnant women. (Data from Haas, 1984; Lutz, 1977; Smith, 2003, and all their colleagues.)

Abnormal Cytological Results

The incidence of abnormal cervical cytology during pregnancy is at least as high as that reported for nonpregnant women. This is despite the fact that Papanicolaou smear evaluation is more difficult during pregnancy (Connor, 1998). Several types of pathological cellular changes may be identified with cervical cytology, and recommendations for their management have been summarized in the American Society for Colposcopy and Cervical Pathology Consensus Guidelines (Wright and colleagues, 2007a):

1. *Atypical squamous cells of undetermined significance (ASCUS)*—management mirrors that for nonpregnant women. It is acceptable to defer colposcopy until at least 6 weeks postpartum
2. *Low-grade squamous intraepithelial lesions (LSIL)*—colposcopy is preferred for pregnant, nonadolescent women. However, deferring the initial colposcopy until at least 6 weeks postpartum is acceptable. Additional colposcopic and cytological examinations during pregnancy are not encouraged unless evidence of advanced disease is noted during colposcopy
3. *High-grade squamous intraepithelial lesions (HSIL)*—it is recommended that colposcopic examination be performed by clinicians with experience in pregnancy-induced cytological changes. Lesions suspicious for high-grade disease or cancer should be biopsied. In the event of unsatisfactory colposcopy, repeat examination should be performed in 12 weeks. After delivery, repeat cytology or colposcopy should generally be delayed for at least 6 weeks to allow reparative healing
4. *Atypical glandular cells (AGC)*—initial evaluation is identical for that of nonpregnant women and colposcopy is recommended. For obvious reasons, endocervical curettage should not be performed during pregnancy.

Colposcopy and Biopsy. During pregnancy, colposcopic evaluation is easier to perform because the transformation zone is better exposed due to physiological eversion. Colposcopically directed biopsies are used liberally to assess any suspicious lesions (Palle and co-workers, 2000). Multiple biopsies need not all be taken on one occasion but rather may be obtained over time. Biopsy sites may actively bleed because of hyperemia, but this can be stopped with Monsel solution, silver nitrate, vaginal packing, or suture.

Loop electrosurgical excision procedure (LEEP) and cone biopsy usually are reserved to exclude invasive cancer. If possible, conization is avoided in pregnant women because of an increased incidence of hemorrhage, abortion, and preterm labor. Indeed, conization during pregnancy is less than satisfactory for two main reasons:

1. The epithelium and underlying stroma within the endocervical canal cannot be excised extensively because of the risk of membrane rupture. Of 376 conizations during pregnancy reviewed by Hacker and colleagues (1982), residual neoplasia was found in 43 percent of subsequent specimens
2. Blood loss is common. Averette and colleagues (1970) reported that nearly 10 percent of 180 pregnant women required transfusion after cone biopsy.

Cervical Intraepithelial Neoplasia

Women with histologically confirmed intraepithelial neoplasia may be followed with cytology and colposcopically directed biopsies, allowed to delivery vaginally, and provided definitive treatment after delivery. Therefore, colposcopic examination during pregnancy should have the exclusion of invasive cancer as its primary goal (American College of Obstetricians and Gynecologists, 2008). For pregnant women with *cervical intraepithelial neoplasia (CIN) 1*, the recommended management is reevaluation postpartum. For those with CIN 2 or 3 in the absence of invasive disease or advanced pregnancy, additional colposcopic and cytological examinations are acceptable at intervals no more frequent than every 12 weeks. Repeat biopsy is recommended only if appearance of the lesion worsens or if cytology suggests invasive cancer. Alternatively, deferring reevaluation until at least 6 weeks postpartum is acceptable (Wright and co-workers, 2007b).

In a study by Yost and colleagues (1999), there was spontaneous postpartum regression in 68 percent of women with CIN 2 and 70 percent of those with CIN 3 neoplasia. Although 7 percent of women with CIN 2 lesions progressed to CIN 3, no lesion progressed to invasive carcinoma. Ackermann and colleagues (2006) described the outcomes of 77 women with carcinoma in situ (CIS) diagnosed during pregnancy and managed conservatively. One third had postpartum regression, two thirds had persistent CIS, and only two women had microinvasive cancer diagnosed by cone biopsy after delivery. For adenocarcinoma in situ (AIS), management is similar as for CIN 3. Lacour and colleagues (2005) performed cold knife conization in five of 11 such women before 19 weeks.

Thus, unless invasive cancer is identified, treatment of these lesions antepartum is not recommended (Wright and co-workers, 2007b). A diagnostic excisional procedure is recommended only if invasion is suspected.

Invasive Cervical Cancer

The incidence of invasive carcinoma has been cited to be about 1 per 2000 pregnancies (Anderson and colleagues, 2001). In our experiences with a high-risk population both from Parkland Hospital and from the University of Alabama, invasive cervical cancer is not nearly so common. The incidence is probably closer to that of 1 in 27,000 as reported by Smith and colleagues (2003).

Pregnancy impedes both the staging and treatment of cervical carcinoma. Cervical cancer is staged clinically rather than surgically. The extent of cancer is more likely to be underestimated in pregnant women. Specifically, induration of the base of the broad ligaments, which characterizes tumor spread beyond the cervix, may be less prominent due to cervical, paracervical, and parametrial softening of pregnancy.

Diagnostically, limited use of CT scanning to evaluate the pelvis is acceptable during pregnancy. MR imaging is a useful adjunct to ascertain disease extent, including urinary tract and lymph node involvement as shown in **Figure 57-4** (Gilstrap and colleagues, 2001; Oto and associates, 2007). Cystoscopy and sigmoidoscopy can be performed as necessary to ascertain mucosal involvement.

Stage-for-stage, the survival rate for invasive cervical carcinoma is not profoundly different for pregnant and nonpregnant women. Van der Vange and colleagues (1995) performed a case-control study of 44 women with pregnancy-associated cervical cancer. The overall 5-year survival rate was approximately 80 percent in both pregnant women and nonpregnant controls.

FIGURE 57-4 Sagittal T-2 weighted magnetic resonance image of a gravid uterus at 32 weeks' gestation with a large cervical mass representing carcinoma (*arrows*).

Management. Treatment of cervical cancer in pregnant women is individualized and depends on the stage, pregnancy duration, and individual desire to continue pregnancy (Hunter and associates, 2008). The American College of Obstetricians and Gynecologists (2002) recommends a multidisciplinary approach. Treatment for microinvasive disease diagnosed by cone biopsy follows guidelines similar to those for intraepithelial disease. In general, continuation of pregnancy and vaginal delivery are considered safe, and definitive therapy is reserved until postpartum.

On the other hand, invasive cancer demands relatively prompt therapy. During the first half of pregnancy, immediate treatment is advisable but depends on the decision to continue the pregnancy. During the latter half of pregnancy, one option is to await not only fetal viability but also fetal maturity (Greer and colleagues, 1989). In a review of 12 pregnant women past 20 weeks with less than stage IIB carcinoma, van Vliet and colleagues (1998) concluded that delayed treatment was reasonable in women without bulky lesions. Takushi and associates (2002) described outcomes in 28 pregnant women, of whom 22 had stage I disease, and reached similar conclusions. Most other studies of women with early stages of cervical cancer indicate that intentional delay in treatment did not appear to worsen prognosis (American College of Obstetricians and Gynecologists, 2002;

Goff and associates, 2000). Staging using laparoscopic lymphadenopathy is another option (Alouini and associates, 2008).

Preferred treatment for invasive carcinoma in most women with stage I and early stage IIA lesions less than 3 cm is radical hysterectomy plus pelvic lymphadenectomy. Before 20 weeks, hysterectomy is usually performed with the fetus in situ. In later pregnancy, however, hysterotomy may first be necessary.

Although many elect surgery, both radical surgery and radiation result in similar cure rates for early cervical cancer during pregnancy (American College of Obstetricians and Gynecologists, 2002). Surgical treatment is favored because it preserves ovarian and sexual function as well as avoids exposure of the intestinal and urinary tracts to radiation and its adverse effects. Nisker and Shubat (1983) described 49 cases of stage IB cervical cancer complicating pregnancy and reported a 30-percent severe complication rate from radiotherapy compared with only 7 percent with surgery.

There is a growing experience with pregnancy following radical trachelectomy for fertility preservation in stage IB1 and IB2 cervical cancer. Shepherd and colleagues (2006) presented outcomes for 123 such women cared for at their institution. Of 63 women who attempted pregnancy, 19 had 28 live births. All had classical cesarean deliveries, and a fourth were before 32 weeks. Ungár and colleagues (2006) performed abdominal radical trachelectomy prior to 20 weeks for stage IB1 carcinoma in five pregnant women. Although three aborted spontaneously, the other two delivered healthy term newborns. Yahata and associates (2008) treated four women at 16 to 23 weeks for stage IA1 adenocarcinoma with KTP laser conization and all delivered at term. And Van Calsteren and co-workers (2008) reported similar success in a woman at 8 weeks with stage IB2 adenocarcinoma. It is clearly too early to conclude that this approach should be used in lieu of more definitive treatment.

Radiotherapy is given for more extensive cancer. If a woman chooses treatment early in pregnancy, external irradiation is given, and then if spontaneous abortion does not ensue, curettage is performed. During the second trimester, spontaneous abortion may be delayed and may necessitate hysterotomy in up to a fourth of cases. About a week following abortion, external beam radiation therapy is begun, followed by intracavitary radium application. After 24 weeks, the risk of delay to allow fetal pulmonary maturation is unknown, but many judge this to be a reasonable approach, especially for early-stage lesions.

Delivery. The mode of delivery is controversial, especially for small, early-stage lesions. The effect on prognosis of vaginal delivery through a cancerous cervix is unknown (American College of Obstetricians and Gynecologists, 2002). Most favor abdominal delivery based on theoretical considerations that tumor may spread when there is cervical tearing. In addition, bulky or friable lesions may bleed significantly with vaginal delivery. Finally, recurrences in the episiotomy scar have been reported (Cliby and colleagues, 1994). In their review, Goldman and Goldberg (2003) described 12 such cases. In most of these, recurrent lesions were manifest within 6 months, but one woman was asymptomatic for 5 years.

With cesarean delivery, a classical incision is preferred. An incision in the lower uterine segment increases the risk of cutting through tumor, which can cause significant blood loss.

Prognosis. The overall prognosis for all stages of cervical cancer during pregnancy is probably similar to that for nonpregnant women (Sood and Sorosky, 1998). The results from several reports suggest no difference in survival when pregnant women are compared with nonpregnant women (Table 57-4).

TABLE 57-4. Five-Year Survival Rates of Pregnant and Nonpregnant Women Treated for Cervical Cancer

	5-Year Survival			
	Pregnant		Nonpregnant	
Investigators	Number	(Percent) Survivors)	Number	(Percent) Survivors)
Sablinska et al (1977)				
Stage I	114	(72)	208	(76)

Stage IA, IB, IIA	21	(85)	18	(85)

[a]NS = not stated.

Endometrial Carcinoma

Because endometrial carcinoma characteristically develops in women past reproductive age, it is seen only rarely with pregnancy. Schammel and colleagues (1998) reviewed 14 cases and described an additional 5. Most are well-differentiated adenocarcinomas, and treatment usually consists primarily of abdominal hysterectomy and bilateral salpingo-oophorectomy. To preserve fertility in 19 nonpregnant women, these investigators described therapy consisting of curettage with or without progestational therapy. At least four viable newborns subsequently were delivered to these women. Gotlieb and associates (2003) reported 13 nonpregnant women treated with progestins for adenocarcinoma. Four of six women with a recurrence were retreated and responded. At least nine neonates have been delivered to these 13 women. Niwa and associates (2005) reported similar outcomes in 12 women, and Signorelli and co-workers (2009) in 21 women. However, Anderson and associates (2001) emphasized that this approach should not be encouraged as standard therapy.

Ovarian Cancer

Malignant ovarian neoplasms are the fourth most common cause of death from cancer in women. They are the leading cause of death from genital tract cancers and eclipse death rates from cervical and uterine cancers combined (American College of Obstetricians and Gynecologists, 2003a). The incidence of ovarian malignancy during pregnancy is not accurately known. From their review, Rahman and co-workers (2002) reported it to average 1 per 20,000 deliveries. A very similar incidence was reported by Smith and associates (2003) from the large California Cancer Registry database. Because most women now undergo sonography during pregnancy, the detection of adnexal masses has increased concomitantly. Certainly, sonography is indicated for women in whom there is a palpable adnexal mass. As discussed in Chapter 40 (p. 904), about 1 of every 1000 pregnant women undergoes surgical exploration for an adnexal mass. Most tumors are either mature cystic teratomas (dermoids) or benign cystadenomas (Boulay and Podczaski, 1998). Perhaps 5 percent of adnexal neoplasms diagnosed during pregnancy are malignant compared with 15 to 20 percent in nonpregnant women (Jacob and Stringer, 1990; Whitecar and associates, 1999). This is likely due to the younger age of pregnant women and due to the disparate number of corpus luteum cysts.

Pregnancy apparently does not alter the prognosis of most ovarian malignancies, but complications such as torsion and rupture may develop. Occasionally, primary or metastatic ovarian tumors cause maternal virilization during pregnancy (Pather and co-workers, 2007; Powell and associates, 2002; Tinkanen and Kuoppala, 2001).

Management

Sonography can be used to help differentiate cystic masses from solid or multiseptated masses. With simple cysts, expectant management may be acceptable, but the latter usually require surgery for diagnosis. Additional information can be obtained using either CT or MR imaging (see Chap. 40, p. 905).

Treatment of ovarian cancer in pregnant women is similar to that for nonpregnant women, but with appropriate modifications depending on gestational age. After frozen section analysis verifies malignancy, surgical staging with careful inspection of all accessible peritoneal and visceral surfaces is performed (Giuntoli and co-workers, 2006; Yazigi and associates, 1988). Malignant tumors apparently confined to one ovary require complete surgical staging, as do tumors of low malignant potential. Procedures include peritoneal washings for cytology, biopsies of the diaphragmatic surface and peritoneum, omentectomy, and biopsies of pelvic and infrarenal para-aortic lymph nodes. However, because of the gravid uterus, some of these components, especially lymphadenectomy, may not be advisable or even technically feasible. If advanced disease is discovered, bilateral adnexectomy and omentectomy would be indicated to remove most tumor burden. Hysterectomy and aggressive surgical debulking procedures such as bowel resection would rarely be indicated in a pregnant patient. Depending on the gestational age, it may be justified to simply remove the tumor and await fetal maturity. In some cases of aggressive or large-volume disease, chemotherapy can be given during pregnancy while awaiting pulmonary maturation. Although maternal CA125 serum levels may be used to monitor disease response during chemotherapy, these values may be too variable during pregnancy to provide an accurate assessment of clinical response (Aslam and associates, 2000; Spitzer and colleagues, 1998).

Prognosis

In most reports, the majority of ovarian cancers found during pregnancy are common epithelial types (Jolles, 1989). Many of the remainder are germ cell tumors, and in the report from Iran by Behtash and colleagues (2008), almost half were of this type. Any type is possible, and endodermal sinus tumors and Burkitt lymphoma of the ovary have been described (Magloire and colleagues, 2006; Motegi and co-workers, 2007). There have been at least 80 or 90 cases of invasive epithelial cell tumors reported coexistent with pregnancy (Dgani and colleagues, 1989; Rahman and associates, 2002). Because of the relatively young age of the pregnant population, tumors with low malignant potential and stage IA disease are seen more often in pregnant women than in nonpregnant women.

Vulvar Cancer

Invasive squamous cell carcinoma of the vulva is primarily a disease of postmenopausal women and thus is only rarely associated with pregnancy. Even so, any suspicious vulvar lesion detected during pregnancy should be biopsied. In their review, Heller and associates (2000) found 23 cases and described a 28-year-old woman with a 4-cm vulvar lesion noted near term. They concluded that radical surgery for stage I disease was feasible during pregnancy, even in the last trimester. Anderson and colleagues (2001) advised that definitive therapy for vulvar cancer can often be delayed because of its slow progression. This is not always the case, however, as Ogunleye and associates (2004) reported recurrence of vulvar carcinoma 11 weeks after treatment during pregnancy. Treatment is individualized according

to the clinical stage and depth of invasion. Vaginal delivery is not contraindicated if the vulvar and inguinal incisions are well healed.

In young women, *vulvar intraepithelial neoplasia* is seen more often than invasive disease and is commonly associated with HPV infection. It may progress to invasive disease, the rate of which seems to have risen in younger women (Messing and Gallup, 1995).

Kuller and colleagues (1990) reviewed five cases of *vulvar sarcoma* first recognized during pregnancy. In four of these, cure was obtained by a variety of therapies. Matsuo and co-workers (2009) evaluated eight cases that were identified during pregnancy or the puerperium. Most present as painless enlarging vulvar masses. Alexander and associates (2004) described a woman with *vulvar melanoma* with placental metastases.

Uterine Leiomyomas

Benign uterine leiomyomas are common in older pregnant women, especially in black women. They are seldom malignant and are considered in detail in Chapter 40 (p. 901).

GASTROINTESTINAL TRACT CANCER

Colorectal Carcinoma

Cancers of the colon and rectum are the second most frequent malignancies in women of all age groups in the United States. Despite that, colorectal tumors seldom complicate pregnancy because they are uncommon before age 40. Smith and colleagues (2003) reported an approximate incidence of 1 per 150,000 deliveries in the California Cancer Registry. Accordingly, fewer than 250 cases of colon cancer have been reported in pregnant women (Walsh and Fazio, 1998). The majority—80 percent—of colorectal carcinomas in pregnant women arise from the rectum.

The most common symptoms of colorectal cancer are abdominal pain, distension, nausea and vomiting, constipation, and rectal bleeding. The diagnosis may be delayed because these symptoms are common in pregnancy. Certainly, if symptoms suggestive of colon disease persist, digital rectal examination, tests for occult blood, and flexible sigmoidoscopy or colonoscopy should be done. Tumors above the peritoneal reflection are uncommon in pregnancy, and Chan and associates (1999a) described only 41 cases in their review. Van Voorhis and Cruikshank (1989) reported two women with colon cancer who had persistent microcytic, hypochromic anemia from occult bleeding.

Treatment of colorectal cancer in pregnant women follows the same general guidelines as for nonpregnant women. When there is no evidence of metastatic disease, surgery is performed. Unfortunately, pregnant women usually present with advanced disease (Walsh and Fazio, 1998). During the first half of the pregnancy, hysterectomy is not necessary to perform colon or rectal resection, and thus therapeutic abortion is not mandated. During later pregnancy, delaying therapy to allow fetal maturation can be considered. Vaginal delivery is usually permitted if obstetrical conditions are favorable, but lower rectal lesions may cause dystocia. Hemorrhage, obstruction, or perforation may force surgical intervention (Minter and colleagues, 2005).

There is no evidence that pregnancy influences the usual course of colorectal cancer (Dahling and associates, 2009). Thus, prognosis is similar to that for identical stages in nonpregnant patients. Carcinoembryonic antigen (CEA) is a useful tumor marker for colon cancer, and although it may be elevated during normal pregnancy, baseline values may be useful (Minter and colleagues, 2005).

Other Gastrointestinal Neoplasms

Gastric cancer is rarely associated with pregnancy, and most reported cases are from Japan. Hirabayashi and associates (1987) reviewed outcomes in 60 pregnant women with this malignancy seen during a 70-year period from 1916 to 1985. A delay in diagnosis during pregnancy is common, and the prognosis is consistently poor (Lee and co-workers, 2009). Davis and Chen (1991) and Chan and colleagues (1999b) each described a woman with gastric cancer who attributed her continued epigastric pain during pregnancy to preexisting peptic ulcer disease. Thus, persistent unexplained upper gastrointestinal symptoms should be evaluated by endoscopy.

Stewart and colleagues (1997) reviewed their experiences with seven pregnancies in five women with *Zollinger–Ellison syndrome*. With this, tumors typically found in the duodenum or pancreas secrete excess gastrin. This leads to excess stomach acid production and gastric ulceration. These authors advise surgical resection before pregnancy, but in women with metastatic disease or in those with previously undiagnosed tumors, antacid and antisecretory treatment during pregnancy usually suffices. Radich and associates (2006) reported a 24-week pregnancy complicated by adenocarcinoma of the small bowel.

At least 21 cases of *carcinoid tumors* complicating pregnancy have been reported. In his review, Durkin (1983) found that most cases were of gastrointestinal origin, and some were incidentally diagnosed at cesarean delivery. *Pancreatic cancer* is rare during pregnancy (Kakoza and co-workers, 2009; Marinoni and associates, 2006). *Primary hepatocellular carcinoma* during pregnancy also is uncommon (Gisi and Floyd, 1999; Hsieh and associates, 1996). Bladerston and co-workers (1998) described a 23-year-old woman at 26 weeks who had a massive intrahepatic cholangiocarcinoma masquerading as HELLP syndrome—hemolysis, elevated liver enzymes, and low platelet count. She died 3 weeks postpartum. Hsu and colleagues (2001) reported spontaneous rupture of hepatocellular carcinoma at 25 weeks that was treated by packing, and pregnancy continued until term.

Gastrointestinal cancers during pregnancy may be discovered as a result of metastases to the ovaries—*Krukenberg tumors.* Obviously, the prognosis is poor in these women (Glišić and coworkers, 2006).

RENAL NEOPLASMS

Walker and Knight (1986) reviewed 71 cases of primary renal neoplasms associated with pregnancy—half were *renal cell carcinoma.* Almost 90 percent of these women had a palpable abdominal mass as the presenting finding. In half, pain was the presenting symptom, and hematuria was also found in half. Only a fourth of these women had the classical triad of hematuria,

pain, and palpable mass. Diagnosis of these and other intra-abdominal or retroperitoneal tumors has been improved by CT and MR imaging studies. Smith and co-workers (1994) added nine new cases since 1986 in their updated review. They suggest that earlier diagnosis is common now because of sonography. Fazeli-Matin and co-workers (1998) described partial nephrectomy in a woman with renal carcinoma at 14 weeks, and Sainsbury and colleagues (2004) reported laparoscopic radical nephrectomy for carcinoma at 11 weeks followed by delivery at term. Two recent studies have shown a response to the kinase inhibitors *sunitinib* and *sorafenib* (Escudier and colleagues, 2007; Motzer and co-workers, 2007).

We have encountered only a small number of pregnant women with renal carcinoma during the past 35 years at Parkland Hospital. Either they presented because of painless hematuria, or the tumor was found by abdominal palpation done routinely in conjunction with cesarean delivery. Currently, because of almost universal use of regional analgesia for cesarean delivery, thorough intra-abdominal inspection is seldom routinely performed.

OTHER TUMORS

Thyroid cancers are the most common endocrine malignancies. Morris (1998) has estimated that approximately 10 percent developing during the reproductive years are diagnosed during pregnancy or within the first year after birth. Most thyroid cancers are well-differentiated and follow an indolent course. Tewari and associates (1998) described a woman with Graves thyrotoxicosis and thyroid storm who was subsequently found to also have papillary adenocarcinoma. Rossing and colleagues (2000) have presented intriguing findings suggesting that thyroid stimulation during pregnancy and lactation may result in a transient increased growth of papillary thyroid cancer. Diagnosis is usually by fine-needle aspiration. Treatment consists primarily of surgery performed during the second trimester or after delivery (Nam and associates, 2005).

Soft-tissue and *bone tumors*, although rare in pregnancy, can usually be successfully managed with surgery during pregnancy (Maxwell and associates, 2004). Cheung and co-workers (2009) detailed the difficult management of advanced tongue cancer diagnosed at 25 weeks' gestation.

Tumors of the central nervous system complicated about 1 in 67,000 deliveries in the California Cancer Registry (Smith and co-workers, 2003). Isla and colleagues (1997) described seven cases of primary brain tumors in more than 126,000 deliveries from Hospital La Paz in Madrid. According to Finfer (1991), the types of tumors are the same as for same-aged nonpregnant women, and about a third each are gliomas or meningiomas. Tewari and co-workers (2000) described eight pregnant women with a malignant brain tumor and another two with postpartum gestational choriocarcinoma metastatic to the brain. Maternal outcomes were horrific—five women died, and two survivors had significant neurological defects.

CHAPTER 58

Infectious Diseases

MATERNAL AND FETAL IMMUNOLOGY 1210
VIRAL INFECTIONS 1211
BACTERIAL INFECTIONS 1220
PROTOZOAL INFECTIONS 1226
MYCOTIC INFECTIONS 1229
EMERGING INFECTIONS 1229
TRAVEL PRECAUTIONS DURING PREGNANCY 1229
BIOTERRORISM 1230

Infections have historically been a major cause of maternal and fetal morbidity and mortality worldwide, and they remain so in the 21st century. Factors such as maternal serological status, timing of infection during pregnancy, mode of acquisition, and immunological status influence disease outcome.

MATERNAL AND FETAL IMMUNOLOGY

Pregnancy-Induced Immunological Changes

Even after intensive study, many of the maternal immunological adaptations to pregnancy are not well elucidated (see Chap. 5, p. 116). Some of the abnormal aspects of human immunity are considered in Chapter 54 (p. 1145). And finally, factors dealing with the maternal-fetal interface that allow immunological tolerance of the fetus as a graft are discussed in Chapter 3 (p. 58). Suffice it to say that these myriad changes also affect to a certain degree maternal response to infections. An understanding of fetal and newborn immunology is also imperative as the fetus is susceptible to many of these infections.

Fetal and Newborn Immunology

The active immunological capacity of the fetus and neonate is compromised compared with that of older children and adults. According to Stirrat (1991), fetal cell-mediated and humoral immunity begin to develop by 9 to 15 weeks. The primary fetal response to infection is immunoglobulin M (IgM). Passive immunity is provided by IgG transferred across the placenta. By 16 weeks, this transfer begins to increase rapidly, and by 26 weeks, fetal concentrations are equivalent to those of the mother. After birth, breast feeding is protective against some infections, although this protection begins to decline at 2 months of age (World Health Organization Collaborative Study Team, 2000).

Vertical transmission of infection refers to passage from the mother to her fetus of an infectious agent through the placenta, during labor or delivery, or by breast feeding. Thus, preterm rupture of membranes, prolonged labor, and obstetrical manipulations may increase the risk of neonatal infection. Those occurring less than 72 hours after delivery are usually caused by bacteria acquired in utero or during delivery, whereas infections after that time most likely were acquired afterward. **Table 58-1** details specific infections by mode and timing of acquisition.

Neonatal infection, especially in its early stages, may be difficult to diagnose because neonates often fail to express classic clinical signs. If the fetus was infected in utero, there may be depression and acidosis at birth for no apparent reason. The neonate may suck poorly, vomit, or develop abdominal distension. Respiratory insufficiency may develop, which may present similarly to idiopathic respiratory distress syndrome (see Chap. 29, p. 605). The neonate may be lethargic or jittery. The response to sepsis may be hypothermia rather than hyperthermia, and the total leukocyte and neutrophil counts may be depressed.

TABLE 58-1. Specific Causes of Some Fetal and Neonatal Infections

Intrauterine
- Transplacental
  - Viruses: varicella-zoster, Coxsackie, human parvovirus B19, rubella, cytomegalovirus, human immunodeficiency virus

  - Bacteria: staphylococcus, coliforms
  - Viruses: herpes simplex, varicella zoster

Neonatal
- Human transmission: staphylococcus, herpes simplex virus
- Respirators and catheters: staphylococcus, coliforms

Hospital-acquired infections are dangerous for preterm neonates, and individuals who care for them are a major source of infection (Stoll and Hansen, 2003). Ventilatory systems and indwelling venous and arterial umbilical catheters may cause life-threatening infection. Thus, a very-low-birthweight infant who survives the first few days is still at considerable risk of dying from infection acquired in the intensive care nursery.

Ascending infections caused by bacteria—for example, *Escherichia coli*, group B streptococci, and *Ureaplasma urealyticum*—are the most common cause of infectious perinatal mortality from sepsis. In developed countries, 10 to 25 percent of stillbirths may be caused by infectious pathogens (Goldenberg and Thompson, 2003). In high-prevalence areas, syphilis and malaria in nonimmune women are also major causes of stillbirths.

VIRAL INFECTIONS

Varicella-Zoster Virus (VZV)

This double-stranded DNA herpesvirus is acquired predominately during childhood, and 95 percent of adults have serological evidence of immunity (Plourd and Austin, 2005). Primary infection—*varicella* or *chicken pox*—is transmitted by direct contact with an infected individual, although respiratory transmission has been reported. The incubation period is 10 to 21 days, and a nonimmune woman has a 60- to 95-percent risk of becoming infected after exposure. She is then contagious from 1 day prior to the onset of the rash until the lesions are crusted over.

Clinical Manifestations

Varicella infection presents with a 1- to 2-day flulike prodrome, which is followed by pruritic vesicular lesions that crust over in 3 to 7 days. Infection tends to be more severe in adults, and almost half of varicella deaths are within the 5 percent of nonimmune adults (Centers for Disease Control and Prevention, 1999).

Mortality is predominately due to varicella pneumonia, which is thought to be more severe during adulthood and particularly in pregnancy. Harger and associates (2002) reported that 5 percent of infected pregnant women developed pneumonitis. Maternal mortality rates with pneumonia have decreased to 1 to 2 percent (Chandra and colleagues, 1998). Symptoms of pneumonia usually appear 3 to 5 days into the course of illness. It is characterized by fever, tachypnea, dry cough, dyspnea, and pleuritic pain. Nodular infiltrates are similar to other viral pneumonias (see Chapter 46, p. 1003). Although resolution of pneumonitis parallels that of skin lesions, fever and compromised pulmonary function may persist for weeks.

Herpes Zoster. If primary varicella infection is reactivated years later, it causes *herpes zoster* or *shingles* (Gilden and coworkers, 2000). There is no evidence that zoster is more frequent or more severe in pregnant women. And from their review of 366 cases during pregnancy, Enders and associates (1994) found little evidence that zoster causes congenital malformations. Zoster is contagious if blisters are broken, although less so than primary varicella infection.

Diagnosis

Maternal varicella is usually diagnosed clinically. The virus may also be isolated by scraping the vesicle base during primary infection and performing a Tzanck smear, tissue culture, or direct fluorescent antibody testing. Also, available nucleic acid amplification techniques are very sensitive. Congenital varicella may be diagnosed using nucleic acid amplification techniques on amnionic fluid, although a positive result does not correlate well with the development of congenital infection (Mendelson and colleagues, 2006).

Fetal and Neonatal Varicella Infection

In women with chicken pox during the first half of pregnancy, the fetus may develop congenital varicella syndrome. Some features include chorioretinitis, microphthalmia, cerebral cortical atrophy, growth restriction, hydronephrosis, and skin or bone defects (**Fig. 58-1**) (Auriti and associates, 2009). Enders and co-workers (1994) evaluated 1373 pregnant women with varicella infection. When maternal infection developed before 13 weeks, only two of 472 pregnancies—0.4 percent—had neonates with congenital varicella. The highest risk was between 13 and 20 weeks, during which time seven of 351 exposed fetuses—2 percent—had evidence of congenital varicella. After 20 weeks' gestation, they found no clinical evidence of congenital infection. Thus, congenital infections, particularly after 20 weeks, are uncommon. At least nine case reports have reported central nervous system abnormalities and skin lesions in fetuses who developed congenital varicella in weeks 21 to 28 of gestation (Koren, 2005).

FIGURE 58-1 Atrophy of the lower extremity with bony defects and scarring in a fetus infected during the first trimester by varicella. (Reprinted from Paryani SG, Arvin AM: Intrauterine infection with varicella zoster virus after maternal varicella. *N Engl J Med* 314(24):1542–1546, with permission. Peripartum Infection. Perinatal varicella exposure just before or during delivery, and therefore before maternal antibody has been formed, poses a serious threat to newborns. Attack rates range from 25 to 50 percent, and mortality rates approach 25 percent. In some instances, neonates develop disseminated visceral and central nervous system disease, which is commonly fatal. For this reason, varicella-zoster immune globulin should be administered to neonates born to mothers who have clinical evidence of varicella 5 days before and up to 2 days after delivery. Varicella-zoster immune globulin—*VZIG*—production was discontinued in the United States in 2005. The Centers for Disease Control and Prevention (CDC) (2006c) recommends use of an unlicensed Canadian varicella zoster immune globulin—*VariZIG*. The sole authorized distributor for the United States is FFF Enterprises (Temecula, CA, 1-800-843-7477 or www.fffenterprises.com).

