PRETERM LABOR WITH INTACT MEMBRANES 821

Low birthweight defines neonates who are born too small. *Preterm or premature births* are terms used to define neonates who are born too early. With respect to gestational age, a newborn may be preterm, term, or postterm. With respect to size, a newborn may be normally grown and *appropriate for gestational age*; small in size, thus, *small for gestational age*; or overgrown and consequently, *large for gestational age*. In recent years, the term *small for gestational age* has been widely used to categorize newborns whose birthweight is usually below the 10th percentile for gestational age. Other frequently used terms have included *fetal-growth restriction* or *intrauterine growth restriction*. The term *large for gestational age* has been widely used to categorize newborns whose birthweight is above the 90th percentile for gestational age. The term *appropriate for gestational age* designates newborns whose weight is between the 10th and 90th percentiles. Thus, infants born before term can be small or large for gestational age but still fit the definition of preterm. *Low birthweight* refers to births 500 to 2500 g; *very low birthweight* refers to births 500 to 1500 g; and *extremely low birthweight* refers to births 500 to 1000 g. In 1960, a neonate weighing 1000 g had a 95-percent risk of death. Today, a neonate with the same birthweight has a 95-percent chance of surviving (Ingelfinger, 2007). This remarkable improvement in survival is due to the widespread application of neonatal intensive care in the early 1970s.

MORTALITY RATES OF PRETERM INFANTS

In the United States in 2005, 28,384 infants died in their first year of life (**Table 36-1**). *Preterm birth*, which is defined as delivery before 37 completed weeks, was implicated in approximately two thirds of these deaths. As shown in Table 36-1, *late preterm births*, defined as those 34 to 36 weeks' gestation, composed approximately 70 percent of all preterm births. As discussed in Chapter 1 (p. 4), although the infant mortality rate for the United States has declined substantively over the past century, it has remained static from 2000 to 2005 (MacDorman and Matthews, 2008). Thus, the issue of preterm birth remains a major health problem.

The rates of preterm birth—the largest contributor to infant mortality—began to increase in the United States in 1996. As shown in **Figure 36-1**, medically indicated preterm births are largely responsible for this rise. Equally disturbing is the persistent racial disparity such that black infants are twice as likely to die within the first year of life, and almost two thirds of this disparity can be attributed to preterm birth (Schempf and colleagues, 2007). Some investigators attribute this inequity to class (racial) disparities in health related to socioeconomic issues (Collins and co-workers, 2007). Rates of preterm birth in the United States are also higher compared with those of other industrialized countries (Ananth and associates, 2009; Joseph and colleagues, 2007). For example, the preterm birth rate was 12.3 percent in the United States in 2003 compared with 7.7 percent in Canada. Part of this difference has been attributed

TABLE 36-1. Infant Mortality Rates in the United States in 2005

	Live Births No. (%)	Infant Deaths No. (%)
Total infants	4,138,573 (100)	28,384 (100)
Gestational age at birth		
<32 weeks	83,428 (2)	15,287 (54)
32–33 weeks	65,853 (1.6)	1099 (4)
34–36 weeks	373,663 (9)	1727 (10)
37–41 weeks	3,346,237 (81)	8116 (29)
≥42 weeks	239,850 (6)	637 (2)
Unknown	29,542 (0.7)	516 (2)

to the use of menstrual dates for calculation of gestational age in the United States compared with the use of clinical estimates in Canada.

MORBIDITY IN PRETERM INFANTS

A variety of morbidities, largely due to organ system immaturity, are significantly increased in infants born before 37 weeks' gestation compared with those delivered at term (Table 36-2). For approximately 40 years, complications in infants born before 34 weeks have been the primary focus. Only recently, *late preterm* infants—34 to 36 weeks—have gained attention because of increased morbidity rates compared with those of term infants. Attention has also been given to increasingly small preterm infants—very low-birthweight and extremely low-birthweight. These infants predominantly suffer not only the immediate complications of prematurity but also long-term sequelae such as neurodevelopmental disability. Indeed, live births once considered "abortuses" because they weighed less than 500 g are now classified as live births. There were 6666 such births recorded in the United States in 2006 (Martin and colleagues, 2009). Remarkable strides have been made in neonatal survival for infants born preterm. This is especially true for those born after 28 weeks. Shown in Figure 36-2 are survival rates for more than 18,000 infants born between 400 and 1500 g or between 22 and 32 weeks' gestation (Fanaroff and associates, 2007). Importantly, the results are shown as a function of both birthweights *and* gestational age. After achieving a birthweight of ≥ 1000 g or a gestational age of 28 weeks (for females) to 30 weeks (for males), survival rates reach 95 percent.