Management

Exposure to Virus

Because most adults (95 percent) are VZV seropositive, even exposed pregnant women with a negative history for chicken pox should be tested for VZV serology. At least 70 percent of these will be seropositive, and thus immune. Exposed pregnant women who are susceptible should be given VariZIG within 96 hours of exposure to prevent or attenuate varicella infection.

Infection

Pregnant women diagnosed with primary varicella infection should be isolated from other pregnant women. Because pneumonia often presents with few symptoms, a chest radiograph is considered. Most women require only supportive care, but those who require intravenous fluids and especially those with pneumonia are hospitalized. Intravenous acyclovir therapy is given—500 mg/m^2 or 10 to 15 mg/kg every 8 hours.

Vaccination

An attenuated live-virus vaccine—*Varivax*—was approved in 1995. Two doses, given 4 to 8 weeks apart, are recommended for adolescents and adults with no history of varicella. This results in 97-percent seroconversion (Centers for Disease Control and Prevention, 2007e). Importantly, vaccine-induced immunity diminishes over time, and the breakthrough infection rate is about 5 percent at 10 years (Chaves and co-workers, 2007). **The vaccine is not recommended for pregnant women and should not be given to women who may become pregnant during the month following each vaccine dose.** A registry of 362 vaccine-exposed pregnancies reports no cases of congenital varicella syndrome or other congenital associated malformations (Shields and colleagues, 2001). The attenuated vaccine virus is not secreted in breast milk. Thus, postpartum vaccination should not be delayed because of breast feeding (Bohlke and associates, 2003).

A vaccine for the prevention of herpes zoster—*Zostavax*—was licensed in 2006 but is currently not recommended for individuals younger than 60 years (Centers for Disease Control and Prevention, 2007a).

Influenza

These respiratory infections are caused by members of the family *Orthomyxoviridae*. *Influenza A* and *B* form one genus of these RNA viruses, and both cause epidemic human disease. Influenza A viruses are subclassified further by hemagglutinin (H) and neuraminidase (N) surface antigens. Symptoms include fever, dry cough, and systemic symptoms, and infection can be confirmed with rapid enzyme immunoassay or immunofluorescence assay (Salgado and co-workers, 2002).

Influenza A is more serious and usually develops during winter. Infection usually is not life-threatening in otherwise healthy adults, but pregnant women appear to be more susceptible to serious pulmonary involvement (Cox and associates, 2006; Neuzil and colleagues, 1998). In early 2003, widespread influenza A commonly infected pregnant women. At Parkland Hospital, more than 100 women were hospitalized for infection, and 12 percent had pulmonary infiltrates seen on chest radiograph.

Treatment

There are currently two classes of antiviral medications available. The *adamantanes* include amantadine and rimantadine, which were used for years for treatment and chemoprophylaxis of influenza A. In 2005, influenza A resistance to adamantine was reported to be more than 90 percent in the United States, up from 2 percent in 2001. Currently, the Centers for Disease Control and Prevention (2007b) recommends against adamantane use, but the drugs may again be effective for subsequent mutated strains.

The second class of anti-influenzal drugs are *neuraminidase inhibitors* that are highly effective for the treatment of early

influenza A and B. *Oseltamivir* is taken orally for both treatment and chemoprophylaxis, and *zanamivir* is inhaled for treatment. During the 2007–2008 flu season, sudden and rapid resistance was detected for H1N1 strains of influenza A (Gooskens and colleagues, 2009). In December 2008, a CDC Health Advisory was issued with recommendations for treatment of influenza A with oseltamivir and amantadine or rimantadine. If the predominate strain in the community is known to be H1N1, then an adamantane derivative is given. If the strain is know to be H3N2, then oseltamivir is given instead. Local isolates can be determined by visiting the Web site for the Centers for Disease Control and Prevention.

There is limited experience with all four of these antiviral agents in pregnant women. They are category C drugs used when the potential benefits outweigh the risks. At Parkland Hospital, we recommend starting oseltamivir treatment within 48 hours of symptom onset (75 mg orally twice daily for 5 days). Prophylaxis with oseltamivir 75 mg orally once daily for 10 days is also recommended for significant exposures.

In the spring of 2009, respiratory infections caused by a novel influenza A H1N1 viral strain were identified. The Centers for Disease Control and Prevention (2009) recommends that pregnant women with confirmed or suspected H1N1 infection should be given treatment with oseltamivir for 5 days. If possible, treatment should begin within 48 hours of symptom onset. Finally, pregnant women who are in close contact with an infected or suspected infected person should receive a 10-day course of chemoprophylaxis with zanamivir or oseltamivir.

Fetal Effects

There is no firm evidence that influenza A virus causes congenital malformations (Irving and colleagues, 2000; Saxén and associates, 1990). Conversely, Lynberg and co-workers (1994) reported increased neural-tube defects in neonates born to women with influenza early in pregnancy possibly associated with early hyperthermia. Finally, there is controversial evidence that fetal exposure to influenza A may predispose to schizophrenia in later life (Kunugi and associates, 1995; McGrath and Castle, 1995).

Prevention

Vaccination against influenza throughout the influenza season, but optimally in October or November, is recommended by the Centers for Disease Control and Prevention (2007a) for all women who will be pregnant during the influenza season. This is especially important for those affected by chronic medical disorders such as diabetes, heart disease, asthma, or human immunodeficiency virus (HIV) infection. Inactivated vaccine prevents clinical illness in 70 to 90 percent of healthy adults, and importantly, there is no evidence of teratogenicity (see Chap. 8, p. 207). Moreover, Zaman and associates (2008) found decreased rates of influenza in infants up to 6 months of age whose mothers were vaccinated during pregnancy.

Only 44 percent of obstetricians who were surveyed provided influenza vaccination in pregnancy (Schrag and co-workers, 2003). Many did not offer vaccine because of reimbursement issues or availability of vaccination elsewhere. Although most who are offered vaccine choose to be vaccinated, in 2004 only 14 percent of healthy pregnant women received it (Centers for Disease Control and Prevention, 2007a). A trivalent, cold-adapted, live attenuated-virus vaccine was approved for intranasal use in 2003 but is not recommended for pregnant women.

Mumps

This uncommon adult infection is caused by an RNA paramyxovirus. Because of childhood immunization, up to 90 percent of adults are seropositive (Haas and associates, 2005). The virus primarily infects the salivary glands and hence its name—mumps—is derived from Latin, "to grimace." It also may involve the gonads, meninges, pancreas, and other organs. It is transmitted by direct contact with respiratory secretions, saliva, or through fomites. Treatment is symptomatic, and mumps during pregnancy is no more severe than in nonpregnant adults.

The live attenuated Jeryl-Lynn vaccine strain is part of the MMR vaccine—measles, mumps, and rubella—and is contraindicated in pregnancy (American College of Obstetricians and Gynecologists, 2003). No malformations attributable to MMR vaccination in pregnancy have been reported, but pregnancy should be avoided for 30 days after mumps vaccination (Centers for Disease Control and Prevention, 1998, 2002a). The vaccine may be given to susceptible women postpartum, and breast feeding is not a contraindication.

Fetal Effects

Women who develop mumps in the first trimester may have an increased risk of spontaneous abortion. Infection in pregnancy is not associated with congenital malformations, and fetal infection is rare (Centers for Disease Control and Prevention, 1998; Siegel, 1973).

Rubeola (Measles)

Most adults are immune to measles due to childhood immunization. In a study in pregnant women, 17 percent were found to be seronegative (Haas and co-workers, 2005). The infection is highly contagious, and when measles becomes epidemic, unvaccinated women have an increased risk of pneumonia and severe diarrhea with adverse perinatal outcomes (American Academy of Pediatrics, 2006; Centers for Disease Control and Prevention, 2005). Measles occurs most often in late winter and spring and is characterized by fever, coryza, conjunctivitis, and cough. The characteristic rash—Koplik spots—develops on the face and neck and then spreads to the back, trunk, and extremities. Treatment is supportive.

Passive maternal immunization is given with immune serum globulin—0.25 mL/kg with a maximum dose of 15 mL, administered intramuscularly within 6 days of exposure. Active vaccination is not performed during pregnancy, but susceptible women can be vaccinated routinely postpartum (American College of Obstetricians and Gynecologists, 2003; Centers for Disease Control and Prevention, 1998). Breast feeding is not contraindicated with vaccination (Ohji and associates, 2009).

Fetal Effects

The virus does not appear to be teratogenic (Siegel, 1973). There is an increased frequency of abortion, preterm delivery, and low-birthweight neonates with maternal measles (American Academy of Pediatrics, 2006; Siegel and Fuerst, 1966). If a woman develops measles shortly before birth, there is considerable risk of serious infection developing in the neonate, especially in a preterm neonate.

Rubella (German Measles)

This RNA togavirus typically causes infections of minor importance in the absence of pregnancy. Infection in the first trimester, however, is directly responsible for abortion and severe congenital malformations. Transmission occurs via nasopharyngeal secretions, and the transmission rate is 80 percent to susceptible individuals. The peak incidence is late winter and spring.

Clinical Manifestations

In adults, rubella is usually a mild, febrile illness with a generalized maculopapular rash beginning on the face and spreading to the trunk and extremities. Other symptoms may include arthralgias or arthritis, head and neck lymphadenopathy, and conjunctivitis. The incubation period is 12 to 23 days. Viremia usually precedes clinical signs by about a week, and adults are infectious during viremia and through 5 to 7 days of the rash. Up to a half of maternal infections are subclinical despite viremia that may cause fetal infection with malformations.

Congenital Rubella Syndrome. Rubella is one of the most teratogenic agents known with the sequela of fetal infection being worst during organogenesis (see Chap. 4, p. 80). Miller and colleagues (1982) have shown that 80 percent of pregnant women with rubella infection and a rash during the first 12 weeks have a fetus with congenital infection. At 13 to 14 weeks, this incidence was 54 percent, and by the end of the second trimester, it was 25 percent. According to Reef and colleagues (2000), congenital rubella syndrome includes one or more of the following:

- Eye defects—cataracts and congenital glaucoma
- Heart disease—patent ductus arteriosus and pulmonary artery stenosis
- Sensorineural deafness—the most common single defect
- Central nervous system defects—microcephaly, developmental delay, mental retardation, and meningoencephalitis
- Pigmentary retinopathy
- Neonatal purpura
- Hepatosplenomegaly and jaundice
- Radiolucent bone disease

Neonates born with congenital rubella may shed the virus for many months and thus be a threat to other infants as well as to susceptible adults who come in contact with them.

The *extended rubella syndrome*, with progressive panencephalitis and type 1 diabetes, may not develop clinically until the second or third decade of life. As many as a third of neonates who are asymptomatic at birth may manifest such developmental injury (Webster, 1998).

Diagnosis

Rubella may be isolated from the urine, nasopharynx, and cerebrospinal fluid. But the diagnosis is usually made with serological analysis. Specific IgM antibody can be detected using enzyme-linked immunoassay from 4 to 5 days after onset of clinical disease, but it can persist for up to 8 weeks after appearance of the rash (American College of Obstetricians and Gynecologists, 1992). Importantly, rubella reinfection can give rise to transient low levels of IgM. Best and associates (2002) reviewed low rubella-specific IgM antibody levels in pregnant women without a rash in locales in which rubella seldom occurs. They were able to exclude recent maternal infection by detecting high rubella IgG avidity in most cases. Rubella IgG avidity assays were recently reviewed by Mubareka and associates (2007).

Nonimmune persons demonstrate peak serum IgG antibody titers 1 to 2 weeks after the onset of the rash or 2 to 3 weeks after the onset of viremia. This rapid antibody response may complicate serodiagnosis unless samples are initially collected within a few days after the onset of the rash. If, for example, the first specimen was obtained 10 days after the rash, detection of IgG antibodies would fail to differentiate between very recent disease and preexisting immunity to rubella.

Confirmation of fetal infection is possible in confirmed cases of maternal rubella in the first half of pregnancy. Sonography is not sensitive, nor specific. However, some abnormalities identified by sonography include fetal-growth restriction; ventriculomegaly, intracranial calcification, microcephaly, and microphthalmia; cardiac malformations; meconium peritonitis; and hepatosplenomegaly. Tanemura and associates (1996) found rubella RNA in chorionic villi, amnionic fluid, or fetal blood in 23 percent of 34 suspected cases. Detection of second-trimester fetal rubella infection using fetal blood has been described by Tang and colleagues (2003).

Management and Prevention

There is no specific treatment for rubella. Droplet precautions for 7 days after the onset of the rash are recommended. Primary prevention relies on comprehensive vaccination programs (Coonrod and co-workers, 2008). Although large epidemics of rubella have virtually disappeared in the United States because of immunization, up to 10 percent of women in the United States are susceptible (Haas and associates, 2005). Cluster outbreaks during the 1990s mainly involved foreign-born persons born outside the United States, as congenital rubella is still common in developing nations (Banatvala and Brown, 2004; Reef and co-workers, 2002).

To eradicate rubella and prevent congenital rubella syndrome completely, a comprehensive approach is recommended for immunizing the adult population (Centers for Disease Control and Prevention, 1998). MMR vaccine should be offered to nonpregnant women of childbearing age who do not have evidence of immunity whenever they make contact with the healthcare system.

Vaccination of all susceptible hospital personnel who might be exposed to patients with rubella or who might have contact with pregnant women is important. Rubella vaccination should be avoided 1 month before or during pregnancy because the vaccine contains attenuated live virus (Centers for Disease

Control and Prevention, 2002a). Although there is a small overall theoretical risk of about 1 percent, according to pooled data from the Centers for Disease Control and Prevention, there is no evidence that the vaccine induces malformations.

Despite native or vaccine-induced immunity, subclinical rubella maternal *reinfection* may develop during outbreaks. And although fetal infection can rarely occur, no adverse fetal effects have been described.

Respiratory Viruses

More than 200 antigenically distinct respiratory viruses cause the common cold, pharyngitis, laryngitis, bronchitis, and pneumonia. Rhinovirus, coronavirus, and adenovirus are major causes of the common cold. The RNA-containing rhinovirus and coronavirus usually produce a trivial, self-limited illness characterized by rhinorrhea, sneezing, and congestion. The DNA-containing adenovirus is more likely to produce cough and lower respiratory tract involvement, including pneumonia.

Fetal Effects

Teratogenic effects are controversial. Women with a common cold had a four- to fivefold increased risk of fetal anencephaly in a 393-woman cohort in the Finnish Register of Congenital Malformations (Kurppa and associates, 1991). In another population study, Shaw and co-workers (1998) analyzed California births from 1989 to 1991 and concluded that low attributable risks for neural-tube defects were associated with many illnesses in early pregnancy.

Adenoviral infection is a common cause of childhood myocarditis. Towbin and colleagues (1994) and Forsnes and associates (1998) used polymerase chain reaction (PCR) to identify and link adenovirus to fetal myocarditis and nonimmune hydrops.

Hantaviruses

These RNA viruses are members of the family *Bunyaviridae*. They are associated with a rodent reservoir, and transmission involves inhalation of virus excreted in rodent urine and feces. Prevention focuses on lowering exposure to infected rodents (Centers for Disease Control and Prevention, 2002b). An outbreak in the Western United States occurred in 1993 due to Sin Nombre virus. The resulting Hantavirus pulmonary syndrome was characterized by severe adult respiratory distress syndrome with a case-fatality rate of 45 percent.

Hantaviruses are a heterogenous group of viruses with low and variable rates of transplacental transmission. Howard and co-workers (1999) reported the syndrome to cause maternal death, fetal demise, and preterm birth. They found no evidence of vertical transmission of the Sin Nombre virus. Vertical transmission, however, occurred inconsistently in association with hemorrhagic fever with renal syndrome caused by another Hantavirus species, the Hantaan virus.

Enteroviruses

These viruses are a major subgroup of RNA picornaviruses that include poliovirus, coxsackievirus, and echovirus. They are trophic for intestinal epithelium but can also cause widespread maternal, fetal, and neonatal infections that may include the central nervous system, skin, heart, and lungs. Most maternal infections, however, are subclinical, yet can be fatal to the fetus-neonate (Goldenberg and Thompson, 2003). Hepatitis A is an enterovirus that is discussed in Chapter 50 (p. 1069).

Coxsackievirus

Infections with coxsackievirus group A and B are usually asymptomatic. Symptomatic infections—usually with group B—include aseptic meningitis, polio-like illness, hand foot and mouth disease, rashes, respiratory disease, pleuritis, pericarditis, and myocarditis. No treatment or vaccination is available. Coxsackievirus may be transmitted by maternal secretions to the fetus at delivery in up to half of mothers who seroconverted during pregnancy (Modlin, 1988). Transplacental passage has also been reported (Ornoy and Tenenbaum, 2006).

Congenital malformations may be increased slightly in pregnant women who had serological evidence of coxsackievirus (Brown and Karunas, 1972). Coxsackie viremia can cause fetal hepatitis, skin lesions, myocarditis, and encephalomyelitis, all of which may be fatal. Koro'lkova and associates (1989) have also described cardiac anomalies. Finally, the association between maternal coxsackievirus infection and insulin-dependent diabetes in the offspring has been rarely reported (Dahlquist, 1996; Hyoti, 1995; Viskari, 2002, and all of their associates).

Poliovirus

Most of these highly contagious but rare infections are subclinical or mild. The virus is trophic for the central nervous system, and it can cause paralytic poliomyelitis. Siegel and Goldberg (1955) demonstrated that pregnant women not only were more susceptible to polio but also had a higher death rate. Perinatal transmission has been observed, especially when maternal infection developed in the third trimester (Bates, 1955). Inactivated subcutaneous polio vaccine is recommended for susceptible pregnant women who must travel to endemic areas or are placed in other high-risk situations. Live oral polio vaccine has been used for mass vaccination during pregnancy without harmful fetal effects (Harjulehto and associates, 1989).

Parvovirus

Human parvovirus B19 causes *erythema infectiosum*, or *Fifth disease*. The B19 virus is a small, single-stranded DNA virus that replicates in rapidly proliferating cells such as erythroblast precursors (Young and Brown, 2004). This can lead to anemia, which is its central fetal effect. Only individuals with the erythrocyte membrane P antigen are susceptible. In women with severe hemolytic anemia—for example, sickle-cell disease—parvovirus infection may cause an aplastic crisis.

The main mode of parvovirus transmission is respiratory or hand-to-mouth contact, and the infection is common in spring months. The maternal infection rate is highest in women with school-age children and in day-care workers, but not usually schoolteachers. Viremia develops 4 to 14 days after exposure. By adulthood only 40 percent of women are susceptible. The annual

seroconversion rate is 1 to 2 percent but is greater than 10 percent during epidemic periods (Dembinski and colleagues, 2003).

Clinical Manifestations

In 20 to 30 percent of adults, infection is asymptomatic. Fever, headache, and flulike symptoms may begin in the last few days of the viremic phase. Several days later, a bright red rash with erythroderma affects the face, giving a *slapped cheek* appearance. The rash becomes lacelike and spreads to the trunk and extremities. Adults often have milder rashes and develop symmetrical polyarthralgia that may persist several weeks. There is no evidence that parvovirus infection is altered by pregnancy (Valeur-Jensen and colleagues, 1999). Recovery includes production of IgM antibody 10 to 12 days postinfection. IgM persists for 3 to 6 months. Several days after IgM production, IgG antibody is detectable and persists for life with natural immunity.

Fetal Infection

There is vertical transmission to the fetus in about a third of maternal parvovirus infections (de Jong and associates, 2006). Fetal infection has been associated with abortion, nonimmune hydrops, and stillbirth (Goldenberg and Thompson, 2003; McClure and Goldenberg, 2009). In a review of 1089 cases of maternal B19 infection from nine studies, Crane (2002) reported an overall fetal loss rate of 10 percent. It was 15 percent for infection before 20 weeks but only 2.3 percent after 20 weeks. Its role in later unexplained stillbirths is unclear because most data are from retrospective cohorts with incomplete maternal and fetal histological evaluations (Norbeck, 2002; Skjöldebrand-Sparre, 2000; Tolfvenstam, 2001, and all their colleagues). Currently, there are no data to support evaluating asymptomatic mothers and stillborn fetuses for parvovirus infection.

Parvovirus is the most common infectious cause of nonimmune hydrops in autopsied fetuses (Rogers, 1999). That said, this complication develops only in about 1 percent of infected women and usually is caused by infection in the first half of gestation (Crane, 2002; Enders and co-workers, 2004).

Yaegashi (2000) has extensively investigated the development and pathophysiology of parvovirus B19 fetal hydrops. At least 85 percent of cases of fetal infection developed within 10 weeks of maternal infection, and the mean interval was 6 to 7 weeks. More than 80 percent of hydrops cases were found in the second trimester, with a mean gestational age of 22 to 23 weeks. The critical period for maternal infection leading to fetal hydrops was estimated to be between 13 and 16 weeks—coincident with the period in which fetal hepatic hemopoiesis is greatest.

Diagnosis

As shown in **Figure 58-2**, the diagnosis of maternal infection is generally made by serological testing for specific IgG and IgM antibodies (Butchko and Jordan, 2004; Enders and co-workers, 2006). Viral DNA may be detectable by PCR in maternal serum during the prodrome but not after the rash develops. Fetal infection can be identified by detecting viral DNA in amnionic fluid or fetal serum parvoviral IgM with cordocentesis (Schild and colleagues, 1999). Fetal and maternal viral loads do not predict fetal morbidity and mortality (de Haan and associates, 2007).

Management

The majority of parvovirus-associated hydrops develops in the first 10 weeks after infection (Enders and colleagues, 2004). Thus, serial sonography every 2 weeks should be performed in women with recent infection (see Fig. 58-2). Middle cerebral artery (MCA) Doppler evaluation can also be used to predict fetal anemia (see Chap. 16, p. 364). Delle Chiaie (2001) and Cosmi (2002) and their colleagues have shown that elevated peak systolic velocity values in the fetal middle cerebral artery accurately predict fetal anemia (**Fig. 58-3**). Fetal blood sampling is warranted with hydrops to assess the degree of fetal anemia. Fetal myocarditis may induce hydrops with less severe anemia.

Depending on gestational age, fetal transfusion for hydrops may improve outcome in some cases (Enders and co-workers, 2004; Schild and colleagues, 1999; von Kaisenberg and Jonat, 2001). Mortality rates as high as 30 percent have been reported in hydropic fetuses without transfusions. With transfusion, 94 percent of hydrops cases resolve within 6 to 12 weeks, and the overall mortality rate is less than 10 percent. Most fetuses require only one transfusion because hemopoiesis resumes as infection resolves. The technique for fetal transfusion is described in Chapter 13 (p. 300).

Prognosis

Long-term neurodevelopmental outcomes after fetal transfusion for B19 infection-induced anemia are conflicting. Nagel and colleagues (2007) reviewed 25 transfusions in 24 hydropic fetuses. There was abnormal neurodevelopment in 5 of 16 survivors—32 percent—at 6 months to 8 years. Outcomes were not related to severity of fetal anemia or acidemia, and these investigators hypothesized that the infection itself induced cerebral damage. Conversely, Dembinski and colleagues (2003) followed 20 children for a mean of 52 months after transfusion. They found no significant neurodevelopmental delay despite severe fetal anemia. At this time, more data are required to definitively assess long-term outcomes.

Prevention

There is currently no approved vaccine for human parvovirus B19, and there is no evidence that antiviral treatment prevents maternal or fetal infection (Broliden and colleagues, 2006). Decisions to avoid higher-risk work settings are complex and require assessment of exposure risks. Pregnant women should be counseled that risks for infection are about 5 percent for casual, infrequent contact; 20 percent for intense, prolonged work exposure such as for teachers; and 50 percent for close, frequent interaction such as in the home. Workers at day-care centers and schools need not avoid infected children because infectivity is greatest before clinical illness. Finally, infected children do not require isolation.

Cytomegalovirus

This ubiquitous DNA herpesvirus eventually infects most humans. Cytomegalovirus (CMV) is the most common perinatal

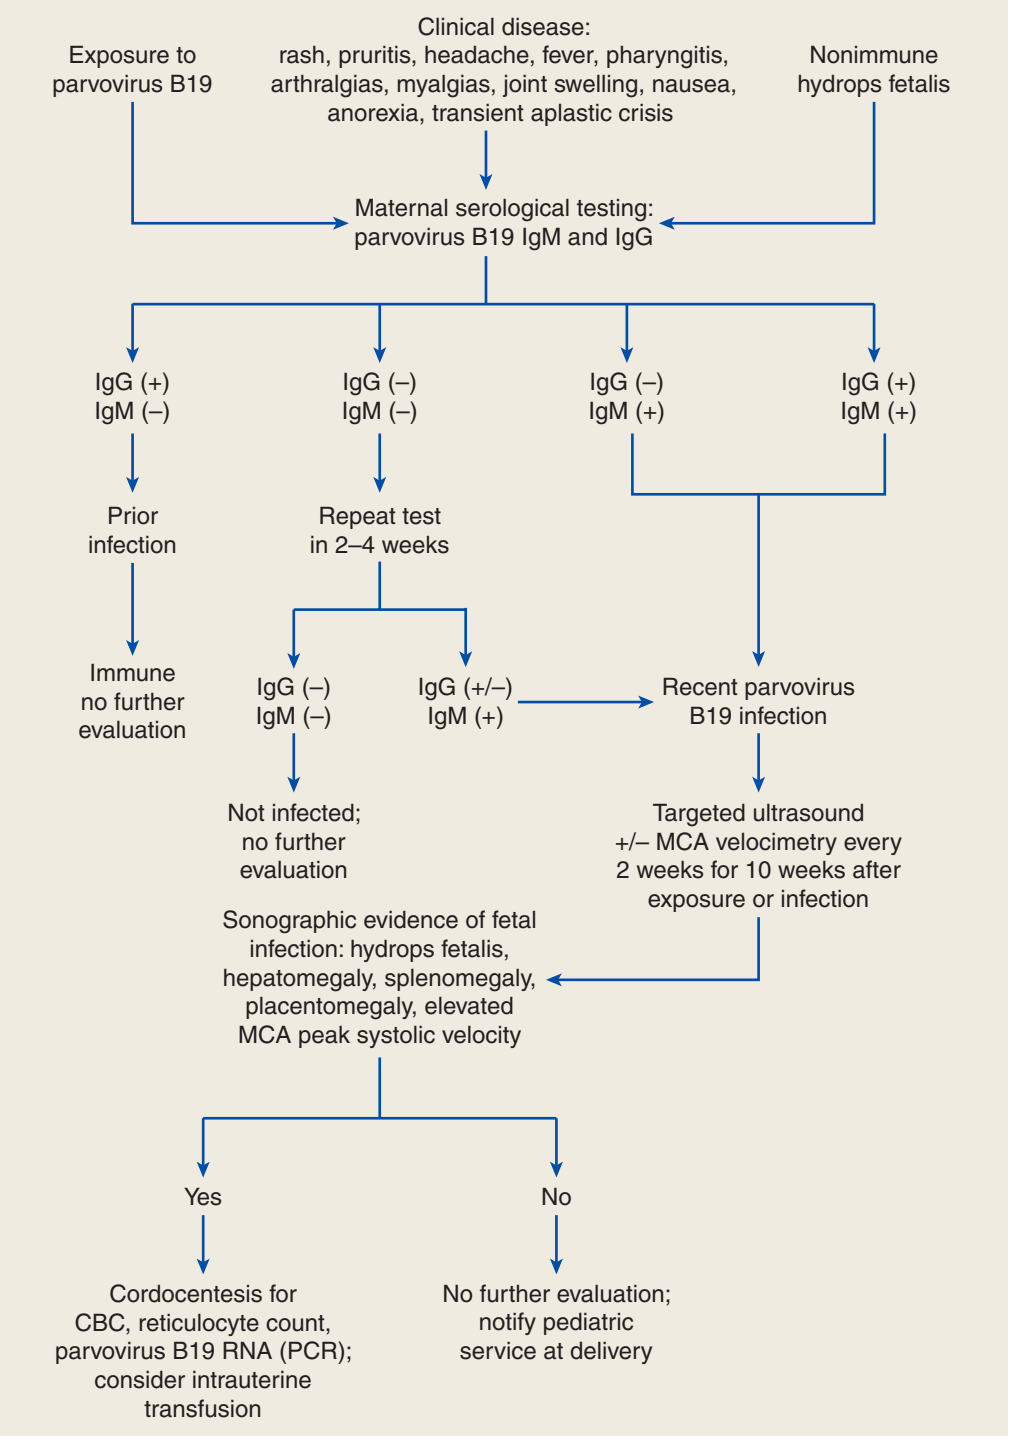

FIGURE 58-2 Algorithm for evaluation and management of human parvovirus B19 infection in pregnancy. CBC = complete blood count; IgG = immunoglobulin G; IgM = immunoglobulin M; MCA = middle cerebral artery; PCR = polymerase chain reaction; RNA = ribonucleic acid.

infection in the developed world, and evidence of fetal infection is found in from 0.2 to 2 percent of all neonates (Revello and Gerna, 2004). CMV is present in body fluids, and person-to-person transmission usually occurs by contact with infected nasopharyngeal secretions, urine, saliva, semen, cervical secretions, or blood. There may be intrauterine or intrapartum infection or neonatal infection from breast feeding. Day-care centers are a common source of infection, and by 2 to 3 years of age, children usually acquire infection from one another and may transmit it to their parents (Demmler, 1991; Pass, 1991). Fortunately, Revello and co-workers (2008) have shown that CMV DNA in maternal peripheral blood is not a risk factor for iatrogenic fetal transmission during amniocentesis.

Up to 85 percent of women from lower socioeconomic backgrounds are seropositive by the time of pregnancy, whereas only half of women in higher income groups are immune.

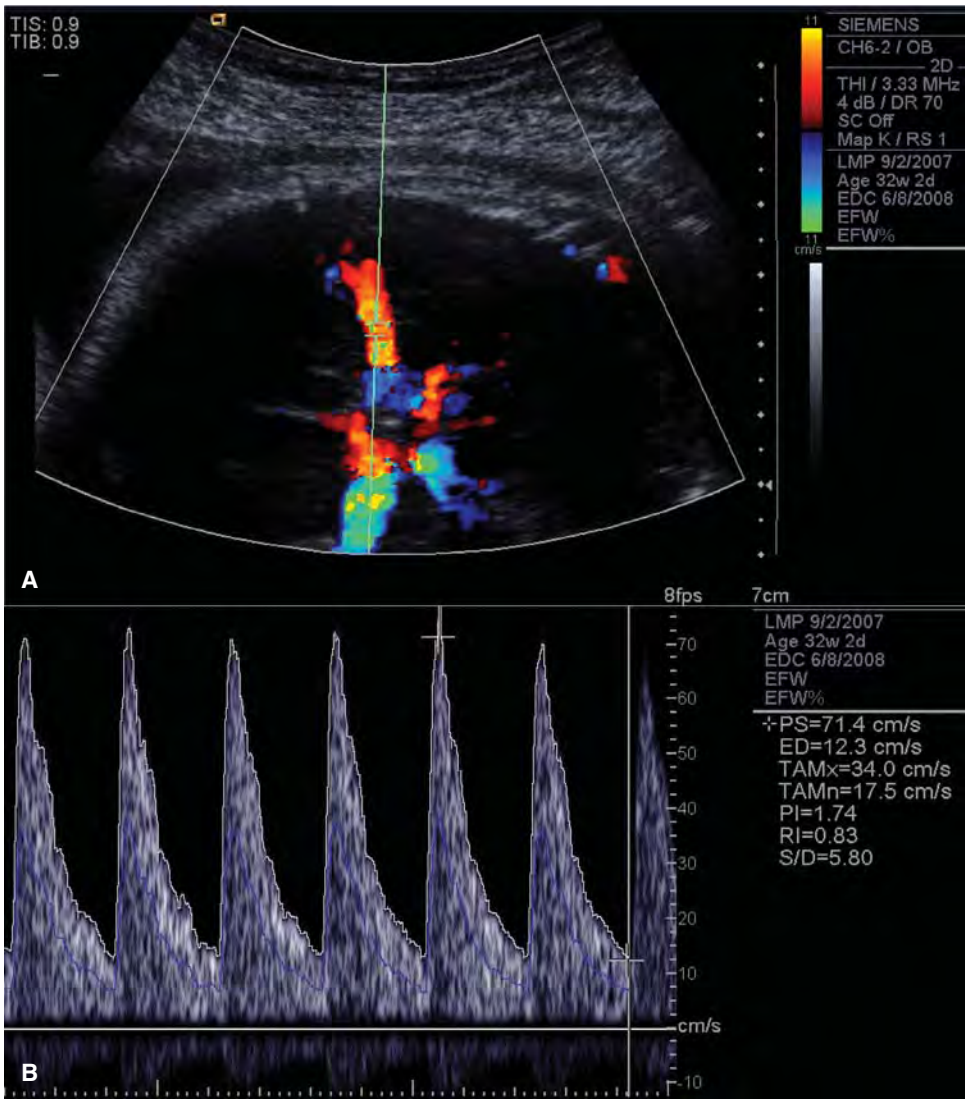

FIGURE 58-3 Middle cerebral artery Doppler images showing elevated peak systolic velocity.

However, similar to other herpesviral infections, following primary infection, CMV becomes latent, and there is periodic reactivation with viral shedding. This occurs despite serum IgG antibody, which does not prevent recurrence-reactivation, exogenous reinfection, and does not prevent congenital infection. The risk of infection manifest by seroconversion among antibody-negative women during pregnancy is 1 to 4 percent.

Clinical Manifestations

Pregnancy does not increase the risk or severity of maternal CMV infection. Most infections are asymptomatic, but about 15 percent of infected adults have a mononucleosis-like syndrome characterized by fever, pharyngitis, lymphadenopathy, and polyarthritis. Immunocompromised women may develop myocarditis, pneumonitis, hepatitis, retinitis, gastroenteritis, or meningoencephalitis. Nigro and associates (2003) reported that most women in a cohort with primary infection had elevated serum aminotransferases or lymphocytosis. Reactivation disease usually is asymptomatic, although viral shedding is common.

Primary maternal CMV infection is transmitted to the fetus in about 40 percent of cases and can cause severe morbidity (Fowler and co-workers, 1992; Liesnard and associates, 2000). In contrast, recurrent maternal infection infects the fetus in only 0.15 to 1 percent of cases. Transplacental fetal infection is more likely during the first half of pregnancy. Naturally acquired immunity during pregnancy results in a 70-percent reduction of risk of congenital CMV infection in future pregnancies (Fowler and colleagues, 2003). And because maternal immunity does not prevent recurrences, maternal antibodies do not prevent fetal infection. Some seropositive women can also be reinfected with a different strain of virus that can cause fetal infection with symptomatic congenital disease (Boppana and associates, 2001).

Congenital Infection

Symptomatic—apparent—congenital CMV infection is a syndrome that may include growth restriction, microcephaly, intracranial calcifications, chorioretinitis, mental and motor re-tardation, sensorineural deficits, hepatosplenomegaly, jaundice, hemolytic anemia, and thrombocytopenic purpura. The pathogenesis of these outcomes have recently been reviewed by Cheeran and co-workers (2009). Of the estimated 40,000 infected neonates born each year, only 5 to 6 percent demonstrate this syndrome (Fowler and associates, 1992). Thus, most infected infants are asymptomatic at birth, but some develop late-onset sequelae such as hearing loss, neurological deficits, chorioretinitis, psychomotor retardation, and learning disabilities.

Diagnosis

Routine prenatal CMV serological screening is currently not recommended (American College of Obstetricians and Gynecologists, 2000; Collinet and associates, 2004; Peckham and coworkers, 2001). *Primary infection* is diagnosed by seroconversion of CMV-specific IgG in paired acute and convalescent sera assayed simultaneously. It is preferable to document maternal CMV IgM antibody. Unfortunately, specific IgM antibody may be present with primary infection, recurrent infection, or reactivation infection, thus limiting its utility for serological diagnosis (Duff, 2007). CMV IgM is also found in only 75 to 90 percent of women with

acute infection (Stagno, 1985). As shown in Figure 58-4, when CMV-specific IgG and IgM are detected, complimentary tests are used to date the infection (Grangeot-Keros and Cointe, 2001). The measurement of specific IgG avidity is valuable in confirming primary CMV infection (Lazzarotto and associates, 2004). The IgG antibody response matures from low-avidity to high-avidity production over several weeks to months (Revello and Gerna, 2004). Finally, viral culture may be useful, though a minimum of 21 days is required before culture is reported as negative.

Imaging Studies. Perinatal infection may be suspected from abnormalities seen with sonography, computed tomography (CT), or magnetic resonance (MR) imaging. Findings include microcephaly, ventriculomegaly, and cerebral calcifications; ascites, hepatomegaly, splenomegaly, and hyperechoic bowel; hydrops; and oligohydramnios (Malinger and colleagues, 2003). Abnormal sonographic findings seen in combination with positive findings in fetal blood or amniotic fluid are predictive of an approximate 75-percent risk of symptomatic congenital infection (Enders and co-workers, 2001).

Amnionic Fluid Studies. CMV nucleic acid amplification testing of amnionic fluid is considered the gold standard for the diagnosis of fetal infection (Nigro and colleagues, 2005; Revello and Gerna, 2004). Amnionic fluid testing may be coupled with sonography. Guerra and colleagues (2007) evaluated 430 fetuses of women with primary infection using targeted sonography and amnionic fluid DNA analysis. Of these, only a third were confirmed to be infected. However, as emphasized by Bodéus (1999) and Antsaklis (2000) and their associates, a negative amnionic fluid culture or PCR assay result does not always exclude fetal infection.

Management and Prevention

The management of the immunocompetent pregnant woman with primary or recurrent CMV is limited to symptomatic treatment. If recent primary CMV infection is confirmed, amnionic fluid analysis should be offered. Counseling regarding fetal outcome depends on the stage of gestation during which primary infection is documented. Even with the high infection rate with

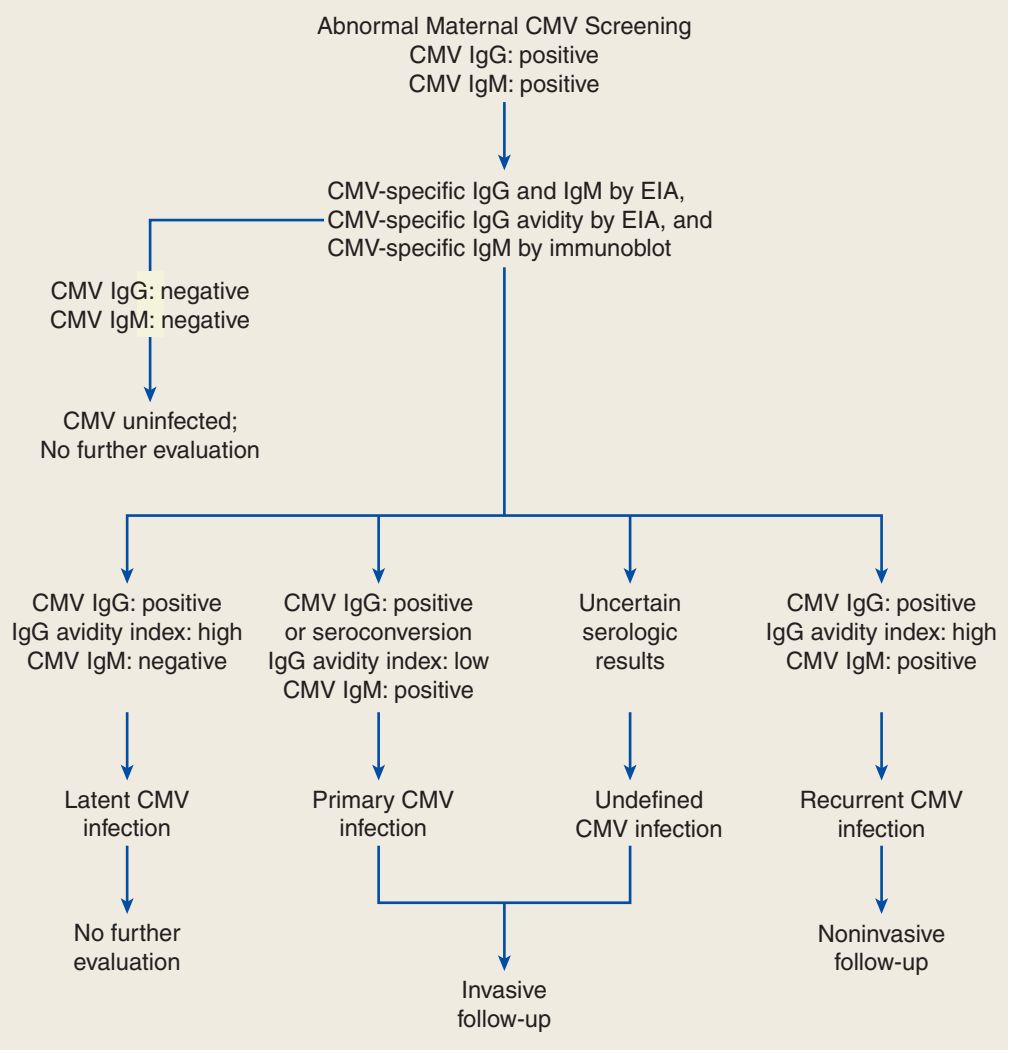

FIGURE 58-4 Algorithm for evaluation of suspected maternal primary cytomegalovirus (CMV) infection in pregnancy. EIA = enzyme immunoassay; IgG = immunoglobulin G; IgM = immunoglobulin M.

primary infection in the first half of pregnancy, most fetuses develop normally. Pregnancy termination may be an option for some.

Kimberlin and co-workers (2003) showed that intravenous ganciclovir administered for 6 weeks to neonates with symptomatic central nervous system disease prevents hearing deterioration at 6 months and possibly later. Conversely, antiviral chemotherapy given antepartum is not effective to prevent in utero CMV transmission. Passive immunization with CMV-specific hyperimmune globulin significantly lowers the risk of congenital CMV infection when given to pregnant women with primary disease (Nigro and co-workers, 2005). Further clinical trials are necessary before this becomes standard of care.

There is no CMV vaccine. Prevention of congenital infection relies on prevention of maternal primary infection, especially in early pregnancy. Basic measures such as good hygiene and hand washing have been promoted, particularly for women with toddlers in day-care settings (Fowler, 2000). Although there may be sexual transmission from infected partners, there are no data on the efficacy of preventive strategies (Nigro and co-workers, 2003).

BACTERIAL INFECTIONS

Group A Streptococcus

More specifically known as *Streptococcus pyogenes*, this bacteria remains an important cause of infection in pregnant women. It is the most frequent bacterial cause of acute pharyngitis and is associated with a number of systemic and cutaneous infections. *S. pyogenes* produces a number of toxins and enzymes, and infections especially with *M3 super antigen strains* are particularly severe (Rogers and colleagues, 2007; Sriskandan and associates, 2007).

Streptococcal pharyngitis, scarlet fever, and erysipelas are seldom life-threatening. Management is similar in pregnant and nonpregnant women, usually treatment with penicillin. Puerperal infections caused by *S. pyogenes* are rarely encountered today (see Chap. 31, p. 661) (O'Brien and colleagues, 2002). The most common postpartum group A streptococcal infections are bacteremia without a septic focus—46 percent; pelvic infection—28 percent; peritonitis—8 percent; and septic abortion—7 percent. Over the past two decades, *S. pyogenes* has acquired a toxic shock-like toxin (TSST) that produces an often fatal syndrome (Brown, 2004; Daif and associates, 2009). The case-fatality rate for postpartum group A infection is 3 to 4 percent (Chuang and associates, 2002). A mortality rate of almost 75 percent was reported by Udagawa and co-workers (1999). In addition, these infections were fatal in two of three pregnant women at Parkland Hospital in 1992 (Nathan and colleagues, 1993). Prompt penicillin treatment, often with surgical debridement, may be lifesaving (Centers for Disease Control and Prevention, 2002c).

Group B Streptococcus (GBS)

Of group B streptococci, *Streptococcus agalactiae* is a major cause of neonatal morbidity and mortality. It colonizes the gastrointestinal and genitourinary tract in 20 to 30 percent of pregnant women, which serves as a source for perinatal transmission (Schrag and associates, 2002, 2003; Wendel and colleagues, 2002). Maisey and co-workers (2007), as well as others, showed that this gram-positive coccus has adhesive pili that confer invasiveness. Throughout pregnancy, GBS is isolated in a transient, intermittent, or chronic fashion. Most likely the organism is always present in these same women, but isolation is not always homologous.

Clinical Infection

The spectrum of maternal and fetal GBS infections range from asymptomatic colonization to septicemia. *S. agalactiae* has been implicated in adverse pregnancy outcomes, including preterm labor, prematurely ruptured membranes, clinical and subclinical chorioamnionitis, and fetal and neonatal infections. GBS can also cause maternal bacteriuria, pyelonephritis, and postpartum metritis. Maternal osteomyelitis and postpartum mastitis have also been described (Barbosa-Cesnik and associates, 2003; Berkowitz and McCaffrey, 1990).

Neonatal sepsis has received the most attention due to its devastating consequences and available effective preventative measures. Infection less than 7 days after birth is defined as *early-onset disease* (Schrag and colleagues, 2000). Many investigators use a threshold of less than 72 hours of life as most compatible with intrapartum acquisition of disease (Stoll and associates, 2002a; Wendel and co-workers, 2002). We and others have also encountered a number of unexpected intrapartum stillbirths from GBS infections. In many neonates, septicemia involves signs of serious illness that usually develop within 6 to 12 hours of birth—these include respiratory distress, apnea, and hypotension. At the outset, therefore, neonatal infection must be differentiated from respiratory distress syndrome caused by insufficient surfactant production of the preterm neonate (see Chap. 29, p. 605). The mortality rate with early-onset disease has declined to about 4 percent, and preterm newborns are affected disparately.

Late-onset disease caused by GBS usually manifests as meningitis 1 week to 3 months after birth. These cases are most often caused by serotype III organisms. The mortality rate, although appreciable, is less for late-onset meningitis than for early-onset sepsis. Unfortunately, it is not uncommon for surviving infants of both early- and late-onset disease to exhibit devastating neurological sequelae.

Neonatal Prophylaxis

As group B neonatal infections evolved beginning in the 1970s before widespread intrapartum chemoprophylaxis, rates of early-onset sepsis ranged from 2 to 3 per 1000 live births. In 2002, the Centers for Disease Control and Prevention, the American College of Obstetricians and Gynecologists, and the American Academy of Pediatrics revised guidelines for perinatal prevention of GBS disease. They recommended universal culture screening for rectovaginal GBS at 35 to 37 weeks followed by intrapartum antibiotic prophylaxis for women identified to be carriers of GBS (see p. 1221). Subsequent to implementation of these guidelines, the incidence of GBS neonatal sepsis has

decreased to 0.33 cases per 1000 live births in 2003 to 2005 (Centers for Disease Control and Prevention, 2007d). It is worrisome, however, that widespread intrapartum antimicrobial prophylaxis has been associated with increased risk for non-streptococcal early-onset sepsis in preterm and especially very-low-birthweight neonates (Eschenbach, 2002; Towers and Briggs, 2002). In one example, marked reduction in group B streptococcal sepsis in preterm neonates was offset by increased *E. coli* sepsis (Stoll and associates, 2002b; Stoll and Hansen, 2003).

Late-onset neonatal GBS sepsis is less well understood. Cited rates vary from 0.5 to 2 cases per 1000 live births and account for about half of GBS disease in newborns (Lin and colleagues, 2003). The incidence of late-onset disease has remained stable despite widespread use of intrapartum antimicrobials (Centers for Disease Control and Prevention, 2009). This suggests that GBS screening and chemoprophylaxis intervention may not affect late-onset disease.

Recommended Prevention Strategies

In the absence of randomized trials, consensus opinions and guidelines for prevention strategies of neonatal GBS infection have been promulgated by the Centers for Disease Control and Prevention (2002d) and endorsed by the American College of Obstetricians and Gynecologists (2002a). These guidelines, shown in **Figure 58-5**, advocate a culture-based screening approach to identify women who should be given intrapartum antimicrobial prophylaxis. Their recommendations were derived from a multistate, retrospective cohort study of live births in 1998 and 1999 from the Active Bacterial Surveillance/Emerging Infections Program Network.

There are further recommendations for management of preterm labor or preterm prematurely ruptured membranes (**Fig. 58-6**). It is emphasized that there are insufficient data to suggest a single management scheme for GBS-positive women with arrested preterm labor or preterm prematurely ruptured

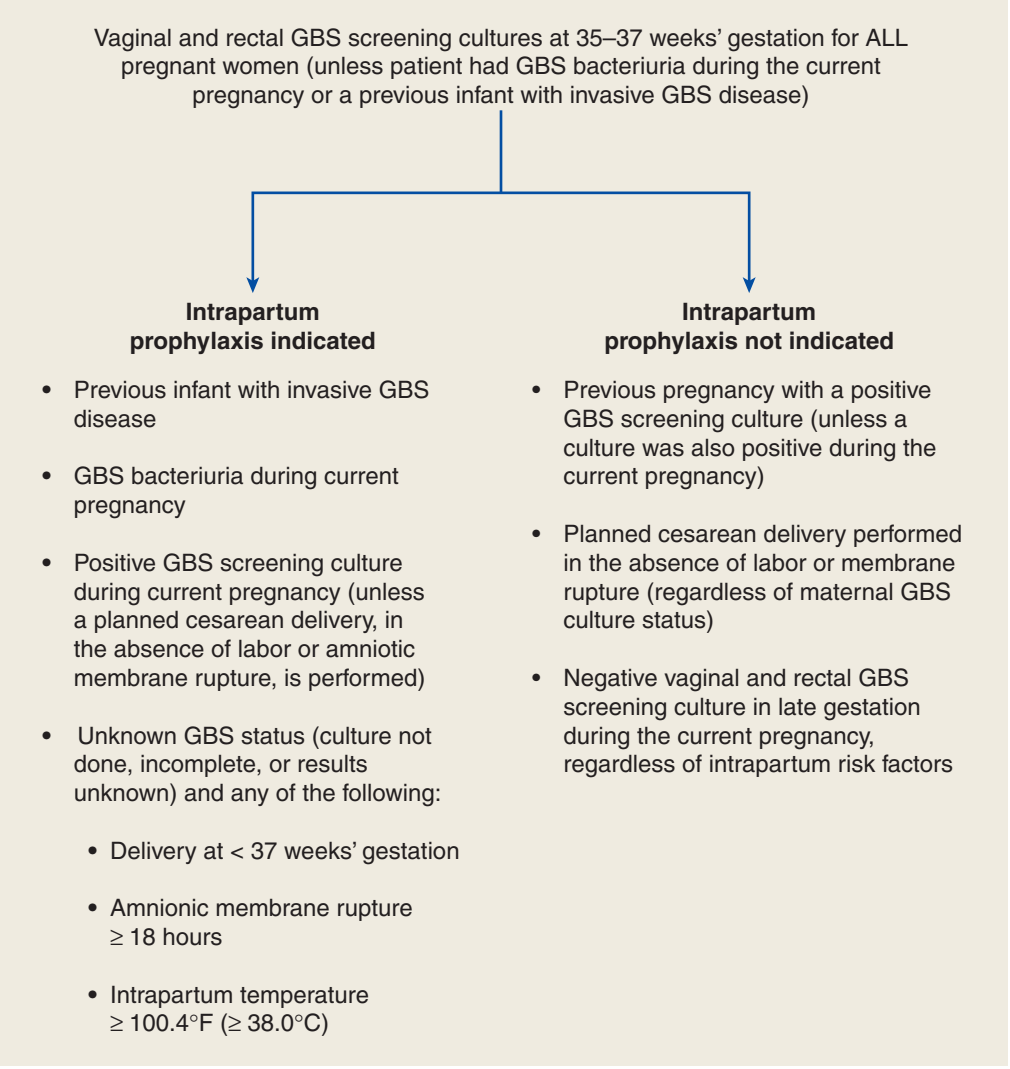

FIGURE 58-5 Indications for intrapartum prophylaxis to prevent perinatal group B streptococcal (GBS) disease under a universal prenatal screening strategy based on combined vaginal and rectal cultures taken at 35 to 37 weeks' gestation. (From Centers for Disease Control and Prevention, 2002d.)

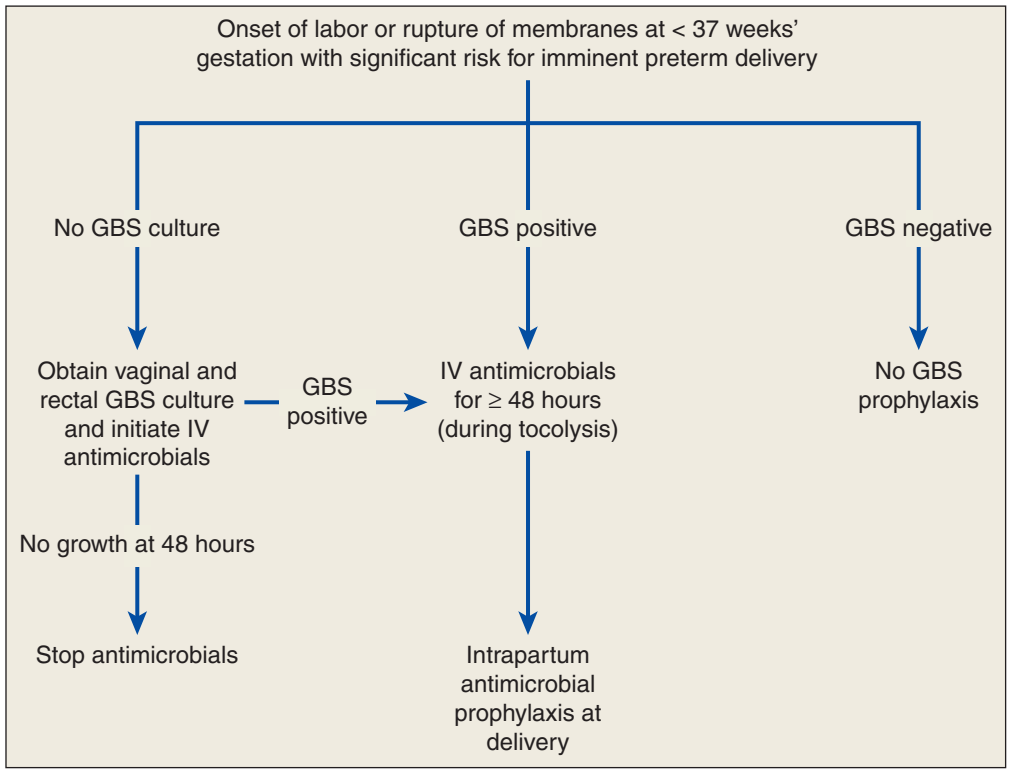

FIGURE 58-6 Sample algorithm for prophylaxis for women with group B streptococcal (GBS) disease and threatened preterm delivery. This algorithm is not an exclusive course of management, and variations that incorporate individual circumstances or institutional preferences may be appropriate. IV = intravenous. (Adapted from Centers for Disease Control and Prevention, 2002d.)

membranes (American College of Obstetricians and Gynecologists, 2002a).

With the culture-based approach, women are screened for GBS colonization at 35 to 37 weeks, and intrapartum antimicrobials are given to women with rectovaginal GBS-positive cultures. Previous siblings with GBS invasive disease and prior identification of GBS bacteriuria are also considered indications for prophylaxis. A risk-based approach is recommended for women in labor and whose GBS culture results are not known (see Fig. 58-4).

The choice of antimicrobials may be important in terms of allergic reactions; selection of resistant GBS strains; and emergence of other pathogens, including antimicrobial-resistant strains, that may cause neonatal sepsis. Treatment regimens are shown in **Table 58-2**. Although penicillin is recommended as the first-line agent, ampicillin is an acceptable alternative (Bloom and co-workers, 1996; Centers for Disease Control and Prevention, 2002c). For women with penicillin allergy, if the risk of anaphylaxis is low, cefazolin is recommended (Mitchell and associates, 2001). If the risk of anaphylaxis is high, selection of another agent is dependent on GBS susceptibility testing. Patients with isolates susceptible to clindamycin or erythromycin may be given either drug. Antimicrobial-resistant strains require vancomycin prophylaxis. This treatment scheme is dependent on laboratory capability to perform susceptibility testing. Awareness of the potential for worsening antibiotic resistance in the setting of more widespread use is mandatory (Chohan and associates, 2006). The duration of intrapartum prophylaxis required for disease prevention is unknown (Illuzzi and co-workers, 2006). For ampicillin, bactericidal levels are achieved in cord blood by 30 minutes of maternal administration (Colombo and co-workers, 2006).

Risk-Based Treatment versus Universal Culture. There remains significant controversy whether GBS surveillance schemes are worthwhile. As discussed above, there are no randomized controlled trials that compare GBS screening—whether culture-based or risk-based—with no screening. There have also been no randomized trials to compare different screening strategies with no GBS screening or to evaluate any significant impact on overall neonatal sepsis. For these reasons, similar organizations in other countries conclude that there is insufficient evidence to recommend GBS screening (Canadian Task Force on Preventive Health Care, 2002; Jakobi and colleagues, 2003; Royal College of Obstetricians and Gynaecologists, 2003).

A number of alternative prevention strategies have been described with limited evidence for their recommendation. These include intramuscular benzathine penicillin G and chlorhexidine vaginal lavage (Bland and associates, 2000; Rouse and co-workers, 2003). In a preliminary study, Haberland and colleagues (2002) described the efficacy of intrapartum rapid PCR screening for GBS. Currently, real-time PCR for rapid GBS testing is still in the development phase (Bergseng and colleagues, 2007; Chan and associates, 2006).

TABLE 58-2. Regimens for Intrapartum Antimicrobial Prophylaxis for Perinatal GBS Disease

Regimen	Treatment
Recommended	Penicillin G, 5 million units IV initial dose, then 2.5 million units IV every 4 hours until delivery
Alternative	Ampicillin, 2 g IV initial dose, then 1 g IV every 4 hours or 2 g every 6 hours until delivery
If penicillin allergic	
Patients **not** at high risk for anaphylaxis	Cefazolin, 2 g IV initial dose, then 1 g IV every 8 hours until delivery
Patients at high risk for anaphylaxis and with GBS susceptible to clindamycin and erythromycin	Clindamycin, 900 mg IV every 8 hours until delivery *or* Erythromycin, 500 mg IV every 6 hours until delivery
Patients at high risk for anaphylaxis and with GBS resistant to clindamycin or erythromycin or susceptibility unknown	Vancomycin, 1 g IV every 12 hours until delivery

GBS = group B streptococcus.
Adapted from the Centers for Disease Control and Prevention (2002d).

At Parkland Hospital in 1995—and prior to consensus guidelines—we adopted the risk-based approach for intrapartum treatment of women at high risk for GBS infection. In addition, all term neonates who were not given intrapartum prophylaxis were treated in the delivery room with aqueous penicillin G, 50 to 60,000 units intramuscularly. Early-onset GBS infection and sepsis, as well as non-GBS sepsis, all decreased during the study to 0.4 per 1000 live births (Wendel and associates, 2002).

Vaccination

Some protection against serious neonatal infection is conferred by maternal antibodies. Indeed, Lin and colleagues (2001) confirmed that the susceptibility to invasive GBS disease correlates with deficiency in maternal type-specific antibody levels. Baker and co-workers (1988, 1999, 2000) reported that maternal immunization to type III antigen produces antibody in approximately 60 percent of women. Monovalent tetanus toxoid conjugate vaccines are immunogenic for common GBS disease-associated serotypes. Johri and associates (2006) and Larsen and Sever (2008) have reviewed the progress toward vaccine development.

Methicillin-Resistant *Staphylococcus aureus* (MRSA)

Staphylococcal infections are an important cause of skin and soft tissue infections. The recent National Health and Nutrition Examination Survey (NHANES) reported that a third of adults have nasal colonization with *Staphylococcus aureus* (Kuehnert and colleagues, 2006). Seventeen percent of pregnant women have vaginal colonization (Chen and associates, 2006). Unfortunately, multidrug-resistant strains of *S. aureus* are spreading, particularly *methicillin-resistant S. aureus (MRSA)*. These strains also are resistant to penicillinase-resistant penicillins and cephalosporins. There are two varieties. *Community-acquired MRSA* strains—referred to as *CA-MRSA*—colonize healthy persons without historical risks for MRSA acquisition. Nosocomial MRSA infections are termed *healthcare-associated MRSA*.

MRSA has become the most common identifiable cause of skin and soft tissue infections in general emergency rooms (Moran and colleagues, 2006). There is also an increased frequency of CA-MRSA documented in pregnant women over the past few years (Chen, 2006; Hidron, 2005; Laibl, 2005, and all their colleagues). Beigi and co-workers (2009) reported that approximately 14,300 pregnant or postpartum women experience an invasive MRSA infection annually. Infections tend to involve skin and soft tissues. Abscesses or cellulitis form especially in HIV-infected women, injection drug users, and diabetics. Skin lesions such as that shown in **Figure 58-7** appear to resemble

FIGURE 58-7 Typical presentation of a skin lesion caused by infection with community-acquired methicillin-resistant *S. aureus*—CA-MRSA. Patients often present with what they describe as an infected spider bite.

infected insect bites. At Parkland Hospital, we have isolated CA-MRSA from postoperative wound infections and puerperal mastitis (Laibl and co-workers, 2005).

Management

Most uncomplicated, noninvasive skin and soft tissue infections should be managed by abscess drainage. Pus is cultured and staphylococcal susceptibility testing is performed. CA-MRSA strains are usually not resistant to antistaphylococcal antimicrobials other than methicillin. Erythromycin and clindamycin resistance is variable, but most strains are sensitive to flu-oroquinolones, trimethoprim-sulfamethoxazole, gentamicin, rifampin, or vancomycin (Eady and Cove, 2003; Naimi and colleagues, 2003). Parenteral vancomycin therapy should be reserved for serious CA-MRSA infections such as wound infections and mastitis.

Pregnancy and CA-MRSA

Currently, there are no evidence-based guidelines for management. For example, it is not known if these women or their immediately families require decolonization. Careful surveillance is necessary to assure resolution of infection. Recurrences are common. The frequency and significance of intrapartum transmission is unclear, and there are no recommendations regarding prophylaxis to prevent neonatal or surgical wound infections. Outbreaks of skin infections in healthy newborns have been reported by the Centers for Disease Control and Prevention (2006b). In women with culture-proven infection during pregnancy, we routinely add single-dose vancomycin to β-lactam perioperative prophylaxis for cesarean deliveries and fourth-degree perineal injury repair. Breast feeding in these women is not prohibited, but good hygiene and attention to minor skin breaks is encouraged.

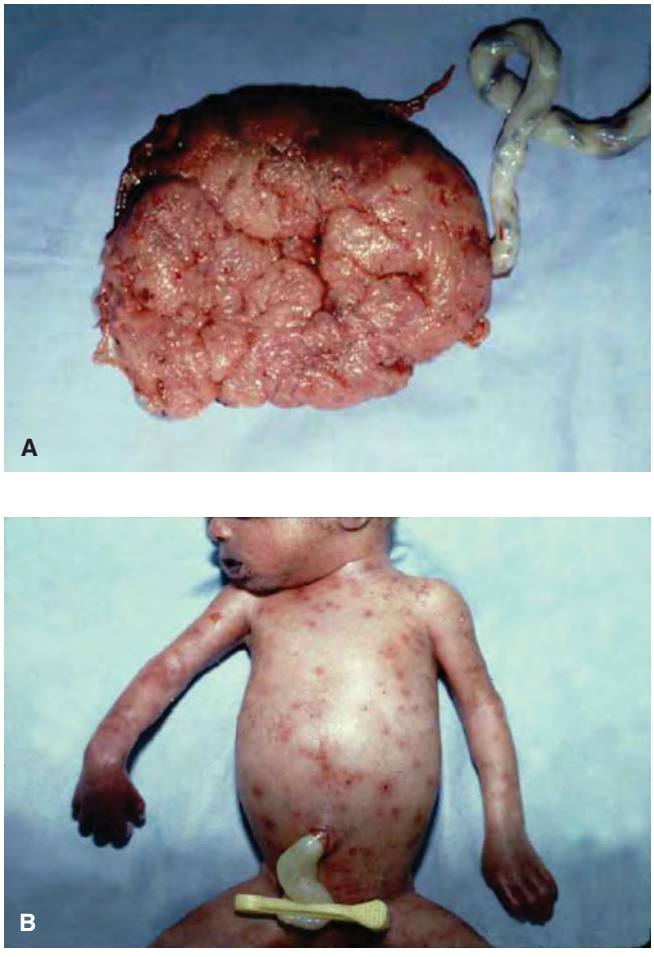

FIGURE 58-8 The pale placenta **(A)** and stillborn infant **(B)** resulted from maternal listeriosis.

Listeriosis

Listeria monocytogenes is an uncommon but probably underdiagnosed cause of neonatal sepsis. This facultative intracellular gram-positive bacillus can be isolated from the feces of 1 to 5 percent of adults. Nearly all cases of listeriosis are thought to be food-borne. Outbreaks have been caused by raw vegetables, coleslaw, apple cider, melons, milk, fresh Mexican-style cheese, smoked fish, and processed foods, such as pâté, hummus, wieners, and sliced deli meats (Janakiraman, 2008; Varma and colleagues, 2007).

Listerial infections are more common in the very old or young, pregnant women, and immunocompromised patients. Voetsch and associates (2007) recently reported data from the Foodborne Diseases Active Surveillance Network Working Group. In 2003, the overall incidence of listeria in the United States decreased to 3.1 cases per million. It is unclear why pregnant women still account for a significant number of these reported cases. One hypothesis is that pregnant women are susceptible because of decreased cell-mediated immunity (Wing and Gregory, 2002). Another is that placental trophoblasts are susceptible to *L. monocytogenes* (Le Monnier and colleagues, 2007).

Clinical Presentation

Listeriosis during pregnancy may be asymptomatic or it may cause a febrile illness that is confused with influenza, pyelonephritis, or meningitis (Mylonakis and colleagues, 2002; Silver, 1998). The diagnosis usually is not apparent until blood cultures are reported as positive. Occult or clinical infection also may stimulate labor (Boucher and Yonekura, 1986). Discolored, brownish, or meconium-stained amnionic fluid is common with fetal infection, even with preterm gestations.

Maternal listeremia causes fetal infection that characteristically produces disseminated granulomatous lesions with *microabscesses* (Topalovski and colleagues, 1993). Chorioamnionitis is common with maternal infection, and placental lesions include multiple, well-demarcated macroabscesses. The two types of neonatal infections are very similar to group B streptococcal sepsis. In a review of 222 cases by Mylonakis and associates (2002), infection resulted in abortion or stillbirth in 20 percent, and neonatal sepsis developed in 68 percent of surviving newborns. A stillbirth caused by listeriosis is shown in Figure 58-8. Voetsch and colleagues (2007) detailed similar findings.

Treatment

Ampicillin plus gentamicin is usually recommended because of synergism. Trimethoprim-sulfamethoxazole can be given to penicillin-allergic women. Maternal treatment may also be effective for fetal infection.

There is no vaccine for listeriosis. Pregnant women should thoroughly cook raw food, wash raw vegetables, and avoid the implicated foods listed previously.

Salmonella and Shigella

Salmonellosis

Infections from *Salmonella* species continue to be a major cause of food-borne illness, although significant declines in incidence have been reported in the past decade (Centers for Disease Control and Prevention, 2006a). Six serotypes account for most cases in the United States, including *Salmonella* subtypes *typhimurium* and *enteritidis*. Non-typhoid *Salmonella* gastroenteritis is contracted through contaminated food. Symptoms including diarrhea, abdominal pain, fever, chills, nausea, and vomiting start 12 to 72 hours after exposure. Diagnosis is made by stool studies. Intravenous crystalloid is given for rehydration. Antimicrobials are not given in uncomplicated infections because they do not commonly shorten illness and may prolong the convalescent carrier state. If gastroenteritis is complicated by bacteremia, antimicrobials are given as discussed below. Rare case reports have linked *Salmonella* bacteremia with abortion (Coughlin, 2002).

Typhoid fever caused by *Salmonella typhi* remains a global health problem, although uncommon in the United States. It is spread by oral ingestion of contaminated food, water, or milk. In pregnant women, the disease is more likely to be encountered during epidemics or in those with HIV infection (Hedriana and colleagues, 1995). In their review, Dildy and associates (1990) reported that antepartum typhoid fever in former years resulted in abortion, preterm labor, and maternal or fetal death.

Fluoroquinolones are the most effective treatment, but alternatives include intravenous third-generation cephalosporins or azithromycin in pregnant women, especially in areas of quinolone resistance (Parry and co-workers, 2002). Typhoid vaccines appear to exert no harmful effects when administered to pregnant women and should be given in an epidemic or before travel to endemic areas.

Shigellosis

Bacillary dysentery caused by *Shigella* is a relatively common, highly contagious cause in adults of inflammatory exudative diarrhea, frequently with bloody stools. Shigellosis is more common in children attending day-care centers and is transmitted via the fecal-oral route (Centers for Disease Control and Prevention, 2006a). Clinical manifestations range from mild diarrhea to severe dysentery, abdominal cramping, tenesmus, fever, and systemic toxicity.

Although shigellosis may be self-limited, careful attention to treatment of dehydration is essential in severe cases. We have cared for pregnant women in whom secretory diarrhea exceeded 10 L/day! Effective treatments during pregnancy include fluoroquinolones, ceftriaxone, azithromycin, or trimethoprim-sulfamethoxazole, although antimicrobial resistance is now emerging (Bhattacharya and Sur, 2003; Centers for Disease Control and Prevention, 2006a).

Hansen Disease

Also known as leprosy, this chronic infection is caused by *Mycobacterium leprae*. Diagnosis is confirmed with PCR. Multidrug therapy with dapsone, rifampin, and clofazimine are recommended for treatment and are generally safe for use during pregnancy (Britton and Lockwood, 2004). Duncan (1980) reported an excessive incidence of low-birthweight newborns born to infected women. The placenta is not involved, and neonatal infection apparently is acquired from skin-to-skin or droplet transmission (Böddinghaus and co-workers, 2007; Duncan and colleagues, 1984). Vertical transmission is common in untreated mothers (Moschella, 2004).

Lyme Disease

Caused by the spirochete *Borrelia burgdorferi*, Lyme disease is the most commonly reported vector-borne illness in the United States (Centers for Disease Control and Prevention, 2007c). Lyme borreliosis follows tick bites of the genus *Ixodes*. Early infection causes a distinctive local skin lesion, *erythema migrans*, which may be accompanied by a flulike syndrome and regional adenopathy. If untreated, disseminated infection follows in days to weeks. Multisystem involvement is common, but skin lesions, arthralgia and myalgia, carditis, and meningitis predominate. If still untreated after several weeks to months, late or persistent infection manifests in perhaps half of patients. Native immunity is acquired, and the disease enters a chronic phase. Although some patients remain asymptomatic, others in the chronic phase develop a variety of skin, joint, or neurological manifestations (Wormser and colleagues, 2006).

Clinical diagnosis is important because serological diagnosis has pitfalls. Serology yields positive results in only approximately half of patients with early disease, whereas most with late, untreated Lyme disease have a positive enzyme-linked immunosorbent assay (ELISA) and/or Western blot assay. Although transplacental transmission has been confirmed, no congenital effects of maternal borreliosis have been conclusively identified (Elliott and colleagues, 2001; Walsh and associates, 2006).

Treatment and Prevention

Optimal treatment of Lyme disease was reviewed by Wormser and associates (2006) for the Infectious Disease Society of America. For early infection, treatment with doxycycline, amoxicillin, or cefuroxime is recommended for 14 days, although doxycycline is usually avoided in pregnancy. Intravenous ceftriaxone, cefotaxime, or penicillin G is given for complicated early infections that include meningitis or carditis. Chronic arthritis and post-Lyme disease syndrome are treated with prolonged oral or intravenous regimens, however, symptoms respond poorly to treatment (Klempner and colleagues, 2001).

A vaccine was withdrawn from the market in 2002 due to low sales. Avoidance of areas in which Lyme disease is endemic and improved tick control in those areas is the most effective

prevention. Self-examination with removal of unengorged ticks within 36 hours of attachment reduces risks of infection (Hayes and Piesman, 2003). For tick bites recognized within 72 hours, a single 200-mg oral dose of doxycycline may reduce the development of Lyme disease. Prompt treatment of maternal early infection should prevent most adverse pregnancy outcomes.

Tuberculosis

Diagnosis and management of tuberculosis during pregnancy is discussed in detail in Chapter 46 (p. 1005).

PROTOZOAL INFECTIONS

Toxoplasmosis

Toxoplasma gondii has a complex life cycle with three forms: (1) a *tachyzoite*, which invades and replicates intracellularly during infection, (2) a *bradyzoite*, which forms tissue cysts during latent infection, and (3) a *sporozoite*, which is found in oocysts that can be environmentally resistant (Jones and associates, 2001). This ubiquitous protozoan is transmitted by eating raw or undercooked meat that is infected with tissue cysts or through contact with oocysts from infected cat feces in contaminated litter, soil, or water. From 1988 to 1994, the seroprevalence of toxoplasmosis was found to be 15 percent in childbearing-aged women (McQuillan, 2004). Thus, 85 percent of pregnant women are likely susceptible to infection.

The incidence of congenital toxoplasmosis varies from 0.8 per 10,000 live births in the United States to 10 per 10,000 in France (Dubey, 2000). Lopez and colleagues (2000) estimate there are between 400 and 4000 cases of congenital toxoplasmosis annually in the United States.

The incidence and severity of congenital infection depend on fetal age at the time of maternal infection. The *risks* for fetal infection increase with duration of pregnancy from 6 percent at 13 weeks to 72 percent at 36 weeks (Fig. 58-9). Freeman and colleagues (2005) studied outcomes in 386 women who seroconverted during pregnancy. In those infected before 20 weeks, 11 percent of newborns had congenital toxoplasmosis. But, the rate was 45 percent if infection was documented after 20 weeks. Conversely, the *severity* of fetal infection is much greater in early pregnancy, and these fetuses are much more likely to have clinical findings of infection (Dunn and associates, 1999).

Clinical Manifestations

Most acute infections in both mothers and neonates are silent and can be detected only by prenatal or newborn serological screening. In some cases, maternal symptoms may include fatigue, fever, muscle pain, and sometimes a maculopapular rash and posterior cervical lymphadenopathy. In immunocompetent adults, initial infection confers immunity, and prepregnancy infection nearly eliminates any risk of vertical transmission. Infection in immunocompromised women, however, may be severe, with reactivation involving encephalitis or mass lesions.

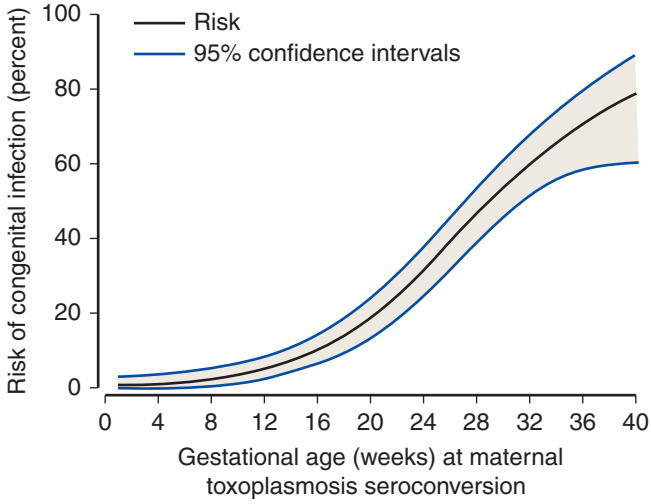

FIGURE 58-9 Risk of congenital toxoplasmosis infection by gestational age at maternal seroconversion. (From *The Lancet,* Vol. 353, No. 9167, D Dunn, M Wallon, F Peyron, et al., Mother-to-child transmission of toxoplasmosis: Risk estimates for clinical counselling, pp. 1829–1833, Copyright 1999, with permission from Elsevier.)

Maternal infection is associated with a fourfold increased preterm delivery rate before 37 weeks (Freeman and associates, 2005). Even so, growth restriction is not increased. Importantly, most infected fetuses are born without obvious stigmata of toxoplasmosis on routine examination. Clinically affected neonates usually have generalized disease with low birthweight, hepatosplenomegaly, jaundice, and anemia. Some primarily have neurological disease with intracranial calcifications such as those shown in Figure 58-10, as well as hydrocephaly or

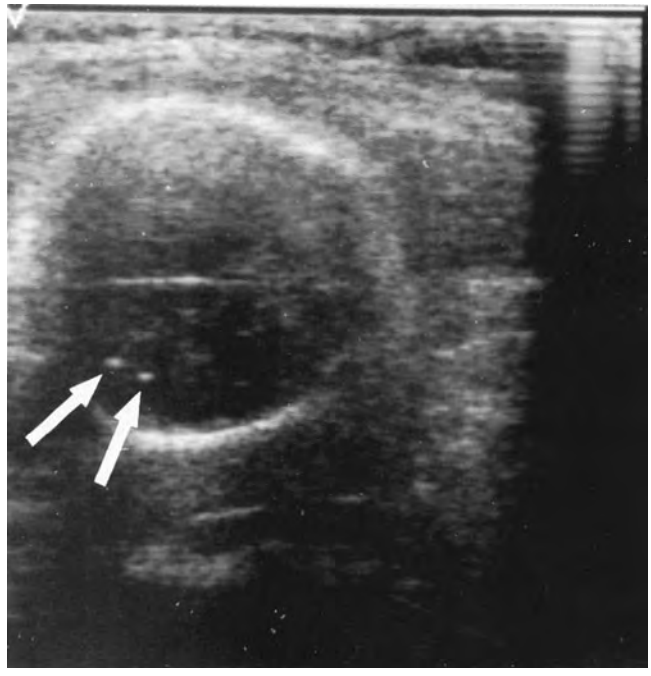

FIGURE 58-10 Sonographic image of intracranial calcifications (*arrows*) in a microcephalic fetus at approximately 30 weeks. (Courtesy of Dr. Rigoberto Santos.)

microcephaly. Many eventually develop chorioretinitis and exhibit learning disabilities. This classical triad—chorioretinitis, intracranial calcifications, and hydrocephalus—is often accompanied by convulsions. Infected neonates with clinical signs are at risk for long-term complications.

Diagnosis

The parasite is rarely detected in tissue or body fluids. Antitoxoplasma IgG develops within 1 to 2 weeks after infection, peaks at 1 to 2 months, and usually persists for life—sometimes in high titers. There is now an avidity test for toxoplasma IgG antibody used in maternal serum testing (Beghetto and colleagues, 2003; Montoya and Liesenfeld, 2004). The functional avidity of IgG antibody is low with primary infection and increases over weeks and months. If high-avidity IgG is determined, infection within the preceding 3 to 5 months is excluded. Although IgM antibodies appear by 10 days after infection and usually become negative within 3 to 4 months, they may remain detectable for years. Thus, IgM antibodies should not be used alone to diagnose acute toxoplasmosis. IgA and IgE antibodies are also useful in diagnosing acute infection. Best results are obtained with the Toxoplasma Serologic Profile performed at the Palo Alto Medical Foundation Research Institute (650-853-4828; toxolab@pamf.org). The panel includes the Sabin Feldman dye test, double-sandwich IgM ELISA, IgA and IgG ELISA, and a differential agglutination test (Montoya and Liesenfeld, 2004).

Prenatal diagnosis of toxoplasmosis is performed using DNA amplification techniques and sonographic evaluation. PCR of amnionic fluid or fetal blood has improved sensitivity over standard isolation techniques (Thalib and associates, 2005). Toxoplasma specific IgM and IgA may be present in amnionic fluid but their absence does not indicate lack of infection. Sonographic evidence of intracranial calcifications, hydrocephaly, liver calcifications, ascites, placental thickening, hyperechoic bowel, and growth restriction has all been used prenatally to help confirm diagnosis.

Management

Because of low prevalence rates, routine prenatal toxoplasma screening is not currently recommended except for women with HIV infection (American College of Obstetricians and Gynecologists, 2000). In areas of high toxoplasmosis prevalence—for example, France and Austria—routine screening has resulted in diminished congenital disease. With IgG antibody confirmed before pregnancy, there is no risk for a congenitally infected fetus (Montoya and Liesenfeld, 2004).

Treatment of pregnant women will likely reduce, but not eliminate, the risk for congenital infection (American College of Obstetricians and Gynecologists, 2000). *Spiramycin* is thought to reduce the risk of congenital infection but not to treat established fetal infection. The drug can be obtained from the Division of Special Pathogens and Immunologic Drug Products at the Food and Drug Administration (301-827-2335). Presumptive treatment with pyrimethamine and sulfonamides has been suggested for primary maternal infection in late pregnancy with negative amnionic fluid testing (Romand and associates, 2001). If fetal infection is diagnosed by prenatal testing, pyrimethamine, sulfonamides, and folinic acid are used to eradicate parasites in the placenta and fetus. The effectiveness of prenatal treatment is controversial, and Thiebart and colleagues as part of the Systematic Review on Congenital Toxoplasmosis (SYROCOT) Study Group (2007) recently performed a meta-analysis and reported a weak association of early treatment with reduced risk of congenital toxoplasmosis.

Prevention

There is no vaccine for toxoplasmosis, but congenital infection may be prevented by: (1) cooking meat to safe temperatures; (2) peeling or thoroughly washing fruits and vegetables; (3) cleaning cooking surfaces and utensils that contain raw meat, poultry, seafood, or unwashed fruits and vegetables; (4) wearing gloves when changing cat litter or delegating this duty; and (5) avoiding feeding cats raw or undercooked meat and keeping cats indoors. However, data supporting the effectiveness of such preventive steps is lacking (Di Mario and co-workers, 2009).

Malaria

The four species of *Plasmodium* that cause human malaria are *vivax, ovale, malariae*, and *falciparum*. Malaria remains the most common human parasitic disease, with nearly 300 to 500 million persons worldwide infected at any given time (Nosten and colleagues, 2007). Malaria has been effectively eradicated in Europe and most of North America except for parts of Mexico. But up to a fourth of pregnant women are infected in endemic areas such as Africa (Desai and co-workers, 2007).

Clinical findings are fever, chills, and flulike symptoms including headaches, myalgia, and malaise, which may occur at intervals. Symptoms are less severe with recurrences. Malaria may be associated with anemia and jaundice, and *falciparum* infections may cause kidney failure, coma, and death. That said, many otherwise healthy but infected adults in endemic areas are asymptomatic. Pregnant women, although often asymptomatic, are said to be more likely to develop traditional symptoms (Desai and associates, 2007; Tagbor, 2005).

Diagnosis

Identification of parasites by microscopic evaluation of a blood smear is considered the gold standard for diagnosis. In women with low parasite densities, however, the sensitivity of microscopy is poor. Malaria-specific antigens are now being used as a target for rapid diagnostic testing. Not only is their sensitivity still an issue in pregnancy, but these tests are not routinely available (Griffith and co-workers, 2007).

Effects on Pregnancy

Malaria, whether symptomatic or asymptomatic, causes a disproportionate rates of morbidity and mortality in pregnancy (Menéndez, 2007; Nosten, 2007; Rogerson, 2007, and all their colleagues). *P. falciparum* infections are more commonly associated with severe morbidity and mortality, and early infection has an increased risk for abortion (Desai and associates, 2007). The incidence of malaria increases significantly in the latter two trimesters and postpartum (Diagne and colleagues, 2000).

Infected erythrocytes as well as monocytes and macrophages accumulate in the vascular areas of the placenta (Fig. 58-11). High levels of placental parasitemia correlate with increased rates of stillbirth, preterm delivery, and fetal-growth restriction (Goldenberg and Thompson, 2003; Rogerson and co-workers, 2007). It is estimated that successful control of malaria in pregnancy would prevent 75,000 to 200,000 infant deaths worldwide every year (Steketee and collaborators, 2001).

Treatment

Most commonly used antimalarial drugs are not contraindicated during pregnancy. Some of the newer agents have antifolic acid activity and theoretically—but not pragmatically—contribute to development of megaloblastic anemia. *Chloroquine* is the treatment of choice for malaria caused by all sensitive *Plasmodium* species (Griffith and associates, 2007; Nosten and colleagues, 2007). For the woman with chloroquine-resistant infection, which constitutes the majority of *falciparum* infections, quinine plus clindamycin is currently recommended. Quinine may induce hyperinsulinemia and thus, possible maternal and fetal hypoglycemia. Mefloquine or atovaquone-proguanil are not currently recommended for treatment during pregnancy, although mefloquine is still recommended for chemoprophylaxis as subsequently discussed.

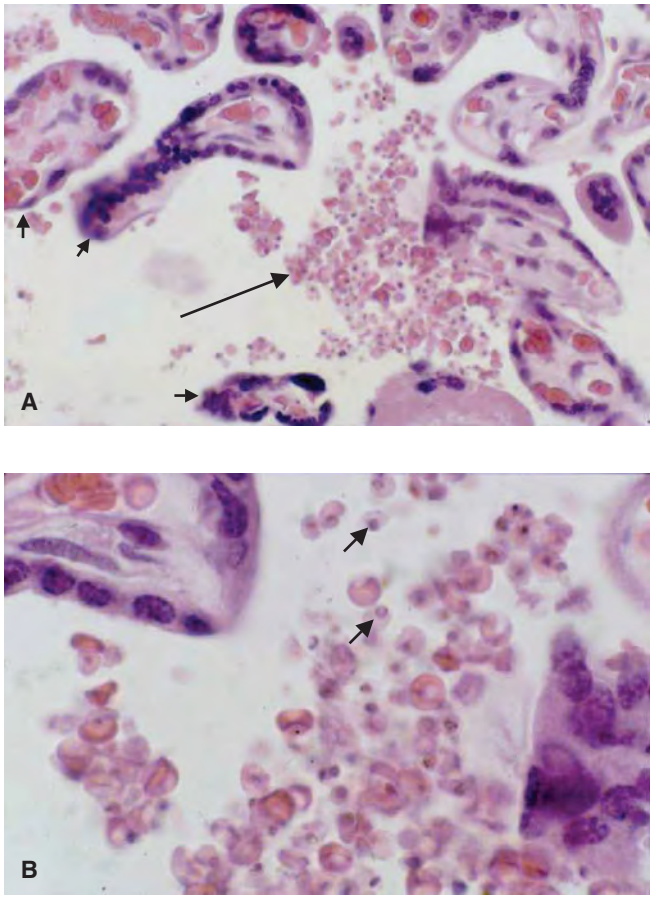

FIGURE 58-11 Photomicrograph of placental malaria. **A.** Multiple infected red blood cells (RBCs) (*long black arrow*) are seen in the intervillous space of this placenta. Multiple villi cut in cross section are shown and three are highlighted (*short arrows*). **B.** Increased magnification of image **(A).** Multiple infected RBCs are seen and two are identified (*arrows*).

The severity of malaria, especially with *falciparum* infection, may be underestimated on initial clinical presentation. A thorough assessment of severity should precede but not delay treatment in pregnant women (Moore and associates, 2003). For severe or complicated malaria, quinidine gluconate is given parenterally. Cardiotoxicity is its major adverse effect, and women receiving this drug should have continuous electrocardiography monitoring. The Centers for Disease Control and Prevention maintains a Malaria Hotline for treatment recommendations (770-488-7788) (Thwing and associates, 2007).

Prophylaxis

Malaria control and prevention relies on chemoprophylaxis when traveling to or living in endemic areas. Vector control is also important, and insecticide-treated netting, pyrethroid insecticides, and DEET-based insect repellent have proven useful to decrease malarial rates in endemic areas. These are well tolerated in pregnancy (Menéndez and co-workers, 2007). Although not currently available, vaccine development targeting sporozoites is under study (Kanoi and Egwang, 2007). If travel is necessary, chemoprophylaxis is recommended.

Chloroquine prophylaxis is safe and well tolerated in pregnancy. It has been shown to decrease placental infection from 20 down to 4 percent in asymptomatic infected women in areas without chloroquine resistance (Cot and associates, 1992). For travelers to areas with chloroquine-resistant *P. falciparum*, mefloquine is currently the only chemoprophylaxis recommended. Primaquine and doxycycline are contraindicated in pregnancy, and there are insufficient data on atovaquone/proguanil to recommend them at this time. Likewise, amodiaquine is used in Africa, but data are limited in pregnant women.

Schwartz and associates (2003) emphasize the complexity of contemporary malaria prophylaxis due to drug resistance and the limitations of common regimens to protect against subsequent relapses from the liver stages of *P. vivax* and *P. ovale.* The latest chemoprophylaxis regimens for pregnancy can be obtained from the Centers for Disease Control and Prevention *Travelers Health* Web site at http://www.cdc.gov/travel/. The Centers for Disease Control and Prevention (2007f) also publish *Health Information for International Travel*, also called the *Yellow Book*, with detailed information.

Amebiasis

Most persons infected with *Entamoeba histolytica* are asymptomatic. Amebic dysentery, however, may take a fulminant course during pregnancy, with fever, abdominal pain, and bloody stools. Prognosis is worse if complicated by a hepatic abscess, which may be serious. Diagnosis is made with a stool sample and can be difficult. Therapy is similar to that for the nonpregnant woman, and metronidazole is the preferred drug for amebic colitis and invasive disease. Noninvasive infections may be treated with paromomycin (Haque and associates, 2003).

MYCOTIC INFECTIONS

Disseminated fungal infection—usually pneumonitis—during pregnancy is uncommon with coccidiomycosis, blastomycosis, cryptococcosis, or histoplasmosis. Their identification and management are considered in Chapter 46 (p. 1004).

EMERGING INFECTIONS

Infectious diseases whose incidence in humans has increased in the past two decades or has high potential to increase in the near future are termed "emerging infections" (Jamieson and colleagues, 2006a, b). They include severe acute respiratory syndrome (SARS), West Nile virus, and H1N1 influenza A (see p. 1212). They also include many of the bioterrorism agents detailed in the next section.

West Nile Virus

This mosquito-borne flavivirus is a human neuropathogen. Since 1999, reported numbers of human and animal infections have increased, and the geographical range of disease activity has expanded (Centers for Disease Control and Prevention, 2004; Morse, 2003). Infection typically is acquired through mosquito bites in late summer, or perhaps through blood transfusion (Harrington and associates, 2003). The incubation period is 3 to 14 days, and most persons have mild or no symptoms. Less than 1 percent of adults develop meningoencephalitis or acute flaccid paralysis (Granwehr and colleagues, 2004). In pregnant women, presenting symptoms are fever, mental status changes, muscle weakness, and coma (Chapa and colleagues, 2003).

The diagnosis is based on clinical symptoms and the detection of West Nile virus IgG and IgM in serum and IgM in cerebrospinal fluid. There is no known effective antiviral treatment, and management is supportive. The primary strategy for preventing exposure in pregnancy is the use of insect repellant containing *N,N*-diethyl-*m*-toluamide (DEET), which is considered safe for pregnant women (Koren and colleagues, 2003). Avoiding outdoor activity and stagnant water and wearing protective clothing is also recommended.

Pregnancy

Animal data suggest that embryos are susceptible to West Nile viral injection (Julander and associates, 2006). Human fetal infection with West Nile virus at 27 weeks resulted in a term neonate with chorioretinitis and severe temporal and occipital lobe leukomalacia (Alpert and co-workers, 2003). O'Leary and colleagues (2006) described cases reported to the West Nile Virus Pregnancy Registry. There were 77 infected pregnant women who had 72 live infants, four miscarriages, and two elective abortions. The preterm birth rate was 6 percent. Only three of 72 infants developed West Nile virus infection, although it could not be established conclusively that infection was acquired congenitally. Of three major malformations *possibly* associated with viral infection, none was definitively confirmed. Thus, any adverse fetal effects of West Nile viral infection are currently unclear.

Severe Acute Respiratory Syndrome (SARS)

Since 2002, there have been several outbreaks of SARS reported in Asia and North America. Its cause is a novel *coronavirus*—SARS-CoV—that is transmitted through droplets, close contact with infected secretions, fluids, and waste (Christian, 2004; Drosten, 2003; Ksiazek, 2003, and all their colleagues). The incubation period is 2 to 16 days, and the early clinical picture is similar to community-acquired pneumonia. SARS exposure or travel to an affected area increases the likelihood of diagnosis (Wenzel and Edmond, 2003).

There appears to be a triphasic pattern to the clinical progression of SARS. The first week is characterized by prodromal symptoms of fever, myalgias, headache, and diarrhea. During the second week, patients may suffer recurrent fever, watery diarrhea, and a dry nonproductive cough with mild dyspnea, and these are coincidental with IgG seroconversion and a declining viral load. Progression at this stage is thought to be due to an overexuberant host immune response. The third and at times lethal phase—seen in about 20 percent of patients—is progression to the acute respiratory distress syndrome (Christian and associates, 2004; Peiris and co-workers, 2003a, b).

Radiographic pulmonary manifestations of SARS include ground-glass opacities and airspace consolidations that can rapidly progress to extensive consolidation within 1 to 2 days. There also may be lymphopenia, thrombocytopenia, and elevated serum lactate dehydrogenase (Tsang and co-workers, 2003).

There currently is no proven treatment (Peiris and associates, 2003a, b; Perlman and Netland, 2009). Most patients have been given broad-spectrum antimicrobials. In pregnancy, oral therapy with clarithromycin plus amoxicillin with clavulanate have been used (So and colleagues, 2003; Wong and co-workers, 2003). Ribavirin to decrease viral replication and corticosteroids to modulate the immune response are controversial and should be reserved for severe illness (Jamieson and associates, 2006a; Mandell and co-workers, 2003).

Pregnancy

Any adverse effects of SARS on perinatal outcome is unclear because of limited published experiences. An increased incidence of miscarriage, fetal-growth restriction, and preterm delivery has been reported (Jamieson and co-workers, 2006b). Small case-control studies indicate that SARS is more severe in pregnant women compared with nonpregnant women with a case-fatality rate of 25 percent (Lam and colleagues, 2004; Wong and co-workers, 2004). There are no documented infections in neonates born to mothers with SARS (Peiris and colleagues, 2003a).

TRAVEL PRECAUTIONS DURING PREGNANCY

Pregnant travelers face obstetrical risks, general medical risks, and potentially hazardous destination risks. Some of these are discussed in detail in Chapter 8 (p. 207). The International Society for Tropical Medicines has comprehensive information available at http://www.istm.org. The Centers for Disease Control and Prevention has extensive travel information regarding pregnancy and breast feeding at its *Travelers' Health* home page at

http://www.cdc.gov/travel/index.htm. There is also extensive information in the *Yellow Book* published by the Centers for Disease Control and Prevention (2007f). The American College of Obstetricians and Gynecologists (2003) also has published recommendations for active and passive immunization in pregnancy, including some vaccination issues pertinent to travel.

BIOTERRORISM

Bioterrorism involves the deliberate release of bacteria, viruses, or other infectious agents to cause illness or death. These natural agents are often altered to increase their infectivity or their resistance to medical therapy. Clinicians should be alert for significant increases in the number of persons with febrile illnesses accompanied by respiratory symptoms or with rashes not easily associated with common illnesses. Clinicians are urged to contact their state health department or bioterrorism Web sites of the Centers for Disease Control and Prevention (www.cdc.gov) for contemporary information and recommendations.

Smallpox

The variola virus is considered a serious weapon because of high transmission and overall 30-percent case-fatality rate. The last case of smallpox in the United States was reported in 1949, and worldwide it was reported in Somalia in 1977. Transmission occurs with prolonged contact, infected body fluids, or contaminated objects such as clothing. Smallpox presents with an acute onset of fever followed by a rash characterized by firm, deep-seated vesicles or pustules in the same stage of development. Nishiura (2006) and Suarez and Hankins (2002) have provided reviews addressing the severe perinatal and maternal morbidity and mortality caused by smallpox.

Because smallpox vaccine is made with live vaccinia virus, pregnancy should be delayed for 4 weeks in recipients. It is generally not given to pregnant women because of the risk of fetal vaccinia, a rare but serious complication. The Centers for Disease Control and Prevention (2003) recommends smallpox vaccination in pregnant women with emergency exposure, and it maintains a registry. Inadvertent vaccination is not ordinarily an indication for pregnancy termination.

Anthrax

Bacillus anthracis is a gram-positive, spore-forming, aerobic bacterium. It can cause three main types of clinical anthrax: inhalational, cutaneous, and gastrointestinal (Swartz, 2001; Holty and colleagues, 2006). The bioterrorist anthrax attacks of 2001 involved inhalational anthrax (Inglesby and co-workers, 2002). Spores are inhaled and deposited in the alveoli, engulfed by macrophages, and germinated in mediastinal lymph nodes. The incubation period is usually less than 1 week but may be as long as 2 months. Initial symptoms are nonspecific and include low-grade fever, nonproductive cough, malaise, and myalgias. Within 1 to 5 days of symptom onset, the second stage is heralded by the abrupt onset of severe respiratory distress and high fevers. Mediastinitis and hemorrhagic thoracic lymphadenitis are common, and there is a widened mediastinum on chest radiograph. Case-fatality rates with inhalational anthrax are high, even with aggressive antibiotic and supportive therapy (Dixon and colleagues, 1999; Holty and associates, 2006).

There are few data regarding anthrax in pregnancy. Kadanali and associates (2003) reviewed two cases of third-trimester cutaneous anthrax treated successfully with penicillin. In both, preterm delivery followed soon after therapy was given.

The American College of Obstetricians and Gynecologists (2002b) and the Centers for Disease Control and Prevention (2001) recommend that asymptomatic pregnant and lactating women with documented exposure to *B. anthracis* be given postexposure prophylaxis with ciprofloxacin, 500 mg orally twice daily for 60 days. Amoxicillin, 500 mg orally three times daily, can be substituted if the strain is proven sensitive. In the case of ciprofloxacin allergy and either penicillin allergy or resistance, doxycycline, 100 mg orally twice daily, is given for 60 days. Risks from anthrax far outweigh any fetal risks from doxycycline.

The anthrax vaccine is an inactivated, cell-free product that requires six injections during 18 months. Vaccination is generally avoided in pregnancy because there are no safety data (Centers for Disease Control and Prevention, 2002e). That said, anthrax vaccine is an essential adjunct to postexposure antimicrobial prophylaxis, even in pregnancy (American College of Obstetricians and Gynecologists, 2002b).

Other Bioterrorism Agents

Francisella tularensis—tularemia, *Clostridium botulinum*—botulism, *Yersinia pestis*—plague, and viral hemorrhagic fevers—for example, Ebola, Marburg, Lassa, and Machupo, are also category A bioterrorism agents. There are multiple agents listed as category B and C. The guidelines for these biological agents are evolving and are detailed in the Centers for Disease Control and Prevention Bioterrorism Web site at www.bt.cdc.gov/agent.

CHAPTER 59

Sexually Transmitted Diseases

SYPHILIS 1235
GONORRHEA 1239
CHLAMYDIAL INFECTIONS 1240
HERPES SIMPLEX VIRUS 1241
CHANCROID 1245
HUMAN PAPILLOMAVIRUS 1245
VAGINITIS 1246
HUMAN IMMUNODEFICIENCY VIRUS (HIV) INFECTION 1246

Sexually transmitted diseases (STDs), also called sexually transmitted infections (STIs), are common during pregnancy and should be aggressively sought and treated (Coonrad and colleagues, 2008). Importantly, education, screening, treatment, and prevention are essential components of prenatal care (Piper and colleagues, 2003). STDs that affect pregnant women and potentially affect the fetus include syphilis, gonorrhea, trichomoniasis, and chlamydial, hepatitis B, human immunodeficiency virus (HIV), herpes simplex virus–1 and -2 (HSV-1, -2), and human papillomavirus (HPV) infections. Recommended treatment protocols for most adhere to the frequently updated guidelines provided by the Centers for Disease Control and Prevention (2006b). Treatment of most STDs is clearly associated with improved pregnancy outcome and prevention of perinatal mortality (Goldenberg and associates, 2003, 2009; Gray and co-workers, 2001).

SYPHILIS

Despite the availability of adequate therapy for more than 60 years, syphilis remains a major issue for both mother and fetus. Syphilis rates reached an all time low in 2000, but from 2001 through 2006 for the United States, there has been a steady increase in primary and secondary syphilis rates (Centers for Disease Control and Prevention, 2006b). The rate of syphilis in 2006 among both sexes was 3.3 cases per 100,000 individuals, a 13.8-percent increase from the year prior. Among women for the same year, the rate of primary and secondary syphilis was 1.0 case per 100,000 population. Congenital syphilis rates were 8.5 per 100,000 live births.

Pathogenesis and Transmission

The causative agent for syphilis is *Treponema pallidum.* Minute abrasions on the vaginal mucosa provide a portal of entry for the spirochete. Cervical eversion, hyperemia, and friability increase the risk for transmission. Spirochetes replicate and then disseminate through lymphatic channels within hours to days. The incubation period averages 3 weeks—3 to 90 days—depending on host factors and inoculum size. The early stages of syphilis include primary, secondary, and early latent syphilis. These are associated with the highest spirochete loads and transmission rates of up to 30 to 50 percent. Transmission rates in late-stage disease are much lower because of smaller inoculum sizes.

The fetus acquires syphilis by several routes. Spirochetes readily cross the placenta to cause congenital infection. Because of fetal immunocompetence prior to approximately 18 weeks, the fetus generally does not manifest the immunological inflammatory response characteristic of clinical disease before this time (Silverstein, 1962). Although transplacental transmission is the most common route, neonatal infection may follow after contact with spirochetes through lesions at delivery or across the membranes.

Increased rates of maternal syphilis have been linked to substance abuse, especially crack cocaine; to inadequate prenatal care; and to inadequate screening (Johnson, 2007; Lago, 2004; Trepka, 2006; Warner, 2001; Wilson, 2007, and all their colleagues). In a study of prenatal syphilis during four decades,

Klass and associates (1994) concluded that the continued prevalence of prenatal syphilis was associated with substance abuse, HIV infection, lack of prenatal care, treatment failures, and reinfection. A report from Maricopa County, Arizona, added minority race or ethnicity as risk factors (Taylor and co-workers, 2008).

Clinical Manifestations

Antepartum syphilis can cause preterm labor, fetal death, and neonatal infection (Saloojee and associates, 2004; Watson-Jones and colleagues, 2002). Any stage of maternal syphilis may result in fetal infection, but risk is directly related to maternal spirochete load (Fiumara and colleagues, 1952; Golden and co-workers, 2003). Maternal syphilis is staged according to clinical features and disease duration:

1. Primary syphilis is diagnosed by the characteristic chancre, which develops at the site of inoculation. It is usually painless, with a raised, red, firm border and a smooth base (**Fig. 59-1**). Nonsuppurative lymphadenopathy may develop. A chancre will usually resolve spontaneously in 2 to 8 weeks, even if untreated. Multiple lesions may be found, predominantly in HIV-1 co-infected women
2. Secondary syphilis is diagnosed when the spirochete is disseminated and affects multiple organ systems. Manifestations develop 4 to 10 weeks after the chancre appears and include dermatological abnormalities in up to 90 percent of women. A diffuse macular rash, plantar and palmar target-like lesions, patchy alopecia, and/or mucous patches may be seen (**Fig. 59-2**). Condylomata lata are flesh-colored papules and nodules found on the perineum and perianal area. They are teeming with spirochetes and are highly infectious. Most women with secondary syphilis will also express constitutional symptoms such as fever, malaise, anorexia, headache, myalgias, and arthralgias. Up to 40 percent of women will have cerebrospinal fluid abnormalities, although only 1 to 2 percent will develop aseptic meningitis
3. *Latent syphilis* develops when primary or secondary syphilis is not treated. It is characterized by reactive serological testing, but resolved clinical manifestations. *Early latent syphilis* is latent disease acquired within the preceding 12 months. Disease diagnosed beyond 12 months is either *late latent syphilis* or *latent syphilis of unknown duration. Tertiary* or *late syphilis* is a slowly progressive disease affecting any organ system but is rarely seen in reproductive-aged women.

FIGURE 59-1 Primary syphilis. Photograph of a chancre with a raised, red, firm border and smooth base.

FIGURE 59-2 Target lesions on the palms of a pregnant woman with secondary syphilis.

As noted, congenital infection is uncommon before 18 weeks. However, once fetal syphilis develops, it manifests as a continuum of involvement (**Fig. 59-3**). Fetal hepatic abnormalities are followed by anemia and thrombocytopenia, then ascites and hydrops (Hollier and colleagues, 2001). Stillbirth remains a major complication (Di Mario and associates, 2007). The newborn may have jaundice with petechiae or purpuric skin lesions, lymphadenopathy, rhinitis, pneumonia, myocarditis, or nephrosis.

With syphilitic infection, the placenta becomes large and pale (**Fig. 59-4**). Microscopically, villi lose their characteristic arborization and become thicker and clubbed (Kapur and co-workers, 2004). Sheffield and colleagues (2002c) described such large villi in more than 60 percent of placentas from 33 infected pregnancies. Blood vessels markedly diminish in number, and in advanced cases, they almost entirely disappear as a result of endarteritis and stromal cell proliferation. Perhaps related, Lucas and co-workers (1991) demonstrated increased vascular resistance in uterine and umbilical arteries of infected pregnancies. In a study of 25 untreated women, Schwartz and associates (1995) reported that necrotizing funisitis was present in a third.

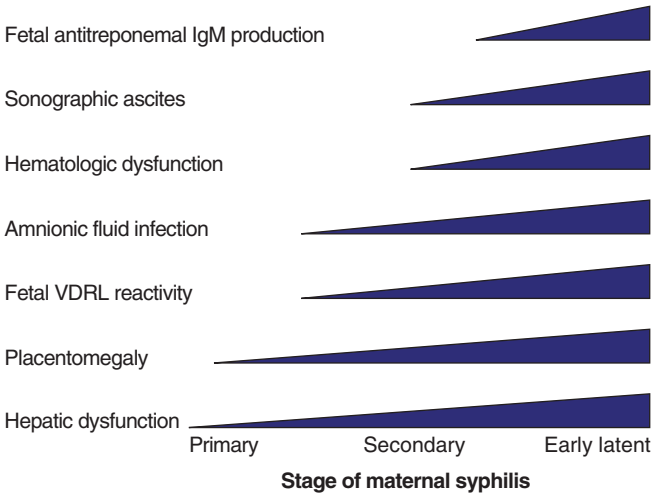

FIGURE 59-3 Hypothesized continuum of fetal syphilis infection. VDRL = Venereal Disease Research Laboratory. (Reprinted from Hollier LM, Harstad TW, Sanchez PJ, et al: Fetal syphilis: Clinical and laboratory characteristics, *Obstetrics & Gynecology*, 2001, vol. 97, no. 6, pp. 947–953, with permission.)

Spirochetes were detected in almost 90 percent using silver and immunofluorescent staining.

Diagnosis

T. pallidum cannot be cultured from clinical specimens. Definitive diagnosis of early-stage lesions is made using darkfield examination and direct fluorescent antibody testing of lesion exudates (Centers for Disease Control and Prevention, 2006b). In asymptomatic patients or for screening purposes, serological testing is used. The *Venereal Disease Research Laboratory (VDRL) slide test* or the *rapid plasma reagin (RPR) test* is performed at the first prenatal visit. Testing is required by law in many states (Connor and colleagues, 2000; Hollier and associates, 2003). Serological tests yield positive results in most women with primary syphilis and in all of those with secondary and latent syphilis. These nontreponemal tests are quantitated and expressed as titers. Titers reflect disease activity, and thus they increase during early syphilis and often exceed levels of 1:32 in secondary syphilis. Following treatment of primary and secondary syphilis, serological testing at 3 to 6 months usually confirms a fourfold drop in VDRL or RPR titers. Those with treatment failure or reinfection may lack this decline. Because

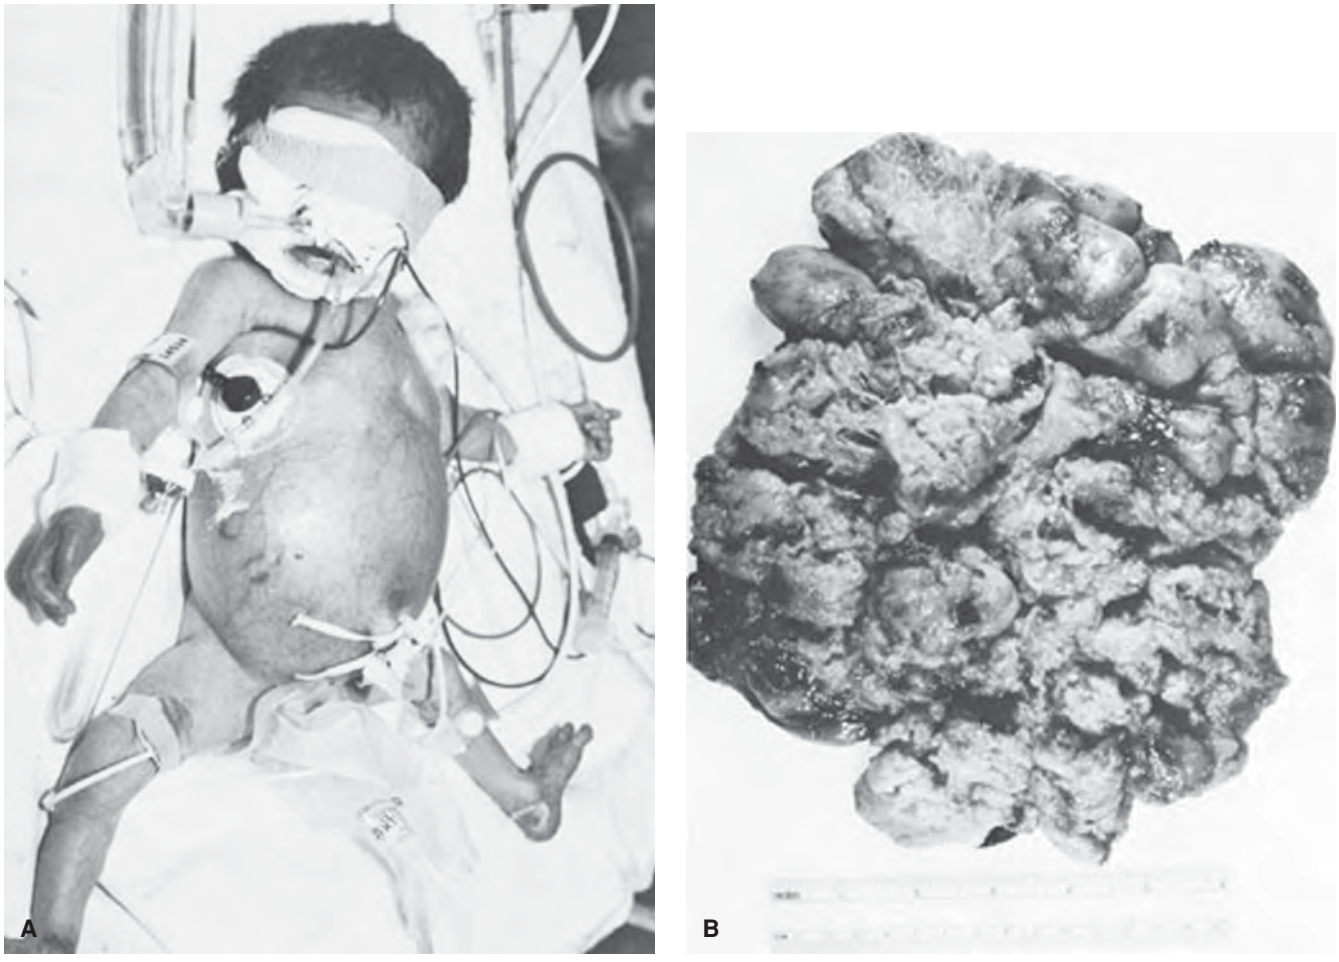

FIGURE 59-4 Congenital syphilis. **A.** A 29-week-old, severely ill neonate with an enlarged abdomen caused by marked hepatosplenomegaly plus ascites. **B.** The large syphilitic placenta of the same neonate weighed 1200 g, almost the birthweight of the newborn.

TABLE 59-1. Recommended Treatment for Pregnant Women with Syphilis

Category	Treatment
Early syphilis[a]	Benzathine penicillin G, 2.4 million units intramuscularly as a single injection—some recommend a second dose 1 week later
More than 1-year duration[b]	Benzathine penicillin G, 2.4 million units intramuscularly weekly for three doses
Neurosyphilis[c]	Aqueous crystalline penicillin G, 3–4 million units intravenously every 4 hours for 10–14 days *or* Aqueous procaine penicillin, 2.4 million units intramuscularly daily, plus probenecid 500 mg orally four times daily, both for 10–14 days

[a]Primary, secondary, and latent syphilis of less than 1-year duration.
[b]Latent syphilis of unknown or more than 1-year duration; tertiary syphilis.
[c]Some recommend benzathine penicillin, 2.4 million units intramuscularly after completion of the neurosyphilis treatment regimens.
From the Centers for Disease Control and Prevention (2006b).

VDRL titers do not correspond directly to RPR titers, consistent use of one test for surveillance is recommended.

Reagin tests lack specificity, and a treponemal-specific test is therefore used to confirm positive results (Pope and Fears, 2000; Young, 2000). These include the *fluorescent treponemal antibody absorption tests (FTA-ABS)*, the *microhemagglutination assay* for antibodies to *T. pallidum* (MHA-TP), or the *Treponema pallidum passive particle agglutination (TP-PA) test.* These treponemal-specific tests generally remain positive throughout life. Rapid syphilis testing for "point of care" diagnosis is currently being developed and may be useful in limited-prenatal care settings (Centers for Disease Control and Prevention, 2006b; Greer and Wendel, 2008). For women at high risk for syphilis, a nontreponemal screening test should be repeated in the third trimester and again at delivery (Centers for Disease control and Prevention, 2006b; Meyers and colleagues, 2008).

The prenatal diagnosis of congenital syphilis is difficult. Sonographic evaluation may be suggestive or even diagnostic, and hydrops fetalis, ascites, hepatomegaly, placental thickening, and hydramnios all suggest infection (see Chapter 29, p. 626). Importantly, an infected fetus often has a normal sonographic examination. Polymerase chain reaction (PCR) is specific for detection of *T. pallidum* in amnionic fluid, and treponemal DNA has been found in 40 percent of pregnancies infected before 20 weeks (Nathan and colleagues, 1997; Wendel and associates, 1991). Fetal syphilis has also been verified by amnionic fluid darkfield examination or rabbit infectivity testing in 64 percent of a cohort of women with untreated syphilis (Hollier and coworkers, 2001). Although prenatal diagnosis can be made by funipuncture or amniocentesis, its clinical utility is not yet clear.

Treatment

Syphilis therapy during pregnancy is given to eradicate maternal infection and to prevent congenital syphilis. Parenteral penicillin G remains the preferred treatment for all stages of syphilis during pregnancy. Currently recommended treatment guidelines are shown in Table 59-1 and are the same as for nonpregnant adults. Some authorities recommend a second dose of benzathine penicillin G 1 week after the initial dose.

In retrospective analyses, benzathine penicillin G has been shown to be highly effective for early maternal infection. In a study of 340 pregnant women so treated, Alexander and associates (1999) reported six cases—1.8 percent—of congenital syphilis. Four of these six neonates were from a group of 75 women with secondary syphilis. The other two were identified in those delivered from a group of 102 women with early latent syphilis. Congenital syphilis was generally confined to neonates of women treated after 26 weeks and is likely related to the duration and severity of fetal infection. Sheffield and coworkers (2002b) reported that high maternal serological titers, preterm delivery, and delivery shortly after antepartum therapy are all risks of maternal treatment failure to prevent neonatal infection.

There are no proven alternatives to penicillin therapy during pregnancy. Erythromycin may be curative for the mother, but because of limited transplacental passage, it does not prevent all congenital disease (Berman, 2004; Wendel, 1988). The cephalosporins, such as ceftriaxone, and the newer macrolide, azithromycin, may prove useful (Augenbraun, 2002; Augenbraun and Workowski, 1999; Zhou and colleagues, 2005). Azithromycin therapy results in significant maternal and fetal serum drug levels (Ramsey and colleagues, 2003). Its efficacy in pregnancy, however, has not been adequately evaluated, and both resistance and treatment failures have been reported in adults (Centers for Disease Control and Prevention, 2004; Lukehart, 2004; Wendel, 2002; Zhou, 2007, and all their associates). Tetracyclines, including doxycycline, are effective for treatment of syphilis in the nonpregnant woman. However, these are generally not recommended during pregnancy because of the risk of yellow-brown discoloration of fetal deciduous teeth (see Chap. 14, p. 320).

TABLE 59-2. Oral Desensitization Protocol for Patients with a Positive Skin Test

Penicillin V Suspension Dose[a]	Amount[b] (units/mL)	mL	Units	Cumulative Dose (units)
1	1000	0.1	100	100
2	1000	0.2	200	300
3	1000	0.4	400	700
4	1000	0.8	800	1500
5	1000	1.6	1600	3100
6	1000	3.2	3200	6300
7	1000	6.4	6400	12,700
8	10,000	1.2	12,000	24,700
9	10,000	2.4	24,000	48,700
10	10,000	4.8	48,000	96,700
11	80,000	1.0	80,000	176,700
12	80,000	2.0	160,000	336,700
13	80,000	4.0	320,000	656,700
14	80,000	8.0	640,000	1,296,700

[a]Interval between doses: 15 minutes. Elapsed time: 3 hours and 45 minutes. Cumulative dose: 1.3 million units. Observation period: 30 minutes before parenteral administration of penicillin.
[b]The specific amount of drug was diluted in approximately 30 mL of water and administered orally.
From Wendel and colleagues (1985), with permission.

Women with a history of penicillin allergy should have skin testing performed to confirm the risk of immunoglobulin E (IgE)-mediated anaphylaxis. If confirmed, penicillin desensitization is recommended as shown in **Table 59-2**, and then followed by benzathine penicillin G treatment (Chisholm and associates, 1997; Wendel and co-workers, 1985).

In most women with primary syphilis and approximately half with secondary infection, penicillin treatment causes a *Jarisch-Herxheimer reaction*. Uterine contractions frequently develop with this reaction, and they may be accompanied by late fetal heart rate decelerations (Klein and co-workers, 1990). In a study of 50 pregnant women who received benzathine penicillin for syphilis, Myles and colleagues (1998) reported a 40-percent incidence of a Jarisch-Herxheimer reaction. Of the 31 women monitored electronically, 42 percent developed regular uterine contractions with a median onset of 10 hours, and 39 percent developed variable decelerations with a median onset of 8 hours. All contractions resolved within 24 hours of therapy. Lucas and associates (1991) used Doppler velocimetry and demonstrated acutely increased vascular resistance during this time.

All women with syphilis should be offered counseling and testing for HIV (Koumans and co-workers, 2000). For women with concomitant HIV infection, the Centers for Disease Control and Prevention (2006b) recommend the same treatment as for HIV-negative persons. Some authorities, however, recommend two additional weekly doses of benzathine penicillin G. Clinical and serological surveillance to detect treatment failures is also recommended at 3, 6, 9, 12, and 24 months in HIV-positive patients.

GONORRHEA

The incidence of gonorrhea in the United States for 2006 was 121 cases per 100,000 persons, an increase of 5.5 percent since 2005 (Centers for Disease Control and Prevention, 2006b). The highest rates in women of any ethnicity were in the group aged 15 to 24 years. Its prevalence in prenatal clinics in 2006 was 1.0 percent, although one inner-city STD clinic reported a prenatal prevalence of 4.8 percent (Johnson and colleagues, 2007). Risk factors include single marital status, adolescence, poverty, drug abuse, prostitution, other STDs, and lack of prenatal care. Gonococcal infection is also a marker for concomitant chlamydial infection in up to 40 percent of infected women (Christmas and co-workers, 1989; Miller and colleagues, 2004). In most pregnant women, gonococcal infection is limited to the lower genital tract—the cervix, urethra, and periurethral and vestibular glands. Acute salpingitis is rare in pregnancy, but pregnant women account for a disproportionate number of disseminated gonococcal infections (Ross, 1996; Yip and associates, 1993).

Gonococcal infection may have deleterious effects in any trimester. There is an association between untreated gonococcal cervicitis and septic abortion as well as infection after voluntary abortion (Burkman and co-workers, 1976). Preterm delivery, prematurely ruptured membranes, chorioamnionitis, and postpartum infection are more common in women infected with *Neisseria gonorrhoeae* at delivery (Alger and associates, 1988). Sheffield and colleagues (1999) reviewed outcomes of 25 pregnant women admitted at a mean gestational age of 25 weeks to Parkland Hospital for disseminated gonococcal infection. Although all of the women promptly responded to appropriate

antimicrobial therapy, there was one stillbirth and one spontaneous abortion attributed to gonococcal sepsis.

Screening and Treatment

The U.S. Preventative Services Task Force (USPSTF) recommends gonorrhea screening of all sexually active women, including pregnant women, if they are at increased risk (Meyers and colleagues, 2008). Risk factors include age < 25 years, prior gonococcal infection, other STDs, prostitution, new or multiple sexual partners, drug use, and inconsistent condom use. For women who test positive, screening for syphilis, *Chlamydia trachomatis,* and HIV should precede treatment, if possible. If chlamydial testing is unavailable, presumptive therapy is given. Screening for gonorrhea in women is by culture or nucleic acid amplification tests (NAAT). Rapid tests for gonorrhea, although available, do not yet reach the sensitivity or specificity of culture or NAAT (Greer and Wendel, 2008).

Listed in Table 59-3 are recommendations for treatment of uncomplicated gonococcal infection during pregnancy. Fluoroquinolones are no longer recommended due to rapidly rising antimicrobial resistance (Centers for Disease Control and Prevention, 2007, 2008d). Cefixime tablets, previously in limited supply, are again available (Centers for Disease Control and Prevention, 2008a). In a study of 62 pregnant women with probable endocervical gonorrhea, Ramus and associates (2001) reported that intramuscular ceftriaxone, 125 mg, and oral cefixime, 400 mg, resulted in a 95- and 96-percent cure rate, respectively. Spectinomycin is recommended for women allergic to penicillin or β-lactam antimicrobials. Treatment is recommended for sexual contacts. A test-of-cure is unnecessary if symptoms resolve, but because gonococcal reinfection is common, a second screening in late pregnancy should be considered for women treated earlier during pregnancy (Centers for Disease Control and Prevention, 2006b; Miller and co-workers, 2003).

Gonococcal bacteremia may lead to disseminated gonococcal infection (DGI), which manifests as petechial or pustular skin lesions, arthralgias, septic arthritis, or tenosynovitis. The Centers for Disease Control and Prevention (2006b) have recommended ceftriaxone, 1000 mg intramuscularly or intravenously every 24 hours. Treatment should be continued for 24 to 48 hours after improvement, then therapy changed to an oral agent to complete a week of therapy.

For gonococcal *endocarditis*, antimicrobials should be continued for at least 4 weeks, and for *meningitis*, 10 to 14 days (Centers for Disease Control and Prevention, 2006b). Meningitis and endocarditis rarely complicate pregnancy, but they may be fatal (Bataskov, 1991; Burgis, 2006; Martín, 2008, and all their colleagues).

CHLAMYDIAL INFECTIONS

Chlamydia trachomatis is an obligate intracellular bacterium that has several serotypes, including those that cause *lymphogranuloma venereum (LGV)*. The most commonly encountered strains are those that attach only to columnar or transitional cell epithelium and cause cervical infection. It is the most commonly reported infectious disease in the United States with more than a million cases reported in 2006. It is estimated, however, that there are approximately 2.8 million new cases annually, although most are undiagnosed (Centers for Disease Control and Prevention, 2008c). Selective prenatal screening clinics in 2006 reported a median chlamydia infection rate of 8.1 percent (Centers for Disease Control and Prevention, 2009b).

Although most pregnant women have asymptomatic infection, a third present with urethral syndrome, urethritis, or Bartholin gland infection (Peipert, 2003). Mucopurulent cervicitis may be due to chlamydial or gonococcal infection or both. It may also represent normal, hormonally stimulated endocervical glands with abundant mucus production. Other chlamydial infections not usually seen in pregnancy are endometritis, salpingitis, peritonitis, reactive arthritis, and Reiter syndrome.

The role of chlamydial infection in pregnancy complications remains controversial. Only one study has reported a direct association between *C. trachomatis* and abortion, whereas most show no correlation (Coste, 1991; Paukku, 1999; Rastogi, 2000; Sozio and Ness, 1998; Sugiura-Ogasawara, 2005, and all their associates). It is disputed whether untreated cervical infection increases the risk of preterm delivery, preterm ruptured membranes, and perinatal mortality (Andrews, 2000, 2006; Baud, 2008; Blas, 2007, and all their colleagues).

Chlamydial infection has not been associated with an increased risk of chorioamnionitis nor with pelvic infection after cesarean delivery (Blanco and colleagues, 1985; Gibbs and Schachter, 1987). Conversely, delayed postpartum uterine metritis has been described by Hoyme and associates (1986). The syndrome, which develops 2 to 3 weeks postpartum, is distinct from early postoperative metritis. It is characterized by vaginal bleeding or discharge, low-grade fever, lower abdominal pain, and uterine tenderness.

There is vertical transmission to 30 to 50 percent of neonates delivered vaginally from infected women. Perinatal transmission to neonates can cause pneumonia, and *C. trachomatis* is the most commonly identifiable infectious cause of ophthalmia neonatorum (see Chap. 28, p. 598).

TABLE 59-4. Treatment of *Chlamydia trachomatis* Infections During Pregnancy

Regimen	Drug and Dosage
Preferred choice	Azithromycin, 1000 mg orally as a single dose *or* Amoxicillin, 500 mg orally three times daily for 7 days
Alternatives	Erythromycin base, 500 mg orally four times daily for 7 days *or* Erythromycin ethylsuccinate, 800 mg orally four times daily for 7 days *or* Erythromycin base, 250 mg orally four times daily for 14 days *or* Erythromycin ethylsuccinate, 400 mg orally four times daily for 14 days

From the Centers for Disease Control and Prevention (2006b).

Screening and Treatment

Prenatal screening for *C. trachomatis* is a complex issue, although there is little evidence for its effectiveness in asymptomatic women who are not in high-risk groups (Kohl and colleagues, 2003; Meyers and co-workers, 2007; Peipert, 2003). Identification and treatment of asymptomatic infected women may prevent neonatal infections, but evidence of prevention of adverse pregnancy outcome is lacking. Currently, the U.S. Preventive Services Task Force (2007) and the CDC recommend prenatal screening at the first prenatal visit for women at increased risk for chlamydial infection and again during the third trimester if the high-risk behavior continues. In a study of 149 pregnant women with lower genital tract chlamydia, Miller (1998) found that 17 percent had recurrent chlamydial colonization after treatment. Interestingly, in another study, Sheffield and colleagues (2005) found that 44 percent of pregnant women with asymptomatic cervical chlamydia underwent spontaneous resolution of infection.

Diagnosis is made predominantly by culture or NAAT. Cultures are more expensive and less accurate than newer NAATs, including PCR (Greer and Wendel, 2008). Andrews and associates (1997) reported that a ligase chain reaction assay was both sensitive and specific for genitourinary infection in pregnant women.

Currently recommended regimens are shown in Table 59-4. Azithromycin is first-line treatment and has been found to be safe and efficacious in pregnancy (Adair, 1998; Jacobson, 2001; Kacmar, 2001; Rahangdale, 2006, and all their colleagues). The fluoroquinolones and doxycycline are avoided in pregnancy, as is erythromycin estolate because of drug-related hepatotoxicity. Subsequent chlamydial testing 3 to 4 weeks after completion of therapy is recommended.

Lymphogranuloma Venereum

Several serovars of *C. trachomatis* cause LGV. The primary genital infection is transient and seldom recognized. Inguinal adenitis may develop and at times lead to suppuration. It may be confused with chancroid. Ultimately, the lymphatics of the lower genital tract and perirectal tissues may be involved, with sclerosis and fibrosis, which can cause vulvar elephantiasis and severe rectal stricture. Fistula formation involving the rectum, perineum, and vulva also may evolve.

For treatment during pregnancy, erythromycin, 500 mg orally four times daily, is given for 21 days (Centers for Disease Control and Prevention, 2006b). Although data regarding efficacy are scarce, some authorities recommend azithromycin given in multiple doses daily for 3 weeks.

HERPES SIMPLEX VIRUS

Genital herpes simplex virus (HSV) infection is one of the most common sexually transmitted diseases—there are an estimated 50 million adolescents and adults currently affected (Centers for Disease Control and Prevention, 2006b). In 2006 alone, there were 371,000 initial office visits for genital herpes (Centers for Disease Control and Prevention, 2009b). Although most women are unaware of their infection, about one in five has serological evidence for HSV-2 infection (Xu and associates, 2006, 2007). As most cases of HSV are transmitted by persons who are asymptomatic or unaware of their disease, this has become a major public health concern. It is estimated that 0.5 to 2 percent of pregnant women acquire HSV-1 or -2 during pregnancy (Brown and colleagues, 1997).

Pathogenesis and Transmission

Two types of HSV have been distinguished based on immunological and clinical differences. Type 1 is responsible for most nongenital infections, however, more than half of new cases of genital herpes in adolescents and young adults are caused by HSV-1 infection. This is thought to be due to an increase in oral-genital sexual practices (Mertz and associates, 2003; Roberts and colleagues, 2003). Type 2 HSV is recovered almost exclusively from the genital tract and is usually transmitted by sexual contact. Most recurrences—greater than 90 percent—are secondary to HSV-2. There is a large amount of DNA sequence homology between the two viruses, and prior infection with one type attenuates a primary infection with the other type.

Neonatal transmission is by three routes: (1) intrauterine in 5 percent, (2) peripartum in 85 percent, or (3) postnatal in 10 percent (Kimberlin, 2004; Kimberlin and Rouse, 2004). The fetus becomes infected by virus shed from the cervix or lower genital tract. It either invades the uterus following membrane rupture or is transmitted by contact with the fetus at delivery. The rate of transmission is 1 in 3200 to 1 in 30,000 births depending on the population studied (Brown, 2005; Mahnert, 2007; Whitley, 2007, and all their associates). Neonatal herpes is caused by both HSV-1 and HSV-2, although HSV-2 infection predominates. Most infected infants are born to mothers with no reported history of HSV infection.

The risk of neonatal infection correlates with the presence of HSV in the genital tract, the type of HSV, invasive obstetrical procedures, and stage of maternal infection (Brown and associates, 2005, 2007). Infants born to women who acquire genital HSV near the time of delivery have a 30- to 50-percent risk of infection. This is attributed to higher viral loads and the lack of transplacental protective antibodies (Brown and co-workers, 1997). Women with recurrent HSV have less than a 1-percent risk of neonatal infection (Brown and colleagues, 1997; Prober and associates, 1987).

Clinical Manifestations

Once transmitted by genital-genital or oral-genital contact, HSV-1 or -2 replicates at the site of entry. Following mucocutaneous infection, the virus moves retrograde along sensory nerves where it then remains latent in cranial nerves or dorsal spinal ganglia. HSV infections may be categorized into three groups:

1. *First episode primary infection* describes cases in which HSV-1 or -2 is isolated from genital secretions in the absence of HSV-1 or -2 antibodies. Only a third of newly acquired HSV-2 genital infections are symptomatic (Langenberg and colleagues, 1999). The typical incubation period of 2 to 10 days may be followed by a "classic presentation," characterized by a papular eruption with itching or tingling, which then becomes painful and vesicular. Multiple vulvar and perineal lesions may coalesce, and inguinal adenopathy may be severe (**Fig. 59-5**). Transient systemic influenza-like symptoms are common and are presumably caused by viremia. Hepatitis, encephalitis, or pneumonia may develop, although disseminated disease is rare. Cervical involvement is common, but it may be inapparent clinically. Some cases are severe enough to require hospitalization. In 2 to 4 weeks, all signs and symptoms of infection disappear. Many women do not present with the typical lesions—instead, a pruritic or painful abraded area or knife-slit may be present.
2. *First episode nonprimary infection* is diagnosed when HSV is isolated in women who have only the other serum HSV antibody present. For example, HSV-2 is isolated from genital secretions in women already expressing serum HSV-1 antibodies. In general, these infections are characterized by fewer lesions, fewer systemic manifestations, less pain, and briefer duration of lesions and viral shedding. This is likely because of some immunity from cross-reacting antibodies, for example, from childhood-acquired HSV-1 infection. In many cases, it may be impossible to differentiate clinically between the two types of first infection. Thus, serological confirmation may be beneficial.
3. *Reactivation disease* is characterized by isolation of HSV-1 or -2 from the genital tract in women with the same serotype antibodies. During the latency period, in which viral particles reside in nerve ganglia, reactivation is common and mediated through variable but poorly understood stimuli. Reactivation is termed *recurrent infection* and results in herpesvirus shedding. Most recurrent genital herpes is caused by type 2 virus (Centers for Disease Control and Prevention, 2006b). These lesions generally are fewer in number, are less tender, and shed virus for shorter periods—2 to 5 days—than those of primary infection. Typically, they recur at the same sites. Recurrences are most common in the first year after initial infection, and rates slowly decline over several years.

FIGURE 59-5 First-episode primary genital herpes simplex virus infection. (From Wendel and Cunningham, 1991, with permission.)

Asymptomatic viral shedding is defined by HSV as detected by culture or PCR in the absence of signs or symptoms. Most infected women shed virus intermittently, and most HSV transmission to a partner occurs during periods of asymptomatic viral shedding. Gardella and colleagues (2005) reported an HSV culture-positive rate of 0.5 percent

and a PCR-positive rate of 2.7 percent in asymptomatic women presenting for delivery. More data are needed to determine the effect of asymptomatic shedding on neonatal transmission.

Most primary and first-episode infections in early pregnancy are probably not associated with an increased rate of spontaneous abortion or stillbirth (Eskild and co-workers, 2002). In their review, Fagnant and Monif (1989) found only 15 cases of congenital herpetic infection that were acquired during early pregnancy. Brown and Baker (1989) reported that late-pregnancy primary infection may be associated with preterm labor.

Newborn infection may present several ways. Infection may be localized to eye or mouth disease in about 35 percent of cases. Central nervous system disease with encephalitis is seen in 30 percent of cases. Disseminated disease with involvement of multiple major organs is found in 25 percent (**Fig. 59-6**). Localized infection is usually associated with a good outcome. Conversely, even with acyclovir treatment, disseminated infection has a mortality rate of nearly 30 percent (Kimberlin, 2004; Kimberlin and co-workers, 2001a, b). Importantly, serious developmental and central nervous system morbidity is seen in 20 to 50 percent of survivors with disseminated or cerebral infection.

Diagnosis

According to the Centers for Disease Control and Prevention (2006b), clinical diagnosis of genital herpes is both insensitive and nonspecific and should be confirmed by laboratory testing. HSV tests available are either virological or type-specific serological tests.

Virological tests are performed on a specimen from a mucocutaneous lesion. Cell culture is preferred. However, the sensitivity of HSV isolation is relatively low as primary vesicular lesions ulcerate and then crust in recurrent lesions, and viral isolation results sometimes are not available for 1 to 2 weeks. Although PCR assays are more sensitive, and results generally are available in 1 to 2 days, currently these are not yet approved for genital specimens by the Food and Drug Administration (FDA). The PCR assay, however, is the preferred test for HSV detection in spinal fluid. Regardless of the test performed, HSV viral type should be differentiated because HSV type influences counseling and long-term prognosis. *A negative culture or PCR result does not exclude the presence of infection. False-positive results are rare.*

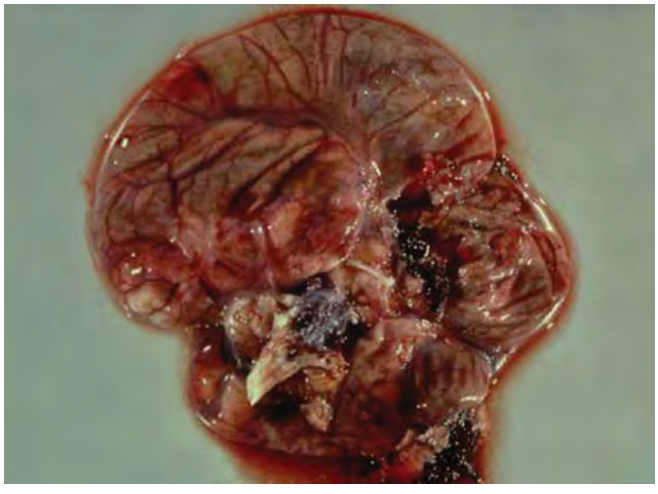

FIGURE 59-6 Cross-section showing necrotic brain tissue in a newborn who died from disseminated herpesvirus infection.

Several serological assay systems are available to detect antibody to HSV glycoproteins G1 and G2 (Anzivino and co-workers, 2009). These proteins evoke type-specific antibody responses to HSV-1 and HSV-2 infection (Ashley, 2001). These tests have the potential to reliably differentiate HSV-1 from HSV-2 antibody and permit confirmation of clinical infection as well as to identify asymptomatic carriers. The FDA has approved type-specific tests that are enzyme-linked immunosorbent assay (ELISA) or blot-style tests. These include *HerpeSelect ELISA*, *HerpeSelect Immunoblot,* and the *Captia HSV Type Specific test kit* (Centers for Disease Control and Prevention, 2006b). The FDA has also approved two rapid or point-of-care tests—the *biokitHSV-2 Rapid Test* and the *SureVue HSV-2 Rapid Test.* The reported sensitivities for all these tests are 90 to 100 percent with specificities of 91 to 100 percent (Greer, 2008; Laderman, 2008; Wald and Ashley-Morrow, 2002, and all their colleagues). Because nearly all HSV-2 infections are sexually acquired, detection of HSV-2 antibodies is virtually diagnostic of genital infection (Wald, 2004). HSV-1 antibodies may indicate prior oral HSV-1 infection or genital infection.

Prenatal Serological Screening

Brown (2000) and Wald and Ashley-Morrow (2002) have proposed prenatal serological HSV-2 antibody screening of couples. This supposedly would stimulate the need for safer sex practices and for antiviral suppression precautions if there is a discordancy, that is, one seronegative and one seropositive partner. This is controversial, and there is no clinical evidence that it may prevent HSV transmission and neonatal infection (Scoular, 2002; Wilkinson and associates, 2000). Cost-decision analysis for prenatal type-specific antibody screening and suppressive therapy for partners was judged unacceptable by Rouse and Stringer (2000), Barnabas and co-workers (2002), and Thung and Grobman (2005), but potentially cost-effective by Baker and associates (2004). Cleary and associates (2005) calculated that universal prenatal screening would reduce rates of perinatal death and severe sequelae from neonatal HSV. They also found that it would require treatment of 3849 women to prevent one case of neonatal death or disease with severe sequelae. Currently, the American College of Obstetricians and Gynecologists (2007a) does not recommend routine HSV screening of pregnant women.

Management

Antiviral therapy with acyclovir, famciclovir, or valacyclovir has been used for treatment of first-episode genital herpes in nonpregnant patients. Oral or parenteral preparations attenuate clinical infection and the duration of viral shedding. Suppressive therapy has also been given to limit recurrent infections and to

reduce heterosexual transmission (Corey and colleagues, 2004). For intense discomfort, analgesics and topical anesthetics may provide some relief, and urinary retention is treated with an indwelling bladder catheter.

Acyclovir appears to be safe for use in pregnant women (Ratanajamit and associates, 2003). The manufacturer of acyclovir and valacyclovir, in cooperation with the Centers for Disease Control and Prevention, have maintained a registry of outcomes following exposure to these drugs during pregnancy through 1999. More than 700 neonates exposed during the first trimester were evaluated, and they had no increased adverse effects (Reiff-Eldridge and co-workers, 2000; Scott, 1999). There are theoretical concerns about potential neutropenia that is similar to that seen in infants given long-term suppressive therapy (Kimberlin, 2004). At this time, there are insufficient data with famciclovir exposure, although a pregnancy registry is being maintained.

Women with a primary outbreak during pregnancy may be given antiviral therapy to attenuate and decrease the duration of symptoms and viral shedding (Table 59-5). Women with HIV coinfection may require a longer duration of treatment. Those with severe or disseminated HSV are given intravenous acyclovir, 5 to 10 mg/kg, every 8 hours for 2 to 7 days until clinical improvement is observed. This is followed by oral antiviral therapy to complete at least 10 days of total therapy (Centers for Disease Control and Prevention, 2006b). Recurrent HSV infections during pregnancy are treated for symptomatic relief only (see Table 59-5).

Peripartum Shedding Prophylaxis

A number of studies have shown that acyclovir or valacyclovir suppression initiated at 36 weeks will decrease the number of HSV outbreaks at term, thus decreasing the need for cesarean delivery (Hollier and Wendel, 2008). Such suppressive therapy will also decrease viral shedding defined by both culture and PCR techniques (Braig, 2001; Scott, 2002; Sheffield, 2006; Watts, 2003, and all their colleagues). A systemic review of studies of acyclovir prophylaxis given from 36 weeks to delivery was reported by Sheffield and colleagues (2003). They found that delivery suppressive therapy was associated with significantly decreased rates of clinical HSV recurrence, cesarean deliveries for HSV recurrences, total HSV detection, and asymptomatic shedding. Subsequent studies using valacyclovir suppression have shown similar results (Andrews and colleagues, 2006; Sheffield and associates, 2006). Because of these studies, the American College of Obstetricians and Gynecologists (2007a) recommends viral therapy at or beyond 36 weeks for women who have any recurrence during pregnancy. It is unclear whether suppression is needed for women with outbreaks before but not during pregnancy.

Upon presentation for delivery, a woman with a history of HSV should be questioned regarding prodromal symptoms such as vulvar burning or itching. A careful examination of the vulva, vagina, and cervix should be performed and suspicious lesions cultured. Cesarean delivery is indicated for women with active genital lesions or prodromal symptoms (American College of Obstetricians and Gynecologists, 2007a). Of note, 10 to 15 percent of infants with HSV are born to women undergoing cesarean delivery. Cesarean delivery is not recommended for women with a history of HSV infection but no active genital disease at the time of delivery. Moreover, an active lesion in a nongenital area is not an indication for cesarean delivery. Instead, an occlusive dressing is placed, and vaginal delivery allowed.

There is no evidence that external lesions cause ascending fetal infection with preterm ruptured membranes. Major and associates (2003) described expectant management of preterm rupture in 29 women less than 31 weeks. There were no cases of neonatal HSV, and the maximum risk of infection was calcu-

TABLE 59-5. Antiviral Medications for Herpesvirus Infection in Pregnancy

Indication	Pregnancy Recommendation
Primary or first episode infection	Acyclovir, 400 mg orally three times daily for 7–10 days *or* Valacyclovir, 1 g orally twice daily for 7–10 days
Symptomatic recurrent infection	Acyclovir, 400 mg orally three times daily for 5 days *or* Acyclovir, 800 mg orally twice daily for 5 days *or* Valacyclovir, 500 mg orally twice daily for 3 days *or* Valacyclovir, 1 g orally once daily for 5 days
Daily suppression	Acyclovir, 400 mg orally three times daily from 36 weeks until delivery *or* Valacyclovir, 500 mg orally twice daily from 36 weeks until delivery

Adapted from the Centers for Disease Control and Prevention Sexually Transmitted Diseases Treatment Guidelines (2006b).

lated to be 10 percent. The use of antiviral treatment in this setting is reasonable, but of unproven efficacy. For women with a clinical recurrence at delivery, there is not an absolute duration of membrane rupture beyond which the fetus would not benefit from cesarean delivery (American College of Obstetricians and Gynecologists, 2007b).

Women with active HSV may breast feed if there are no active HSV breast lesions. Strict hand washing is advised. Valacyclovir and acyclovir may be used during breast feeding as drug concentrations in breast milk are low. One study found the acyclovir concentration to be only 2 percent of that used for therapeutic dosing of the neonate (Sheffield and associates, 2002a).

CHANCROID

Haemophilus ducreyi can cause painful, nonindurated genital ulcers termed soft chancres that at times are accompanied by painful suppurative inguinal lymphadenopathy. Although common in some developing countries, it had become rare in the United States by the 1970s. By 1987, however, its incidence had increased tenfold during the previous decade, and drug use and sex-for-drugs were shown to be important risk factors (Schmid and co-workers, 1987). Importantly, the ulcerative lesion is a high-risk cofactor for HIV transmission (Centers for Disease Control and Prevention, 2006b).

Diagnosis by culture is difficult because appropriate media are not widely available. Instead, clinical diagnosis is made when typical painful genital ulcer(s) are darkfield negative and herpesvirus tests are negative. No FDA-cleared PCR test is yet available. Recommended treatment in pregnancy is azithromycin, 1 g orally as a single dose; erythromycin base, 500 mg orally three times daily for 7 days; or ceftriaxone, 250 mg in a single intramuscular dose (Centers for Disease Control and Prevention, 2006b).

HUMAN PAPILLOMAVIRUS

Human papillomavirus (HPV) has become one of the most common STDs with more than 30 types infecting the genital area. Most reproductive-aged women become infected within a few years of becoming sexually active, although most infections are asymptomatic and transient. High-risk HPV types 16 and 18 are associated with dysplasia and are discussed in Chapter 57. Mucocutaneous external genital warts are usually caused by HPV types 6 and 11 but may also be caused by intermediate- and high-oncogenic-risk HPV.

The most recent National Health and Nutrition Examination Survey (NHANES) 2003 to 2004 reported an overall HPV prevalence of 27 percent in the female population aged 14 to 59 years (Dunne and associates, 2007). A 27-percent seroprevalence was also reported for subjects 18 through 25 years in the National Longitudinal Study of Adolescent Health (Manhart and associates, 2006). Similar rates of HPV positivity have been reported for pregnant women (Gajewska, 2005; Hagensee, 1999; Hernandez-Giron, 2005; Smith, 2004; Worda, 2005, and all their colleagues).

External Genital Warts

For unknown reasons, genital warts frequently increase in number and size during pregnancy. Acceleration of viral replication by the physiological changes of pregnancy might explain the growth of perineal lesions and progression of some to cervical neoplasm (Fife and co-workers, 1999; Rando and colleagues, 1989). These lesions may sometimes grow to fill the vagina or cover the perineum, thus making vaginal delivery or episiotomy difficult (Fig. 59-7). Because HPV infection may be subclinical and multifocal, most women with vulvar lesions also have cervical infection, and vice versa (Ault, 2003; Spitzer and associates, 1989).

Treatment

There may be an incomplete response to treatment during pregnancy, but lesions commonly improve or regress rapidly following delivery. Consequently, eradication of warts during pregnancy is not always necessary. Therapy is directed toward minimizing treatment toxicity to the mother and fetus and debulking symptomatic genital warts. There are several agents available, but pregnancy limits their use. There is no definitive

FIGURE 59-7 Extensive external genital warts in a woman near term. (From Wendel and Cunningham, 1991, with permission.)

evidence that any one of the subsequently discussed treatments is superior to another (Centers for Disease Control and Prevention, 2006b; Wiley and co-workers, 2002).

Trichloroacetic or bichloracetic acid, 80- to 90-percent solution, applied topically once a week is an effective regimen for external warts. Some prefer *cryotherapy, laser ablation*, or *surgical excision* (Arena and colleagues, 2001; Centers for Disease Control and Prevention, 2006b). *Podophyllin resin, podofilox* 0.5-percent solution or gel, *imiquimod* 5-percent cream, and *interferon* therapy are not recommended in pregnancy because of concerns for maternal and fetal safety (Centers for Disease Control and Prevention, 2006b).

Neonatal Infection

Juvenile-onset recurrent respiratory papillomatosis is a rare, benign neoplasm of the larynx. It can cause hoarseness and respiratory distress in children and is often due to HPV types 6 or 11. In some cases, maternal genital HPV infection is associated with laryngeal papillomatosis, but studies differ in their findings of neonatal transmission rates. Although some have reported rates as high as 50 percent, it is likely that these findings are from maternal contamination or transient HPV infection (Watts and associates, 1998; Winer and Koutsky, 2004). A Danish population-based study indicated a risk of neonatal transmission of 7 per 1000 infected women (Silverberg and co-workers, 2003). Prolonged rupture of membranes was associated with a twofold increased risk, but risk was not associated with the mode of delivery. This low transmission risk has been confirmed in subsequent studies (Heim and associates, 2007; Smith and colleagues, 2004). Finally, long-term follow-up studies are consistent with a very low vertical transmission risk (Manns and colleagues, 1999; Smith and associates, 2004). The benefit of cesarean delivery to decrease transmission risk is unknown, and thus it is currently not recommended solely to prevent HPV transmission (Centers for Disease Control and Prevention, 2006b).

VAGINITIS

Pregnant women commonly develop increased vaginal discharge, which in many instances is not pathological. Occasionally, however, troublesome leukorrhea is the result of vulvovaginal infections that include bacterial vaginosis, candidiasis, or trichomoniasis (Eckert, 2006).

Bacterial Vaginosis

Not an infection in the ordinary sense, bacterial vaginosis is a maldistribution of normal vaginal flora. Numbers of lactobacilli are decreased, and overrepresented species are anaerobic bacteria, including *Gardnerella vaginalis, Mobiluncus*, and some *Bacteroides* species. As many as 30 percent of nonpregnant women have vaginosis (Allsworth and Peipert, 2007; Simhan and associates, 2008). In pregnancy, it is associated with preterm birth (Denney and Culhane, 2009).

Treatment is reserved for symptomatic women, who usually complain of a fishy-smelling discharge. Preferred treatment is with metronidazole, 500 mg twice daily orally for 7 days. Alternatives are 0.75-percent metronidazole gel, 250-mg applicator-dose intravaginally three times daily for 7 days, or 2-percent clindamycin cream, one applicator dose inserted intravaginally at bedtime for 7 days (Centers for Disease Control and Prevention, 2006b). Unfortunately, treatment does not reduce preterm birth, and routine screening is not recommended (American College of Obstetricians and Gynecologists, 2001).

Trichomoniasis

Trichomonas vaginalis can be identified during prenatal examination in as many as 20 percent of women. Symptomatic vaginitis is much less prevalent, and it is characterized by foamy leukorrhea with pruritus and irritation. Trichomonads are demonstrated readily in fresh vaginal secretions as flagellated, pear-shaped, motile organisms that are somewhat larger than leukocytes.

Metronidazole is effective in eradicating *T. vaginalis* administered orally in a single 2-g dose (Centers for Disease Control and Prevention, 2006b). It crosses the placenta and enters the fetal circulation. Rosa and colleagues (1987) found no increased frequency of birth defects in more than 1000 women given metronidazole during early pregnancy. Even so, many recommend against its use in early pregnancy. Some studies have linked trichomonal infection with preterm birth, however, treatment has not decreased this risk (Wendel and Workowski, 2007). Thus, screening and treatment of asymptomatic women is not recommended during pregnancy (see Chap. 36, p. 814).

Candidiasis

Candida albicans can be identified by culture from the vagina during pregnancy in approximately 25 percent of women. Asymptomatic colonization requires no treatment, but the organism may sometimes cause an extremely profuse, irritating discharge associated with a pruritic, tender, edematous vulva. Effective treatment is given with a number of azole creams that include 2-percent butoconazole, 1-percent clotrimazole, 2-percent miconazole, and 0.4- or 0.8-percent terconazole (Centers for Disease control and Prevention, 2006b). Topical treatment is recommended, although oral azoles are generally considered safe (Pitsouni and colleagues, 2008). Clotrimazole, miconazole, nystatin, and terconazole are also available as vaginal tablets (see Chap. 14, p. 319). In some women, infection is likely to recur and require repeated treatment during pregnancy. In these cases, symptomatic infection usually subsides after pregnancy (Sobel, 2007).

HUMAN IMMUNODEFICIENCY VIRUS (HIV) INFECTION

Acquired immunodeficiency syndrome (AIDS) was first described in 1981 when a cluster of patients was found to have defective cellular immunity and *Pneumocystis jiroveci* (formerly *P. carinii*) pneumonia (Gallo and Montagnier, 2003). Worldwide, it was estimated in 2007 that there were 33 million infected persons with HIV/AIDS, 2.7 million new cases of HIV infection, and 2 million HIV-related deaths (United Nations

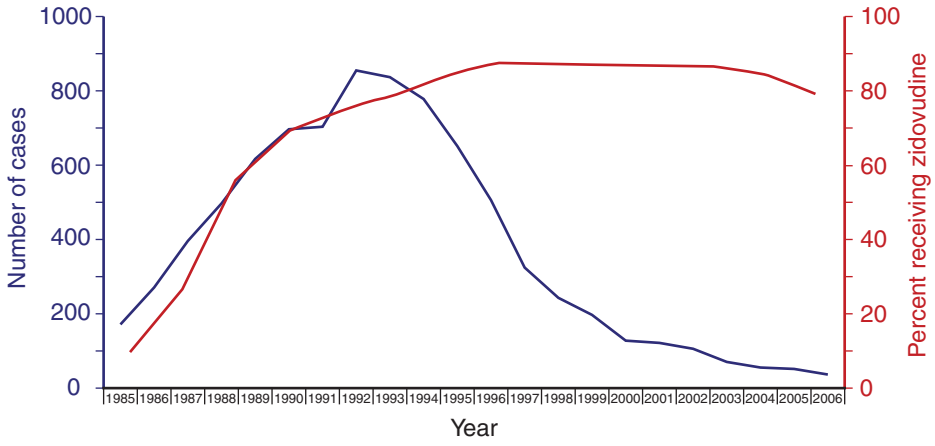

FIGURE 59-8 Estimated number of perinatally acquired AIDS cases by year of diagnosis, 1985 to 2006, in the United States and dependent areas (*blue line*). The red graph line depicts the percentage of women receiving zidovudine during pregnancy. (From the Centers for Disease Control and Prevention, 2009a.)

Programme on HIV/AIDS and World Health Organization, 2007). In the United States through 2006, the Centers for Disease Control and Prevention (2008b) estimated that there were 1.1 million infected individuals and almost a half million deaths. In 2006, women accounted for 26 percent of all HIV/AIDS cases among adults and adolescents, the vast majority of which resulted from heterosexual contact (Centers for Disease Control and Prevention, 2006a).

The estimated number of perinatally acquired AIDS cases had decreased dramatically over the last two decades. This is predominantly due to the implementation of prenatal HIV testing with antiviral therapy given to the pregnant woman and then to her neonate (Fig. 59-8). In addition, *highly active antiretroviral therapy (HAART)* has led to an increasing number of people living with chronic HIV infection (Fenton, 2007).

Etiopathogenesis

Causative agents of AIDS are RNA retroviruses termed *human immunodeficiency viruses*, *HIV-1 and HIV-2*. Most cases worldwide are caused by HIV-1 infection. Transmission is similar to hepatitis B virus, and sexual intercourse is the major mode. The virus also is transmitted by blood or blood-contaminated products, and mothers may infect their fetuses.

The common denominator of clinical illness with AIDS is profound immunosuppression that gives rise to a variety of opportunistic infections and neoplasms. Sexual transmission occurs when mucosal dendritic cells bind to the HIV envelope glycoprotein gp120. These dendritic cells then present the viral particle to thymus-derived lymphocytes, or *T lymphocytes*. These lymphocytes are defined phenotypically by the cluster of differentiation 4 (CD4) glycoprotein surface antigen. The CD4 site serves as a receptor for the virus. Co-receptors are necessary for viral entry into the cell, and two chemokine receptors—CCR5 and CXCR4—are the most commonly identified (Kahn and Walker, 1998; Sheffield and co-workers, 2007). The CCR5 co-receptor is found on the cell surface of CD4 positive ($CD4^+$) cells in high progesterone states such as pregnancy, possibly aiding viral entry (Sheffield and colleagues, 2009).

After initial infection, the level of viremia usually decreases to a *set-point*, and patients with the highest viral burden at this time progress more rapidly to AIDS and death (Fauci, 2007; Kahn and Walker, 1998). Over time, the number of T cells drops insidiously and progressively, resulting eventually in profound immunosuppression. Although it is thought that pregnancy has minimal effects on $CD4^+$ T-cell counts and HIV RNA levels, the latter are often higher 6 months postpartum than during pregnancy (U.S. Public Health Service Task Force, 2008).

Clinical Manifestations

The incubation period from exposure to clinical disease is days to weeks. Acute HIV infection is similar to many other viral syndromes and usually lasts less than 10 days. Common symptoms include fever and night sweats, fatigue, rash, headache, lymphadenopathy, pharyngitis, myalgias, arthralgias, nausea, vomiting, and diarrhea. After symptoms abate, the set-point of chronic viremia is established. The progression from asymptomatic viremia to AIDS has a median time of approximately 10 years (Fauci and Lane, 2008). Route of infection, the pathogenicity of the infecting viral strain, the initial viral inoculum, and the immunological status of the host all affect the rapidity of progression.

A number of clinical and laboratory manifestations will herald disease progression. Generalized lymphadenopathy, oral hairy leukoplakia, aphthous ulcers, and thrombocytopenia are common. A number of opportunistic infections associated with AIDS include esophageal or pulmonary candidiasis; persistent herpes simplex or zoster lesions; condyloma acuminata; pulmonary tuberculosis; cytomegaloviral pneumonia, retinitis, or gastrointestinal disease; molluscum contagiosum; *Pneumocystis jiroveci* pneumonia; toxoplasmosis; and others. Neurological disease is common, and approximately half of patients have central nervous system symptoms. A $CD4^+$ count $<200/mm^3$ is also considered definitive for the diagnosis of AIDS.

There are unique gynecological issues for women with HIV, such as menstrual abnormalities, contraceptive needs, and genital neoplasia as well as other STDs that may persist into pregnancy (Cejtin, 2003; Stuart and associates, 2005). Repeated pregnancy does not have significant effect on the clinical or immunological course of viral infection (Minkoff and colleagues, 2003).

Prenatal HIV Screening

The Center for Disease Control and Prevention (2006c), the American College of Obstetricians and Gynecologists

(2008), the American Academy of Pediatrics (2006), and the United States Preventive Services Task Force (2005) recommend prenatal screening using an *opt-out approach*. This means that the woman is notified that HIV testing is included in a comprehensive set of antenatal tests, but that testing may be declined. Women are given information regarding HIV but are not required to sign a specific consent. Through the use of such *opt-out* strategies, HIV testing rates have increased. Each provider should be aware of specific state laws concerning screening.

In areas in which the incidence of HIV or AIDS is 1 per 1000 person years or greater or in women at high risk for acquiring HIV during pregnancy, repeat testing in the third trimester is recommended (American College of Obstetricians and Gynecologists, 2008). High-risk factors include injection drug use, prostitution, a suspected or known HIV-infected sexual partner, multiple sexual partners, or a diagnosis of another sexually transmitted disease. Several states also recommend or require HIV testing at delivery.

Screening is performed using an ELISA test with a sensitivity of >99.5 percent. A positive test is confirmed with either a Western blot or immunofluorescence assay (IFA), both of which have high specificity. According to the Centers for Disease Control and Prevention (2001a, b), antibody can be detected in most patients within 1 month of infection, and thus, antibody serotesting may not exclude early infection. For acute primary HIV infection, identification of viral p24 core antigen or viral RNA or DNA is possible. False-positive confirmatory results are rare (Branson, 2007; Centers for Disease Control and Prevention, 2006c).

Women with limited prenatal care or with undocumented HIV status at delivery should have a "rapid" HIV test performed. These tests can detect HIV antibody in 60 minutes or less and have sensitivities and specificities comparable with those of conventional ELISAs. A negative rapid test result does not need to be confirmed. A positive rapid test result should be confirmed with a Western blot or IFA test. As shown in **Table 59-6**, peripartum and neonatal interventions to reduce perinatal transmission are based on the initial rapid testing results, and this can be discontinued if the confirmatory test is negative (American College of Obstetricians and Gynecologists, 2008; Centers for Disease Control and Prevention, 2006c).

The Mother-Infant Rapid Intervention at Delivery (MIRIAD) multicenter study indicated that rapid HIV testing can be used to identify infected women so that peripartum antiretroviral prophylaxis can be administered to mother and infant (Bulterys and colleagues, 2004). Branson (2007) reviewed the six FDA-approved rapid tests currently available—four are "point of care tests" and two require a laboratory.

Maternal and Perinatal Transmission

Transplacental HIV transmission can occur early, and the virus has even been identified in specimens from elective abortion (Lewis and co-workers, 1990). In most cases, however, mother-to-child transmission is the most common cause of pediatric HIV infections. Between 15 and 40 percent of neonates born to non-breast-feeding, untreated, HIV-infected mothers are infected. Kourtis and colleagues (2001) have proposed a model for estimation of the temporal distribution of vertical transmission. They estimate that 20 percent of transmission occurs before 36 weeks, 50 percent in the days before delivery, and 30 percent intrapartum (**Fig. 59-9**). Transmission rates for breast feeding may be as high as 30 to 40 percent (Kourtis and associates, 2006, 2007). Vertical transmission is more common with preterm births, especially with prolonged membrane rupture. Analyzing data from the Perinatal AIDS Collaborative Transmission Study, Kuhn and colleagues (1999) reported a 3.7 increased risk with preterm delivery. Landesman and co-workers (1996) reported that HIV-1 transmission at birth was increased from 15 to 25 percent in women whose membranes likely, for similar reasons, were ruptured for more than 4 hours.

In nonpregnant individuals, there is an association between concomitant STDs and horizontal HIV transmission. There is evidence that vertical perinatal transmission may also be increased (Koumans and colleagues, 2000; Schulte and co-workers, 2001). Recently, Cowan and associates (2008) showed that women with maternal HSV-2 antibody had a significant

TABLE 59-6. Strategy for Rapid HIV Testing of Pregnant Women in Labor

If the rapid HIV test result in labor and delivery is positive, the obstetrical provider should take the following steps:

1. Tell the woman she may have HIV infection and that her neonate also may be exposed
2. Explain that the rapid test result is preliminary and that false-positive results are possible
3. Assure the woman that a second test is being performed to confirm the positive rapid test result
4. To reduce the risk of transmission to the infant, immediate initiation of antiretroviral prophylaxis should be recommended without waiting for the results of the confirmatory test
5. Once the woman gives birth, discontinue maternal antiretroviral therapy pending receipt of confirmatory test results
6. Tell the women that she should postpone breast feeding until the confirmatory result is available because she should not breast feed if she is infected with HIV
7. Inform pediatric care providers (depending on state requirements) of positive maternal test results so that they may institute the appropriate neonatal prophylaxis

HIV = human immunodeficiency virus.

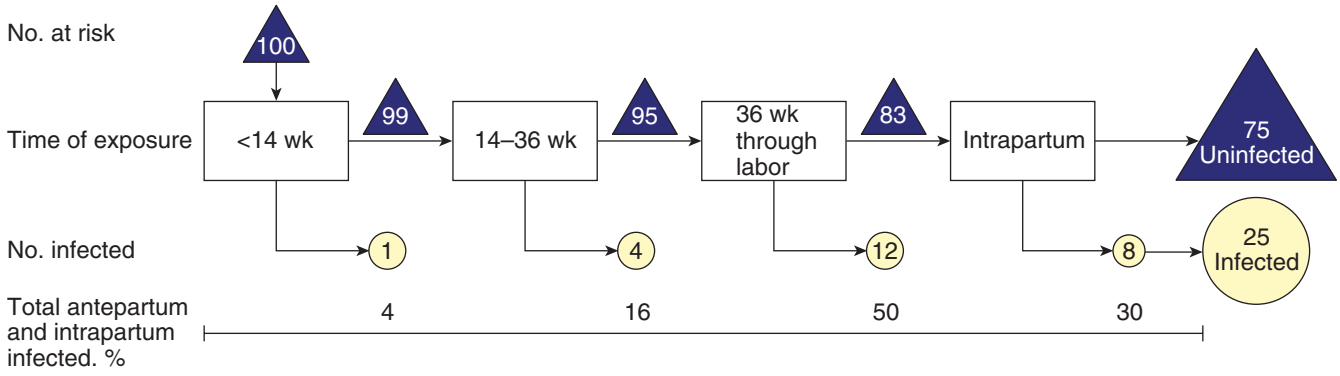

FIGURE 59-9 Estimated rates of perinatal human immunodeficiency virus (HIV) transmission for different times of gestation and delivery in non-breast-feeding populations. Estimates are based on a hypothetical cohort of 100 children born to HIV-infected women without any interventions. Numbers in blue indicated number of children at risk for infection. (From Kourtis and colleagues, 2001, with permission.)

50-percent increased risk of intrapartum HIV-1 maternal-to-child transmission. They attributed up to 25 percent of vertical transmission to maternal HSV-2 co-infection.

Perinatal HIV transmission is most accurately correlated with maternal plasma HIV RNA burden (U.S. Public Health Service Task Force, 2009; Watts, 2002). As shown in **Figure 59-10**, cohort neonatal infection was 1 percent with <400 copies/mL, and it was more than 30 percent when viral RNA levels were >100,000 copies/mL (Cooper and colleagues, 2002). Importantly, zidovudine (ZDV) therapy that reduced these levels to <500 copies/mL also minimized the risk of transmission, although ZDV is effective in reducing transmission across all HIV RNA levels. The investigators also reported that maternal infusions of HIV-1 hyperimmune globulin did not alter the risk of transmission. *Transmission, however, has been observed at all HIV RNA levels, including those that were nondetectable by current assays.* This may be attributed to discordance between the viral load in plasma and in the genital secretions. Because of these findings, the viral load should not be used to determine whether to initiate antiretroviral therapy in pregnancy.

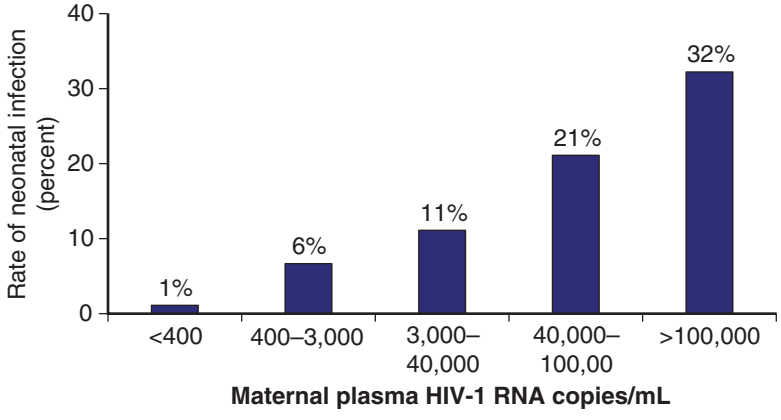

FIGURE 59-10 Incidence of perinatal human immunodeficiency virus (HIV) infection plotted against plasma HIV-1 RNA levels in 1542 neonates born to mothers in the Women and Infants Transmission Study. (Data from Cooper and colleagues, 2002.)

Maternal and Perinatal Outcomes

Although maternal morbidity and mortality rates are not increased in seropositive asymptomatic women, it appears that adverse fetal outcomes may be increased (U.S. Public Health Service Task Force, 2009). In a review of 634 HIV-infected women, Stratton and associates (1999) reported that adverse fetal outcomes were associated with a $CD4^+$ cell proportion of <15 percent. In these otherwise asymptomatic women, the rate of preterm birth was 20 percent and that of fetal-growth restriction was 24 percent. Watts (2002) emphasized that these adverse outcomes were even more prevalent in developing countries.

Preconceptional Counseling

An important aspect of preconceptional counseling includes that of effective contraception if pregnancy is undesired. Certain antiviral medications decrease the efficacy of hormonal contraception. These drug interactions are detailed by the U.S. Public Health Service Task Force (2009) and are discussed in Chapter 32 (p. 678). These recommendations are available at http://AIDSinfo.nih.gov and are updated frequently as new data become available. Counseling should also include education for decreasing high-risk sexual behaviors to prevent transmission and to decrease the acquisition of other sexually transmitted diseases. Currently taken antiretroviral medications are reviewed to be sure that those with high teratogenic potential are avoided if the woman becomes pregnant. A specific example is efavirenz, which has significant teratogenic effects on primate fetuses (Panel on Antiretroviral Guidelines for Adults and Adolescents, 2008). Preference should also include those that decrease HIV RNA viral load effectively prior to pregnancy.

Management During Pregnancy

These women need special attention and are seen in consultation with physicians with special interest in

this field. At Parkland Hospital, the initial assessment of an HIV-infected pregnant woman includes:

- Standard prenatal laboratory surveys that include serum creatinine, hemogram, and bacteriuria screening (see Chap. 8, p. 194)
- Plasma HIV RNA quantification—"viral load" and $CD4^+$ T-lymphocyte count as well as antiretroviral resistance testing
- Serum hepatic transaminase levels
- HSV-1 and -2, cytomegalovirus, toxoplasmosis, and hepatitis C screening
- Baseline chest radiograph
- Tuberculosis skin testing (PPD)
- Evaluation of need for pneumococcal, hepatitis B, and influenza vaccine
- Sonographic evaluation to establish gestational age.

Antiretroviral Therapy

Treatment is recommended for all HIV-infected pregnant women. This may be a departure for those not receiving treatment when nonpregnant because they did not meet certain criteria. Treatment reduces the risk of perinatal transmission regardless of $CD4^+$ T-cell count or HIV RNA level. Antiretroviral therapy is complicated, and pregnancy only adds to the complexity. In general, HAART is begun if the woman is not already receiving one of the regimens. Antiretroviral agents are grouped into several classes and used to design antiretroviral regimens (Table 59-7). The woman is counseled regarding risks and benefits of antiretroviral agents to make an informed decision as to her treatment regimen. Regardless of what regimen is begun, adherence is important because the risk of viral drug resistance is lessened.

The U.S. Public Health Service Task Force (2009) has issued guidelines that detail management of different scenarios during pregnancy (Table 59-8). Women already taking HAART at pregnancy onset are encouraged to continue the regimen if there is adequate viral suppression. The exception previously discussed is *efavirenz*, which should be discontinued in the first trimester because of teratogenicity concerns. Until recently, addition of zidovudine to all regimens was recommended. Currently, however, in women with adequate viremia suppression with a regimen not containing zidovudine, continuation of the current regimen is appropriate. In all women, zidovudine is given intravenously during labor and delivery (Table 59-9).

Women who have never received antiretroviral therapy—*antiretroviral naïve*—fall into two categories:

1. Women who meet the criteria for antiretroviral therapy initiation in nonpregnant adults are given HAART regardless of trimester, using a zidovudine-containing regimen if feasible. Because of an increased risk of hepatotoxicity, *nevirapine* is reserved for women with a $CD4^+$ cell count <250 cells/mm^3. In general, the starting HAART regimen is two nucleoside reverse transcriptase inhibitors (NRTIs) plus a non-nucleoside reverse transcriptase inhibitor (NNRTI) or protease inhibitor(s). At Parkland Hospital as of 2009, our standard regimen in treatment-naïve women is lopinavir/ritonavir—formulated as *Kaletra*—plus zidovudine/lamivudine—formulated as *Combivir*. Nelfinavir is substituted for *Kaletra* if not tolerated.
2. Treatment-naïve HIV-infected pregnant women who do not meet nonpregnant adult indications for antiretroviral therapy are counseled regarding benefits of initiating therapy to prevent perinatal viral transmission. Because of potential teratogenic effects, they may delay therapy until the second trimester. Again, zidovudine should be a component of the regimen if feasible. Although not used at our institution, zidovudine monotherapy is an option for some women who wish to limit medication exposure. Such monotherapy is controversial but may be used for women

TABLE 59-7. Classes of Antiretroviral Drugs

Drug Class	Category[a]
Nucleoside and nucleotide analog reverse transcriptase inhibitors	
Zidovudine	C
Zalcitabine	C
Didanosine	B
Stavudine	C
Lamivudine	C
Abacavir	C
Tenofovir	B
Emtricitabine	B
Non-nucleoside reverse transcriptase inhibitors	
Nevirapine	B
Delavirdine	C
Efavirenz	D
Protease inhibitors	
Indinavir	C
Ritonavir	B
Saquinavir	B
Nelfinavir	B
Amprenavir	C
Atazanavir	B
Fosamprenavir	C
Lopinavir/ritonavir	C
Darunavir	B
Entry inhibitors	
Enfuvirtide	B
Maraviroc	B
Integrase Inhibitors	
Raltegravir	C

TABLE 59-8. Recommendations for Antiviral Drug Use During Pregnancy

Clinical Scenario	Recommendations
HIV-infected woman on antiretroviral therapy who becomes pregnant	• Continue current medication if viral suppression adequate and patient tolerating — Avoid efavirenz in the first trimester • If virus detectable, order HIV antiretroviral drug-resistance testing • If first trimester, continue medications. If stopped, stop all medications and then reinitiate in the second trimester. • If not receiving zidovudine (ZDV) antepartum, start IV ZDV in labor (see Table 59-9)
HIV-infected woman who is antiretroviral naïve and has maternal indications for HAART	• Order HIV antiretroviral drug-resistance testing • Initiate HAART: — Avoid efavirenz in the first trimester — Use ZDV-containing regimen if feasible — Avoid nevirapine in women with a $CD4^+$ count >250 cells/mm^3 • HAART should be initiated as early as possible for maternal indications • If not receiving zidovudine antepartum, start IV ZDV in labor
HIV-infected woman who is antiretroviral naïve with no maternal indication for HAART	• Order HIV antiretroviral drug-resistance testing • Initiate HAART: — Consider delaying therapy until the start of the second trimester — Use ZDV-containing regimen if feasible — Avoid nevirapine in women with a $CD4^+$ count >250 cells/mm^3 • ZDV monotherapy is controversial: — If used, use in women with HIV RNA levels <1000 copies/mL — If not receiving zidovudine antepartum, start IV ZDV in labor
HIV-infected woman previously on antiretroviral medications but not on medications currently	• Order HIV antiretroviral drug-resistance testing • Initiate HAART with regimen based on prior therapy history and resistance testing • Avoid efavirenz in the first trimester • Use ZDV-containing regimen if feasible • Avoid nevirapine in women with a $CD4^+$ count >250 cells/mm^3 • If not receiving zidovudine antepartum, start IV ZDV in labor
HIV-infected woman on no antiretroviral medication who presents in labor	• Order initial HIV laboratory assessment (see p. 1250). • Start zidovudine intravenous protocol (Table 59-9) *or* • Start intravenous zidovudine plus a single dose of nevirapine (NVP). If NVP initiated, consider adding lamivudine for 7 days postpartum to decrease NVP resistance

HAART = highly active antiretroviral therapy; HIV = human immunodeficiency virus.
Adapted from the U.S. Public Health Service Task Force (2008).

with HIV RNA levels <1000 copies/mL who are not receiving treatment.

Another group of women have previously received antiretroviral therapy but are currently not taking medications. Prior antiretroviral use increases their risk of HIV drug resistance, and thus resistance testing is imperative. Regimens may then be tailored based on prior medication use and response as well as current resistance patterns.

The last group includes women who present in labor and who are taking no medications. These women are given intravenous zidovudine intrapartum (see Table 59-9). Some

TABLE 59-9. Pediatric AIDS Clinical Trials Group (PACTG) 076 Zidovudine Regimen

Time of Administration	Zidovudine Regimen
Antepartum	100 mg orally five times daily, initiated at 14 to 34 weeks and continued throughout pregnancy.[a]
Intrapartum	During labor, intravenous zidovudine in a 1-hour initial dose of 2 mg/kg, followed by a continuous infusion of 1 mg/kg/hr until delivery.[b]
Neonate	Begin at 8 to 12 hours after birth, and give syrup at 2 mg/kg every 6 hours for 6 weeks.[c]

[a]Acceptable alternative regimens include 200 mg three times daily or 300 mg twice daily.
[b]For elective cesarean delivery, intravenous zidovudine is begun at least 3 hours prior to surgery. For premature rupture of membranes or labor with a planned operative delivery, the loading dose may be given over the half hour prior to surgery.
[c]Intravenous dosage for infants who cannot tolerate oral intake is 1.5 mg/kg intravenously every 6 hours.
AIDS = acquired immunodeficiency syndrome.
From U.S. Public Health Service (2008).

experts recommend also giving one dose of nevirapine at labor onset, and if chosen, lamivudine administered for 7 days will decrease the development of nevirapine resistance (Arrive and colleagues, 2007; U.S. Public Health Service Task Force, 2009).

Laboratory Assessment

$CD4^+$ T-lymphocyte count, HIV RNA viral load measurement, complete blood count, and liver function tests are done 4 weeks after beginning or changing therapy to assess response and evidence of toxicity. Thereafter, HIV RNA viral load and $CD4^+$ quantification are determined each trimester. If the HIV RNA viral load increases or does not decrease appropriately, then medication compliance and antiretroviral drug resistance are assessed. Poor adherence to therapy appears to be a significant problem in pregnancy. In a study of 549 women from New York by Laine and associates (2000), poor compliance was reported in a third.

Although early studies found an association with glucose intolerance and protease inhibitor use, Tang and colleagues (2006) did not corroborate this. Even so, careful surveillance is important for interactions between antiretroviral drugs as well as therapies for opportunistic infection, methadone, and tuberculosis (Piscitelli and Gallicano, 2001).

Complications of HIV

Management of some HIV complications may be altered by pregnancy. If the $CD4^+$ T-cell count is $<200/mm^3$, primary prophylaxis for *P. jiroveci* (formerly *P. carinii)* pneumonia is recommended with sulfamethoxazole-trimethoprim or dapsone. Pneumonitis is treated with oral or intravenous sulfamethoxazole-trimethoprim or dapsone-trimethoprim. Other symptomatic opportunistic infections that may develop are from latent or newly acquired toxoplasmosis, herpesvirus, mycobacteria, and candida. The National Institutes of Health, Infectious Diseases Society of America, and Centers for Disease Control and Prevention (2008) have published guidelines for prevention and treatment of opportunistic infections.

Perinatal Outcomes

Even with treatment, the incidence of perinatal complications in HIV-infected women is increased. Lorenzi and colleagues (1998) reported that 78 percent of women treated with two reverse transcriptase inhibitors had one or more adverse events, especially preterm delivery. Half of the neonates had adverse events. Newer drug regimens may diminish these complications. Kourtis and colleagues (2007) performed a meta-analysis of 14 studies of HIV-infected women treated with antiretroviral therapy. They did not find an overall increased risk for preterm delivery, although there was a small but significant increased risk in women who were receiving therapy before or early in pregnancy. Tuomala and associates (2002) found no association with preterm birth, low birthweight, or stillbirths when combination antiretroviral therapy was used. These investigators did report that women given combination protease-inhibitor regimens had an increased risk of very-low-birthweight infants. Despite this, combined therapy should not be withheld (Watts, 2002).

At least two follow-up studies of children from the Pediatric AIDS Clinical Trial Group (PACTG) 076 Study found no adverse effects in children at 18 months and up to a mean of 5.6 years after zidovudine exposure (Culnane and associates, 1999; Sperling and colleagues, 1998). Prenatal exposure to HAART may increase the risk for neonatal neutropenia, although no long-term hematological or hepatic toxicities have been identified (Bae and colleagues, 2008). Early data also show a possible effect on infant mitochondrial DNA proliferation and/or expression with maternal antiretroviral drug treatment (Cote and co-workers, 2008).

Prenatal HIV Transmission. Maternal HAART treatment along with intrapartum zidovudine prophylaxis has dramatically reduced the perinatal HIV transmission risk from about 25 percent to 2 percent or less in women. Optimal management of labor is uncertain, but if labor is progressing with intact membranes, artificial rupture and invasive fetal monitoring are avoided. Labor augmentation is used when needed to shorten the interval-to-delivery to further decrease the risk of

transmission. Operative delivery with forceps or vacuum extractor is avoided if possible. Postpartum hemorrhage is managed with oxytocin and prostaglandin analogs because methergine and other ergot alkaloids interact with reverse transcriptase and protease inhibitors to cause severe vasoconstriction.

Cesarean delivery has been recommended to decrease HIV prenatal transmission. A meta-analysis of 15 prospective cohort studies by the International Perinatal HIV Group (1999) included 8533 mother-neonate pairs. Vertical HIV transmission was reduced by approximately half when cesarean delivery was compared with vaginal delivery. And when antiretroviral therapy was given in the prenatal, intrapartum, and neonatal periods along with cesarean delivery, the likelihood of neonatal transmission was reduced by 87 percent compared with other modes of delivery and without antiretroviral therapy. The European Mode of Delivery Collaboration (1999) and others have reported similar findings.

Based on these observations, the American College of Obstetricians and Gynecologists (2000) concluded that scheduled cesarean delivery should be discussed and recommended for HIV-infected women whose HIV-1 RNA load exceeds 1000 copies/mL. Scheduled delivery was recommended as early as 38 weeks to lessen the chances of prematurely ruptured membranes. Although data are insufficient to estimate such benefits of cesarean delivery for women whose HIV RNA levels are below 1000 copies/mL, it is unlikely that scheduled cesarean delivery would confer additional risk reduction (Jamieson and associates, 2007; Read and Newell, 2005; U.S. Public Health Service Task Force, 2009). If cesarean delivery is performed, use of standard perioperative antimicrobials for prophylaxis is recommended.

Breast Feeding

Vertical transmission is increased by breast feeding, and it generally is not recommended in HIV-positive women in this country (Read and co-workers, 2003). The probability of HIV transmission per liter of breast milk ingested is estimated to be similar in magnitude to heterosexual transmission with unsafe sex in adults (Richardson and colleagues, 2003). As with other exposures, risk is related to the maternal HIV RNA level, HIV disease status, breast health, and duration of breast feeding (De Cock and associates, 2000; John-Stewart and co-workers, 2004). Most transmission occurs in the first 6 months, and as many as two thirds of infections in breast-fed infants are from breast milk. In the Petra Study Team (2002) from Africa, the prophylactic benefits of short-course perinatal antiviral regimens were diminished considerably by 18 months of age due to breast feeding. The World Health Organization (2008) has recommended continuing breast feeding promotion with early weaning by 6 months for women living in developing countries in which infectious diseases and malnutrition are the primary causes of infant deaths.

Postpartum Management

Many otherwise healthy women with normal $CD4^+$ T-cell counts and low HIV RNA levels may discontinue treatment after delivery and be closely monitored according to adult guidelines. Psychosocial support is essential during this time, especially while awaiting diagnostic testing for pediatric infection. Contraceptive needs are complex and also may entail condoms in discordantly infected couples. As discussed in Chapter 32 (p. 678), antiretroviral drugs may affect hormone levels of oral contraceptives and possibly of injectable agents (Stuart and Cunningham, 2008). Intrauterine devices may be an acceptable choice in some women with normal immunocompetence and a low risk for STDs. Gynecological care is complex in HIV-infected women and has been comprehensively reviewed by Cejtin (2003).

APPENDIX

Reference Table of Normal Laboratory Values in Uncomplicated Pregnancies

HEMATOLOGY

	Nonpregnant Adult[a]	First Trimester	Second Trimester	Third Trimester	References
Erythropoietin[b] (U/L)	4–27	12–25	8–67	14–222	7, 10, 47
Ferritin[b] (ng/mL)	10–150[d]	6–130	2–230	0–116	7, 10, 39, 42, 45, 47, 62, 70
Folate, red blood cell (ng/mL)	150–450	137–589	94–828	109–663	45, 46, 72
Folate, serum (ng/mL)	5.4–18.0	2.6–15.0	0.8–24.0	1.4–20.7	7, 43, 45, 46, 53, 58, 72
Hemoglobin[b] (g/dL)	12–15.8[d]	11.6–13.9	9.7–14.8	9.5–15.0	10, 45, 47, 58, 62
Hematocrit[b] (%)	35.4–44.4	31.0–41.0	30.0–39.0	28.0–40.0	6, 7, 10, 42, 45 58, 66
Iron, total binding capacity (TIBC)[b] (μg/dL)	251–406	278–403	Not reported	359–609	62
Iron, serum[b] (μg/dL)	41–141	72–143	44–178	30–193	10, 62
Mean corpuscular hemoglobin (MCH) (pg/cell)	27–32	30–32	30–33	29–32	42
Mean corpuscular volume (MCV) ($\times m^3$)	79–93	81–96	82–97	81–99	6, 42, 45, 58
Platelet ($\times 10^9$/L)	165–415	174–391	155–409	146–429	4, 6, 16, 42, 45
Mean platelet volume (MPV) (μm^3)	6.4–11.0	7.7–10.3	7.8–10.2	8.2–10.4	42
Red blood cell count (RBC) ($\times 10^6/mm^3$)	4.00–5.20[d]	3.42–4.55	2.81–4.49	2.71–4.43	6, 42, 45, 58
Red cell distribution width (RDW) (%)	<14.5	12.5–14.1	13.4–13.6	12.7–15.3	42
White blood cell count (WBC) ($\times 10^3/mm^3$)	3.5–9.1	5.7–13.6	5.6–14.8	5.9–16.9	6, 9, 42, 45, 58
Neutrophils ($\times 10^3/mm^3$)	1.4–4.6	3.6–10.1	3.8–12.3	3.9–13.1	4, 6, 9, 42
Lymphocytes ($\times 10^3/mm^3$)	0.7–4.6	1.1–3.6	0.9–3.9	1.0–3.6	4, 6, 9, 42
Monocytes ($\times 10^3/mm^3$)	0.1–0.7	0.1–1.1	0.1–1.1	0.1–1.4	6, 9, 42
Eosinophils ($\times 10^3/mm^3$)	0–0.6	0–0.6	0–0.6	0–0.6	6, 9
Basophils ($\times 10^3/mm^3$)	0–0.2	0–0.1	0–0.1	0–0.1	6, 9
Transferrin (mg/dL)	200–400	254–344	220–441	288–530	39, 42
Transferrin, saturation without iron (%)	22–46[b]	Not reported	10–44	5–37	47
Transferrin, saturation with iron (%)	22–46[b]	Not reported	18–92	9–98	47

COAGULATION

	Nonpregnant Adult[a]	First Trimester	Second Trimester	Third Trimester	References
Antithrombin III, functional (%)	70–130	89–114	78–126	82–116	15, 16, 74
D-Dimer (μg/mL)	0.22–0.74	0.05–0.95	0.32–1.29	0.13–1.7	16, 25, 35, 51, 74, 75
Factor V (%)	50–150	75–95	72–96	60–88	40
Factor VII (%)	50–150	100–146	95–153	149–2110	16
Factor VIII (%)	50–150	90–210	97–312	143–353	16, 40
Factor IX (%)	50–150	103–172	154–217	164–235	16
Factor XI (%)	50–150	80–127	82–144	65–123	16
Factor XII (%)	50–150	78–124	90–151	129–194	16
Fibrinogen (mg/dL)	233–496	244–510	291–538	301–696	16, 25, 42, 51, 74, 75
Homocysteine (μmol/L)	4.4–10.8	3.34–11	2.0–26.9	3.2–21.4	43, 45, 46, 53, 72
International normalized ratio (INR)	0.9–1.04[g]	0.86–1.08	0.83–1.02	0.80–1.09	15, 75
Partial thromboplastin time, activated (aPTT) (sec)	26.3–39.4	23.0–38.9	22.9–38.1	22.6–35.0	15, 16, 42, 75
Prothrombin time (PT) (sec)	12.7–15.4	9.7–13.5	9.5–13.4	9.6–12.9	16, 42, 75
Protein C, functional (%)	70–130	78–121	83–133	67–135	15, 24, 40
Protein S, total (%)	70–140	39–105	27–101	33–101	16, 24, 40
Protein S, free (%)	70–140	34–133	19–113	20–65	24, 40
Protein S, functional activity (%)	65–140	57–95	42–68	16–42	40
Tissue plasminogen activator (ng/mL)	1.6–13[h]	1.8–6.0	2.36–6.6	3.34–9.20	15, 16
Tissue plasminogen activator inhibitor-1 (ng/mL)	4–43	16–33	36–55	67–92	16
von Willebrand measurements					
von Willebrand factor antigen (%)	75–125	62–318	90–247	84–422	73, 74, 76
ADAMTS-13, von Willebrand cleaving protease (%)	40–170[i]	40–160	22–135	38–105	74, 76

BLOOD CHEMICAL CONSTITUTENTS

	Nonpregnant Adult[a]	First Trimester	Second Trimester	Third Trimester	References
Alanine transaminase (ALT) (U/L)	7–41	3–30	2–33	2–25	5, 39, 42, 70
Albumin (g/dL)	4.1–5.3[d]	3.1–5.1	2.6–4.5	2.3–4.2	3, 5, 26, 29, 39, 42, 72
Alkaline phosphatase (U/L)	33–96	17–88	25–126	38–229	3, 5, 39, 42, 70
Alpha-1 antitrypsin (mg/dL)	100–200	225–323	273–391	327–487	42
Amylase (U/L)	20–96	24–83	16–73	15–81	32, 39, 42, 68
Anion gap (mmol/L)	7–16	13–17	12–16	12–16	42
Aspartate transaminase (AST) (U/L)	12–38	3–23	3–33	4–32	5, 39, 42, 70
Bicarbonate (mmol/L)	22–30	20–24	20–24	20–24	42
Bilirubin, total (mg/dL)	0.3–1.3	0.1–0.4	0.1–0.8	0.1–1.1	5, 39
Bilirubin, unconjugated (mg/dL)	0.2–0.9	0.1–0.5	0.1–0.4	0.1–0.5	5, 42
Bilirubin, conjugated (mg/dL)	0.1–0.4	0–0.1	0–0.1	0–0.1	5
Bile acids (μmol/L)	0.3–4.8[j]	0–4.9	0–9.1	0–11.3	5, 14
Calcium, ionized (mg/dL)	4.5–5.3	4.5–5.1	4.4–5.0	4.4–5.3	26, 42, 48, 56
Calcium, total (mg/dL)	8.7–10.2	8.8–10.6	8.2–9.0	8.2–9.7	3, 29, 39, 42, 48, 56, 63
Ceruloplasmin (mg/dL)	25–63	30–49	40–53	43–78	42, 44
Chloride (mEq/L)	102–109	101–105	97–109	97–109	20, 39, 42
Creatinine (mg/dL)	0.5–0.9[d]	0.4–0.7	0.4–0.8	0.4–0.9	39, 42, 45
Gamma-glutamyl transpeptidase (GGT) (U/L)	9–58	2–23	4–22	3–26	5, 42, 39, 70
Lactate dehydrogenase (U/L)	115–221	78–433	80–447	82–524	42, 29, 39, 70
Lipase (U/L)	3–43	21–76	26–100	41–112	32
Magnesium (mg/dL)	1.5–2.3	1.6–2.2	1.5–2.2	1.1–2.2	3, 26, 29, 39, 42, 48, 63
Osmolality (mOsm/kg H_2O)	275–295	275–280	276–289	278–280	17, 63
Phosphate (mg/dL)	2.5–4.3	3.1–4.6	2.5–4.6	2.8–4.6	3, 26, 33, 39, 42
Potassium (mEq/L)	3.5–5.0	3.6–5.0	3.3–5.0	3.3–5.1	20, 26, 29, 39, 42, 63, 66
Prealbumin (mg/dL)	17–34	15–27	20–27	14–23	42
Protein, total (g/dL)	6.7–8.6	6.2–7.6	5.7–6.9	5.6–6.7	26, 29, 42
Sodium (mEq/L)	136–146	133–148	129–148	130–148	17, 26, 29, 39, 42, 63, 66
Urea nitrogen (mg/dL)	7–20	7–12	3–13	3–11	20, 39, 42
Uric acid (mg/dL)	2.5–5.6[d]	2.0–4.2	2.4–4.9	3.1–6.3	17, 39, 42

METABOLIC AND ENDOCRINE TESTS

	Nonpregnant Adult[a]	First Trimester	Second Trimester	Third Trimester	References
Aldosterone (ng/dL)	2–9	6–104	9–104	15–101	21, 34, 69
Angiotensin-converting enzyme (ACE) (U/L)	9–67	1–38	1–36	1–39	20, 54
Cortisol (μg/dL)	0–25	7–19	10–42	12–50	42, 69
Hemoglobin A_{1c} (%)	4–6	4–6	4–6	4–7	48, 49, 59
Parathyroid hormone (pg/mL)	8–51	10–15	18–25	9–26	3
Parathyroid hormone-related protein (pmol/L)	<1.3[e]	0.7–0.9	1.8–2.2	2.5–2.8	3
Renin, plasma activity (ng/mL/hr)	0.3–9.0[e]	Not reported	7.5–54.0	5.9–58.8	20, 34
Thyroid stimulating hormone (TSH) (μIU/mL)	0.34–4.25	0.60–3.40	0.37–3.60	0.38–4.04	39, 42, 57
Thyroxine-binding globulin (mg/dL)	1.3–3.0	1.8–3.2	2.8–4.0	2.6–4.2	42
Thyroxine, free (fT_4) (ng/dL)	0.8–1.7	0.8–1.2	0.6–1.0	0.5–0.8	42, 57
Thyroxine, total (T_4) (μg/dL)	5.4–11.7	6.5–10.1	7.5–10.3	6.3–9.7	29, 42
Triiodothyronine, free (fT_3) (pg/mL)	2.4–4.2	4.1–4.4	4.0–4.2	Not reported	57
Triiodothyronine, total (T_3) (ng/dL)	77–135	97–149	117–169	123–162	42

VITAMINS AND MINERALS

	Nonpregnant Adult[a]	First Trimester	Second Trimester	Third Trimester	References
Copper (μg/dL)	70–140	112–199	165–221	130–240	2 , 30, 42
Selenium (μg/L)	63–160	116–146	75–145	71–133	2, 42
Vitamin A (retinol) (μg/dL)	20–100	32–47	35–44	29–42	42
Vitamin B_{12} (pg/mL)	279–966	118–438	130–656	99–526	45, 72
Vitamin C (ascorbic acid) (mg/dL)	0.4–1.0	Not reported	Not reported	0.9–1.3	64
Vitamin D, 1,25-dihydroxy (pg/mL)	25–45	20–65	72–160	60–119	3, 48
Vitamin D, 24,25-dihydroxy (ng/mL)	0.5–5.0[e]	1.2–1.8	1.1–1.5	0.7–0.9	60
Vitamin D, 25-hydroxy (ng/mL)	14–80	18–27	10–22	10–18	3, 60
Vitamin E (α-tocopherol) (μg/mL)	5–18	7–13	10–16	13–23	42
Zinc (μg/dL)	75–120	57–88	51–80	50–77	2, 42, 58

AUTOIMMUNE AND INFLAMMATORY MEDIATORS

	Nonpregnant Adult[a]	First Trimester	Second Trimester	Third Trimester	References
C3 complement (mg/dL)	83–177	62–98	73–103	77–111	42
C4 complement (mg/dL)	16–47	18–36	18–34	22–32	42
C-reactive protein (CRP) (mg/L)	0.2–3.0	Not reported	0.4–20.3	0.4–8.1	28
Erythrocyte sedimentation rate (ESR) (mm/hr)	0–20[d]	4–57	7–47	13–70	71
IgA (mg/dL)	70–350	95–243	99–237	112–250	42
IgG (mg/dL)	700–1700	981–1267	813–1131	678–990	42
IgM (mg/dL)	50–300	78–232	74–218	85–269	42

SEX HORMONES

	Nonpregnant Adult[a]	First Trimester	Second Trimester	Third Trimester	References
Dehydroepiandrosterone sulfate (DHEAS) (μmol/L)	1.3–6.8[e]	2.0–16.5	0.9–7.8	0.8–6.5	52
Estradiol (pg/mL)	<20–443[d,f]	188–2497	1278–7192	6137–3460	13, 52
Progesterone (ng/mL)	<1–20[d]	8–48		99–342	13, 52
Prolactin (ng/mL)	0–20	36–213	110–330	137–372	3, 13, 38, 49
Sex hormone binding globulin (nmol/L)	18–114[d]	39–131	214–717	216–724	1, 52
Testosterone (ng/dL)	6–86[d]	25.7–211.4	34.3–242.9	62.9–308.6	52
17-Hydroxyprogesterone (nmol/L)	0.6–10.6[d,e]	5.2–28.5	5.2–28.5	15.5–84	52

LIPIDS

	Nonpregnant Adult[a]	First Trimester	Second Trimester	Third Trimester	References
Cholesterol, total (mg/dL)	<200	141–210	176–299	219–349	8, 18, 31, 42
HDL-cholesterol (mg/dL)	40–60	40–78	52–87	48–87	8, 18, 31, 42, 55
LDL-cholesterol (mg/dL)	<100	60–153	77–184	101–224	8, 18, 31, 42, 55
VLDL-cholesterol (mg/dL)	6–40[e]	10–18	13–23	21–36	31
Triglycerides (mg/dL)	<150	40–159	75–382	131–453	8, 18, 31, 39, 42, 55
Apolipoprotein A-I (mg/dL)	119–240	111–150	142–253	145–262	18, 39, 49
Apolipoprotein B (mg/dL)	52–163	58–81	66–188	85–238	18, 39, 49

CARDIAC

	Nonpregnant Adult[a]	First Trimester	Second Trimester	Third Trimester	References
Atrial natriuretic peptide (ANP) (pg/mL)	Not reported	Not reported	28.1–70.1	Not reported	11
B-type natriuretic peptide (BNP) (pg/mL)	<167 (age and gender specific)	Not reported	13.5–29.5	Not reported	11
Creatine kinase (U/L)	39–238[d]	27–83	25–75	13–101	41, 42
Creatine kinase-MB (U/L)	<6[k]	Not reported	Not reported	1.8–2.4	41
Troponin I (ng/mL)	0–0.08	Not reported	Not reported	0–0.064 (intrapartum)	36, 65

BLOOD GAS

	Nonpregnant Adult[a]	First Trimester	Second Trimester	Third Trimester	References
Bicarbonate (HCO_3^-) (mEq/L)	22–26	Not reported	Not reported	16–22	23
Pco_2 (mm Hg)	38–42	Not reported	Not reported	25–33	23
Po_2 (mm Hg)	90–100	93–100	90–98	92–107	23, 67
pH	7.38–7.42 (arterial)	7.36–7.52 (venous)	7.40–7.52 (venous)	7.41–7.53 (venous) 7.39–7.45 (arterial)	23, 26

RENAL FUNCTION TESTS

	Nonpregnant Adult[a]	First Trimester	Second Trimester	Third Trimester	References
Effective renal plasma flow (mL/min)	492–696[d,e]	696–985	612–1170	595–945	19, 22
Glomerular filtration rate (GFR) (mL/min)	106–132[d]	131–166	135–170	117–182	19, 22, 50
Filtration fraction (%)	16.9–24.7[l]	14.7–21.6	14.3–21.9	17.1–25.1	19, 22, 50
Osmolarity, urine (mOsm/kg)	500–800	326–975	278–1066	238–1034	61
24-hr albumin excretion (mg/24 hr)	<30	5–15	4–18	3–22	27, 61
24-hr calcium excretion (mmol/24 hr)	<7.5[e]	1.6–5.2	0.3–6.9	0.8–4.2	66
24-hr creatinine clearance (mL/min)	91–130	69–140	55–136	50–166	22, 66
24-hr creatinine excretion (mmol/24 hr)	8.8–14[e]	10.6–11.6	10.3–11.5	10.2–11.4	61
24-hr potassium excretion (mmol/24 hr)	25–100[e]	17–33	10–38	11–35	66
24-hr protein excretion (mg/24 hr)	<150	19–141	47–186	46–185	27
24-hr sodium excretion (mmol/24 hr)	100–260[e]	53–215	34–213	37–149	17, 66

[a]Unless otherwise specified, all normal reference values are from the seventeenth edition of *Harrison's Principles of Internal Medicine*. (37)
[b]Range includes references with and without iron supplementation.
[c]Reference values are from *Laboratory Reference* Handbook, Pathology Department, Parkland Hospital, 2005.
[d]Normal reference range is specific range for females.
[e]Reference values are from the fifteenth edition of *Harrison's Principles of Internal Medicine*. (12)
[f]Range is for premenopausal females and varies by menstrual cycle phase.
[g]Reference values are from Cerneca et al: Coagulation and fibrinolysis changes in normal pregnancy increased levels of procoagulants and reduced levels of inhibitors during pregnancy induce a hypercoagulable state, combined with a reactive fibrinolysis. (15)
[h]Reference values are from Cerneca et al and Choi et al: Tissue plasminogen activator levels change with plasma fibrinogen concentrations during pregnancy. (15,16)
[i]Reference values are from Mannucci et al: Changes in health and disease of the metalloprotease that cleaves von Willebrand factor. (76)
[j]Reference values are from Bacq Y et al: Liver function tests in normal pregnancy: a prospective study of 102 pregnant women and 102 matched controls. (5)
[k]Reference values are from Leiserowitz GS et al: Creatine kinase and its MB isoenzyme in the third trimester and the peripartum period. (41)
[l]Reference values are from Dunlop W: Serial changes in renal haemodynamics during normal human pregnancy. (19)

Appendix courtesy of Dr. Mina Abbassi-Ghanavati and Dr. Laura G. Greer.

chronic renal disease and, 1040, 1040*t*
in chronic renal insufficiency, 1039
with complete mole and coexisting fetus, 878
in DES-exposed women, 898
in Ehlers-Danlos syndrome, 1160
gonorrhea and, 1239
hospitalization for, 4
hyperthyroidism and, 1129*t*
in inflammatory bowel disease, 1056
in leukemia, 1199
maternal-feta stress and, 164
maternal psychiatric diagnoses and, 1176
morbidity and mortality with, 136, 806
in multifetal pregnancy
prediction of, 880–881
prevention of, 880
risk factors for, 880–881
and neonatal death, 5
oligohydramnios and, 496
with placental hematoma, 579
with placenta previa, 773
of preterm infant, 826
prevention of, in multifetal pregnancy, 880
prior, prenatal consultation for, 198*t*
smoking and, 329
with trichomoniasis, 1246
Preterm fetus/infant
brain disorders in, 611–616
breech presentation of, delivery of, 530
delivery of, 826
diseases common in, 605–628
feeding of, 599
intracranial hemorrhage in, prevention of, 827
long-term outcome for, 807, 807*f*
mental retardation in, 616, 616*t*
necrotizing enterocolitis in, 616
neonatal mortality, cesarean delivery and, 808, 809*f*
non-GBS early-onset sepsis in, 1221
perinatal morbidity and mortality in, 804–805
respiratory distress syndrome in, 590, 605–607
resuscitation of, 807
seizure disorders in, 616
survival of, gestational age and, 804
and symmetrical fetal-growth restriction, 846
viability of, 807
weight gain in, 600
weight loss in, 600
Preterm labor, 162–167
amniocentesis in, 821
appendicitis and, 1059
bacterial vaginosis and, 813
biochemistry of, 162–167
cervical changes in, 814–815
cervical dilatation in, 814–815
diagnosis of, 814–816
Preterm labor *(Cont.):*
ambulatory uterine monitoring and, 815–816
diagnostic criteria for, 814
fetal fibronectin and, 816
genetic influence on, 162–163
infection and, 163–166
pathogenesis of, 165–166, 165*f*
sources of infection, 165–166, 165*f*
inhibition of, 822–826
atosiban for, 826
bed rest for, 823
beta-adrenergic receptor agonists for, 822*f,* 823–824
calcium-channel blockers for, 825–826
hydration for, 823
indomethacin for, 822*f,* 825
magnesium sulfate for, 822, 822*f*
nifedipine for, 822*f,* 825–826
nitric oxide donors for, 826
progesterone for, 822*f*
prostaglandin inhibitors for, 822*f,* 825
ritodrine for, 823
sedation for, 823
terbutaline for, 822*f,* 823
tocolytics for, 822–826, 822*f*
with intact fetal membranes, 821–826
management of, 810, 817–820
intrapartum, 826–827
recommendations for, 826
microbes associated with, 166
multifetal pregnancy and, 156
myomas and, 903
pathogenesis of, 811
physiology of, 162–167
premature rupture of membranes and, 163
with preterm rupture of membranes, management of, 817–820
prevention of, 154–155, 816–817
in renal transplant recipient, 1042
risk factors for, 162, 163–164, 163*f*
signs and symptoms of, 814
spontaneous, 163–164, 810–811
threatened, prenatal consultation for, 199*t*
uterine stretch and, 156
Preterm neonate. *See also* Preterm fetus/infant
definition of, 3
Preterm parturition syndrome, 167
Preterm premature rupture of membranes (PPROM), 163, 811

diagnosis of, 818
infection-induced, 163
in multifetal pregnancy, 880–881
and placental abruption, 764, 764*t*
recurrence, 811
risk factors for, 811
Preterm ruptured membranes
amnionic fluid volume left after, prognostic significance of, 819
and antenatal corticosteroids, 820
bacterial vaginosis and, 813
chlamydial infection and, 1240
Preterm ruptured membranes *(Cont.):*
and chorioamnionitis, 819
expectant management of, 818–819
risks of, 819
gestational age at, and long-term sequelae, 819
hospitalization for, 818
and infection, 819
and intentional delivery, 818
management of, recommendations for, 820, 820*t*
membrane repair for, 820
natural history of, 818
and neonatal death, 819
and preterm labor, management of, 817–820
and time to delivery, 818, 818*f*
Preven Emergency Contraception Kit, 692, 693
Preventive medicine. *See* Preconceptional counseling
Primaquine, contraindications to, 1228
Primary apnea, of neonate, 591, 591*f*
Primary sex cords. *See* Sex cords
Primary villous stalks, development of, 51
Primates, ovarian-endometrial cycle in, 36
Primidone
contraindications to, in breast feeding, 653*t*
and oral contraceptives, interactions, 678*t*
Primigravida, definition of, 194
Primipara(s), definition of, 194
Primitive streak, 51*f*
Primordial germ cells. *See* Germ cells, primordial
Private antigens, 620, 620*t*
Probenecid, hemolytic anemia induced by, 1083
Procainamide, lupus-like syndrome caused by, 1148
Prochlorperazine
for hyperemesis gravidarum, 1052
for migraine, 1165
Proctocolectomy, for ulcerative colitis, 1055
Professional liability, 9–10, 9*t*
Progesterone
action of, 41
and cervical mucus, 191
and cervical ripening, 141
deficiency of, and miscarriage, 226
exogenous, in prevention of preterm birth, 816
and hyperemesis gravidarum, 1051
in lactation, 650
metabolism of, in pregnancy, 68
metabolites of, 68
normal laboratory values
in nonpregnant adult, 1262
in uncomplicated pregnancy, 1262
in ovarian-endometrial cycle, 37*f,* 39*f*
and oxytocin receptor expression, 155–156
in parturition, 68, 154–155
phase 1, 151, 152, 152*f,* 153*f*

Progesterone *(Cont.):*
plasma/serum levels, in pregnancy, 67*f*
in prevention of preterm birth, 816
in prevention of preterm delivery, for multifetal pregnancy, 880
production of
in nonpregnant women, 62*t*
placental, 67, 67*f*
fetal well-being and, 68
in pregnancy, 62*t,* 67, 67*f*
rates of, 67–68
serum levels of
in dying pregnancy, 246
in ectopic pregnancy, 245–246
in normal pregnancy, 246
for sickle-cell hemoglobinopathy, 1089
synthesis of, 40
and ureteral dilatation in pregnancy, 124
and uteroplacental blood flow, 108
vaginal suppositories, in prevention of preterm birth, 816
and vascular tone, in pregnancy, 120–121
and ventilatory chemoreflex, 122
withdrawal of, 151
and parturition, 151, 154–155
and phase 2 parturition, 154–155
and preterm labor, 811
Progesterone receptor(s), 41
isoforms of, 41, 155
and parturition, 154–155
Progesterone receptor antagonists. *See also* Mifepristone (RU 486)
and parturition, 155
Progestin(s). *See also* Oral contraceptives, estrogen plus progestin; Oral contraceptives, progestin-only
androgenic, fetal effects of, 322
in combination oral contraceptive, 674
in estrogen plus progestin contraceptives, mechanism of action of, 673

oral, 682
Progressive systemic sclerosis. *See* Systemic sclerosis
Proguanil, contraindications to, 1228
Prolactin
in amnionic fluid, 47, 127
in breast milk, 650
decidual, 46–47, 127
regulation of, 47
roles of, 47
and hyperemesis gravidarum, 1051
and lactation, 127, 650
normal laboratory values
in nonpregnant adult, 1262
in uncomplicated pregnancy, 1262
in pregnancy, 126–127
production of, 97
Prolactinoma(s), 1139
and pregnancy, 1139
in pregnancy, 126
Prolactin-secreting pituitary tumors. *See* Prolactinoma(s)
Prolonged pregnancy
definition of, 832
in twin gestation, 869
Promethazine
for hyperemesis gravidarum, 1052
for labor pain, 446
for migraine, 1165
Pronephros, 95, 890
Propranolol
for migraine prophylaxis, 1166
for portal hypertension, 1072
for thyroid storm and heart failure, 1130
Propylthiouracil, for hyperthyroidism, 1128
with thyroid storm and heart failure, 1130
Prostacyclin
in gestational hypertension, 714
and vascular tone, in pregnancy, 121
Prostaglandin(s)
abortion induced with, coagulopathy with, 790
accelerated degradation, in phase 1 parturition, 154
in amnionic fluid
before labor, 160, 160*f*
during labor, 160, 160*f*
at term, 160, 160*f*
biosynthesis of, 153–154, 154*f*
in dilatation and curettage, 229
F-series, contraindications to, in asthmatic patients, 997–998
in gestational hypertension, 714
for induced abortion, 229, 233
and intrauterine inflammatory response to infection, 166
for labor induction, in women with prior cesarean delivery, 572–573
in labor management, 399–400
for late postpartum hemorrhage, 648
and menstruation, 44
PGD_2
in phase 1 parturition, 154
and vascular tone, in pregnancy, 121
PGE_1. *See also* Misoprostol (Cytotec)
for cervical ripening, 503, 505*t*
for induced abortion, 233
for labor induction, in women with prior cesarean delivery, 572
and uterine rupture, 572
PGE_2
in amnionic fluid, at term, 160, 160*f*
for cervical ripening, 141, 502–503, 505*t*
administration of, 502
side effects of, 502–503
uterine hyperstimulation with, 503
uterine hypertonus with, 503
uterine tachysystole with, 502–503
for induced abortion, 233
in phase 1 parturition, 154
preparations, 502
for uterine atony, 775
PGF, receptors, 138
Prostaglandin(s) *(Cont.):*
$PGF_{2\alpha}$
in amnionic fluid, at term, 160, 160*f*
for cervical ripening, 141
contraindicated for asthmatic patients, 1001
in luteolysis, 40
and menstruation, 44
metabolite, and uterine labor contractions, 141
PGFM, and uterine labor contractions, 141
PGI_2, in phase 1 parturition, 154
in phase 1 parturition, 153–154, 153*f*
in phase 3 parturition, 159–160

  class II, 970
  definition of, 970
  effects on pregnancy, 971
  idiopathic, 970
  labor and delivery with, 971
  maternal, 970–971
  neonatal, 606
Pulmonary hypertension. *(Cont.):*
  in neonatal respiratory distress, 606
  postnatal oxygen therapy and, 606
  prenatal consultation for, 198*t*
  primary, 970
  prognosis for, 971
  risk factors for, 970
  in sickle-cell hemoglobinopathy, 1088
  and spinal block, 453
  treatment of, 971
Pulmonary hypoplasia
  causes of, 496
  oligohydramnios and, 496, 496*f,* 638
  and parturition, 158
Pulmonary insufficiency, in cystic fibrosis, 1008
Pulmonary physiology, in pregnancy, 996
Pulmonary sequestration, fetal, ultrasound of, 356
Pulmonary stenosis
  hydramnios and, 494
  maternal, 966*t*
    and risk of heart disease in fetus, 961*t*
  recurrence risk for, 282*t*
Pulmonary system, fetal, 95–96
Pulmonary vascular resistance
  calculation of, 928*t*
  in nonpregnant women, 928*t*
  postpartum, 119, 120*t*
  in pregnancy, 119, 120*t,* 928*t,* 958, 959*t*
Pulmonic stenosis
  maternal, 968
  recurrence risk for, 961*t*
Pulseless disease, 1159–1160
Pulse oximetry, fetal, 427–428, 427*f*
  instrumentation for, 427, 427*f*
Pulse wave analysis, as predictor for gestational hypertension, 725
PUPPP. *See* Pruritic urticarial papules and plaques of pregnancy (PUPPP)
PUQE scoring index, 1050
Pure red cell aplasia, erythropoietin therapy and, 1082
Purified protein derivative (PPD) test, for tuberculosis, 1006
Purpura fulminans, 1015
Purtscher retinopathy, 723, 723*f*
Pushing, in labor, 143
Pyelectasis, prenatal sonographic evaluation of, 360–361
Pyelonephritis, 1034
  acute, 1036–1038
    acute respiratory distress syndrome in, 1036, 1037*f*
    anemia with, 1081
    antibiotic therapy for, 1037
    and cerebral palsy, 1036
    clinical findings in, 1036–1037, 1037*f*
    follow-up for, 1038
    lower-tract infection and, 1036
    management of
      in nonresponders, 1038
      oupatient, 1037–1038
      in pregnancy, 1037–1038, 1037*t*

Pyelonephritis *(Cont.):*
microbiology of, 1036
obstructive uropathy and, 1038
one-shot pyelogram in, 1038
outpatient management of, 1037–1038
in pregnancy, 1036–1038
incidence of, 1036
recurrence, 1038
recurrent, prevention of, 1038
renal calculi and, 1038
respiratory insufficiency in, 1036
antepartum, in diabetic pregnancy, 1118–1119
chronic, 1038
fever in, 661
pathogenesis of, 1034–1035
prenatal consultation for, 199*t*
in renal transplant recipient, 1042
and sepsis syndrome, 933, 1036
in sickle-cell hemoglobinopathy, 1086, 1087*t*
with sickle-cell syndromes, 1087
Pyloric stenosis, 280, 281*f*
genetics of, 280, 281*f*
Pyogenic granuloma of pregnancy, 1187
Pyrazinamide, for tuberculosis, 1005, 1006
Pyrexia. *See also* Fever
maternal, epidural analgesia and, 455–456
Pyribenzamine. *See* Tripelennamine (Pyribenzamine)
Pyridostigmine, for myasthenia gravis, 1172
Pyridoxine. *See* Vitamin B_6
Pyriform [term], 21
Pyrimethamine, for toxoplasmosis, 1227
Pyrosis, 1052
in pregnancy, 125
Pyruvate kinase deficiency, 1084

QT interval prolongation, maternal, 975
Quality, of obstetrical care, measurement of, 8
QuantiFERON-TB Gold test, 1006
Quetelet index, 946
Quinacrine pellets, for tubal sterilization, 702
Quinidine
adverse effects of, 1228
cardiotoxicity of, 1228
hemolytic anemia induced by, 1083
lupus-like syndrome caused by, 1148
teratogenicity of, 320
Quinine
for malaria, 1228
teratogenicity of, 320
Quintuplets. *See* Multifetal gestation

Rabies
immune globulin, in pregnancy, 209*t*
postexposure prophylaxis, in pregnancy, 209*t*
vaccine, in pregnancy, 208*t*
Race/ethnicity
and bacterial vaginosis, 814
and infant mortality, 804
and maternal mortality ratio, 5–6, 6*f*
and multifetal pregnancy, 862, 863*t*
and neural tube defects, 288, 288*t*
and obesity, 946–947
and placental abruption, 763
and preeclampsia, 709
and prenatal care use, 189, 190*f*
and preterm birth, 812
and prevalence of obesity, 946–947, 948*f*
and syphilis, 1236
and thalassemia risk, 1091
and twins/twinning, 862, 863*t*
rad (unit), 916*t*
Radial artery(ies), 24*f,* 25, 42*f*
Radiation. *See also* Ionizing radiation
biological effects of, 915
definition of, 915
diagnostic, in pregnancy, 1193
fetal effects of
deterministic, 915
stochastic, 915
and spontaneous abortion, 217–218
thrombocytopenia caused by, 1092
types of, 915
Radiation therapy
for breast cancer
abdominal scatter from, 1197
fetal dose in, 1197
fetal effects of, 1193
for Hodgkin disease, 1198
during pregnancy, 1198
for non-Hodgkin lymphoma, 1199
in pregnancy, 917–918, 1193–1194
fetal protection during, 918
frequency of, 917
Radioactive isotopes, in breast milk, 653
Radiofrequency ablation procedure, fetal, 307–308
Radiograph(s)
in diagnosis of fetal position/presentation, 378
fetal indications for, 918
plain abdominal
in acute pyelonephritis, 1038
in intestinal obstruction, 1057
plain film
fetal indications for, 918
radiation doses from, 916, 916*t*
radiation dose to uterus from, 916*t*
radiation dose to fetus/embryo in, 918
trauma series, radiation dose to fetus/embryo in, 918
upper gastrointestinal, radiation dose to fetus/embryo in, 918, 918*t*
Radiography. *See also* Chest radiography
abdominal, radiation dose to uterus from, 916*t*
hip, radiation doses from, 916*t*
lumbosacral spine, radiation doses from, 916*t*
Radiography. *(Cont.):*
of multifetal pregnancy, 866–867
skull, radiation doses from, 916*t*
Radioiodine
scans using
fetal exposure in, 920*t*
fetal radiation exposure in, 920, 921
of thyroid nodules, contraindications to, in pregnancy, 1135
teratogenicity of, 322–323
therapy with, fetal effects of, 921
for thyroid ablation, contraindications to, 1128
thyroid scans using, fetal exposure in, 920*t,* 921
Radionuclide imaging. *See* Nuclear medicine
Radiopharmaceuticals, 920–921, 920*t,* 959
Ranitidine, for reflux esophagitis, 1052
Rapid acquisition with relaxation enhancement (RARE), 366
Rapid plasma reagin (RPR) test, 1237–1238
Rash, in toxoplasmosis, 1226
Rathke pouch, 97
Reciprocal translocations, 273, 273*f*
Recommended dietary allowances
in lactation, 203*t*
in pregnancy, 202–205.203*t,* 203*t*
Rectocele, 901
Rectouterine cul-de-sac (cul-de-sac of Douglas), 17, 21, 22*f*
sonographic evaluation of, in ectopic pregnancy, 243
Recto-uterine pouch, 17
Rectovaginal septum, 17, 22*f*
Rectum, 22*f*
embryology of, 891*f*
Rectus abdominis muscle, 14, 15*f*
Rectus sheath, 14
Red blood cell(s). *See* Erythrocyte(s)
Red blood cell count, normal laboratory values
in nonpregnant adult, 1259
in uncomplicated pregnancy, 1259
Red cell distribution width, normal laboratory values
in nonpregnant adult, 1259
in uncomplicated pregnancy, 1259
5α-Reductase deficiency, 103
Reflux esophagitis, 1052
and hiatal hernia, 1052
Reflux nephropathy, 1038
Regional analgesia
and heparin, 1022
and spinal hematoma, 1022
Regional enteritis. *See* Crohn disease
Regurgitation, with achalasia, 1053
Reifenstein syndrome, 103, 103*f*
Reiter disease, 1145
Reiter syndrome, chlamydial, 1240
Relaxin, 65–66, 110
action of, 110, 116, 153
chemical characteristics of, 65, 153
genes for, 65, 153

Relaxin *(Cont.):*
and leukocyte function, 64, 65, 116
and myometrial contraction/relaxation, 66, 153
in phase 2 parturition, 156
placental synthesis of, 62
in pregnancy, 66, 110
and renal hemodynamics, 110, 123
secretion of, 153
by corpus luteum, 64, 66, 110
by decidua, 110
hCG and, 64
placental, 110
structure of, 65, 110
synthesis of, 64, 65
Relaxin family peptide receptor 1 (RXFP1), 153
Relaxin receptor(s), 156
rem (unit), 916*t*
Renal agenesis
in infants of diabetic mothers, 1114*t*
and oligohydramnios, 496
and parturition, 158
prenatal sonographic evaluation of, 360
and pulmonary hypoplasia, 95
Renal biopsy
in nephrotic syndrome, 1044
in pregnancy, 1034
Renal blood flow, fetal, 95
Renal calyces
diameters of, in pregnancy, 1033, 1034*f*
dilatation of, in pregnancy, 123*t,* 1033, 1034*f*
Renal cell carcinoma
diagnosis of, 1205–1206
imaging of, 1206
pregnancy complicated by, 1205–1206
Renal cortical necrosis
clinical course of, 1046
gestational hypertension and, 720
incidence of, 1046
pathophysiology of, 1046
prognosis for, 1046
Renal disorders/disease. *See also* Renal failure
chronic, 1039–1041
anemia with, 1081–1082
follow-up in, 1041
management of, 1040–1041
physiological changes in, 1039, 1039*f*
pregnancy and, 1039–1041
with preserved function, pregnancy and, 1040, 1040*t*
and fetal-growth restriction, 848
maternal, and preterm birth, 811
mild impairment in, 1039
moderate impairment in, 1039
with paroxysmal nocturnal hemoglobinuria, 1083
preconceptional counseling about, 177, 184*t*
in pregnancy, chronic renal disease and, 1040, 1040*t*
prenatal consultation for, 198*t*
severe renal insufficiency in, 1039
Renal failure
acute, 1045–1046, 1045*t*
abortion and, 1045, 1045*t*
definition of, 1045
dialysis for, 1045, 1045*t*
eclampsia and, 1045, 1045*t*
gestational hypertension and, 719–720
management of, 1045–1046
maternal morbidity with, 1045, 1045*t*
maternal mortality with, 1045, 1045*t*
obstetrical
causes of, 1045, 1045*t*
outcomes of, 1045, 1045*t*
obstetrical hemorrhage and, 1045, 1045*t*
preeclampsia and, 1045, 1045*t*
in pregnancy, 1045–1046
causes of, 1045, 1045*t*
outcomes of, 1045, 1045*t*
prevention of, 1046
signs and symptoms of, 1045
with acute fatty liver of pregnancy, 1066
chronic, 1040, 1040*f*
pregnancy and, 1040
pregnancy complications in, 1040, 1040*t*
and theca-lutein cysts, 110
with chronic hypertension, 986
with hyperemesis gravidarum, 1051
maternal morbidity due to, 7*t*
mild, 1039
moderate, 1039
obstructive, 1046
with placental abruption, 766
severe, 1039
definition of, 1039
in sickle-cell hemoglobinopathy, 1086
in thrombotic microangiopathies, 1095
Renal filtration fraction, in pregnancy, 123*f*
Renal function
with acute liver diseases of pregnancy, 1064*t*
chronic hypertension and, 986
hypertension and, 986
postpartum, 649
in twin pregnancy, 867
worsening, in pregnancy, in chronic renal disease, 1040, 1040*t*
Renal function tests
interpretation of, pregnancy and, 1033–1034
normal values, in uncomplicated pregnancy, 1264
in pregnancy, 1033–1034
Renal impairment
mild, definition of, 1039
moderate, definition of, 1039
Renal insufficiency. *See* Renal failure
Renal papillary necrosis, sickle-cell trait and, 1089
Renal pelvis/pelves, postpartum, 649
Renal plasma flow (RPF), in pregnancy, 123, 123*f,* 1033
Renal tumor(s), pregnancy complicated by, 1205–1206
Renal vein, thrombosis, in nephrotic syndrome, 1044
Renin
plasma levels, in gestational hypertension, 718
in pregnancy, 120
and vascular reactivity, 120
Renin-angiotensin-aldosterone system, in pregnancy, 120
Renin-angiotensin system, fetal, 95