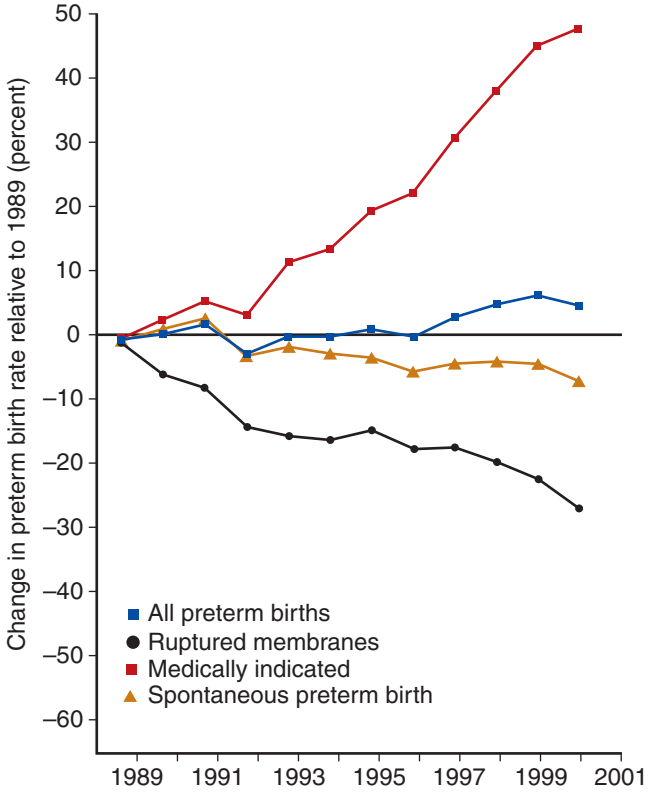

FIGURE 36-1 Rates of births < 37 weeks in the United States from 1989 to 2001. (Reprinted from Ananth CV, Joseph KS, Oyelese Y, et al: Trends in preterm birth and perinatal mortality among singletons: United States, 1989 through 2000, *Obstetrics & Gynecology,* 2005, vol. 105, no. 5, pt. 1, pp. 1084–1091, with permission.)

Resources used to care for low-birthweight infants are a measure of the societal burden of preterm birth. The immediate economic costs of preterm birth alone were estimated to exceed $18 billion in 2003. This represented half of all hospital charges for newborn care in the United States (Behrman and Butler, 2007). The economic consequences of preterm birth that reach beyond the newborn period into infancy, adolescence, and adulthood have not been estimated but must be enormous when the effects of adult diseases associated with prematurity such as hypertension and diabetes are considered (Hofman, 2004; Hovi, 2007; Ingelfinger, 2007; Kaijser, 2009, and all their co-workers).

MORTALITY AND MORBIDITY AT THE LOWER AND UPPER EXTREMES OF PREMATURITY

The tremendous advances in the perinatal and neonatal care of the preterm infant have been found predominantly in those infants delivered at ≤ 33 weeks. With survival of increasingly very immature infants in the 1990s, there has been uncertainty and controversy as to the lower limit of fetal maturation compatible

TABLE 36-2. Major Short- and Long-Term Problems in Very-Low-Birthweight Infants

Organ or System	Short-Term Problems	Long-Term Problems
Pulmonary	Respiratory distress syndrome, air leak, bronchopulmonary dysplasia, apnea of prematurity	Bronchopulmonary dysplasia, reactive airway disease, asthma
Gastrointestinal or nutritional	Hyperbilirubinemia, feeding intolerance, necrotizing enterocolitis, growth failure	Failure to thrive, short-bowel syndrome, cholestasis
Immunological	Hospital-acquired infection, immune deficiency, perinatal infection	Respiratory syncytial virus infection, bronchiolitis
Central nervous system	Intraventricular hemorrhage, periventricular leukomalacia, hydrocephalus	Cerebral palsy, hydrocephalus, cerebral atrophy, neurodevelopmental delay, hearing loss
Ophthalmological	Retinopathy of prematurity	Blindness, retinal detachment, myopia, strabismus
Cardiovascular	Hypotension, patent ductus arteriosus, pulmonary hypertension	Pulmonary hypertension, hypertension in adulthood
Renal	Water and electrolyte imbalance, acid–base disturbances	Hypertension in adulthood
Hematological	Iatrogenic anemia, need for frequent transfusions, anemia of prematurity	
Endocrinological	Hypoglycemia, transiently low thyroxine levels, cortisol deficiency	Impaired glucose regulation, increased insulin resistance

From Eichenwald and Stark (2008) with permission.

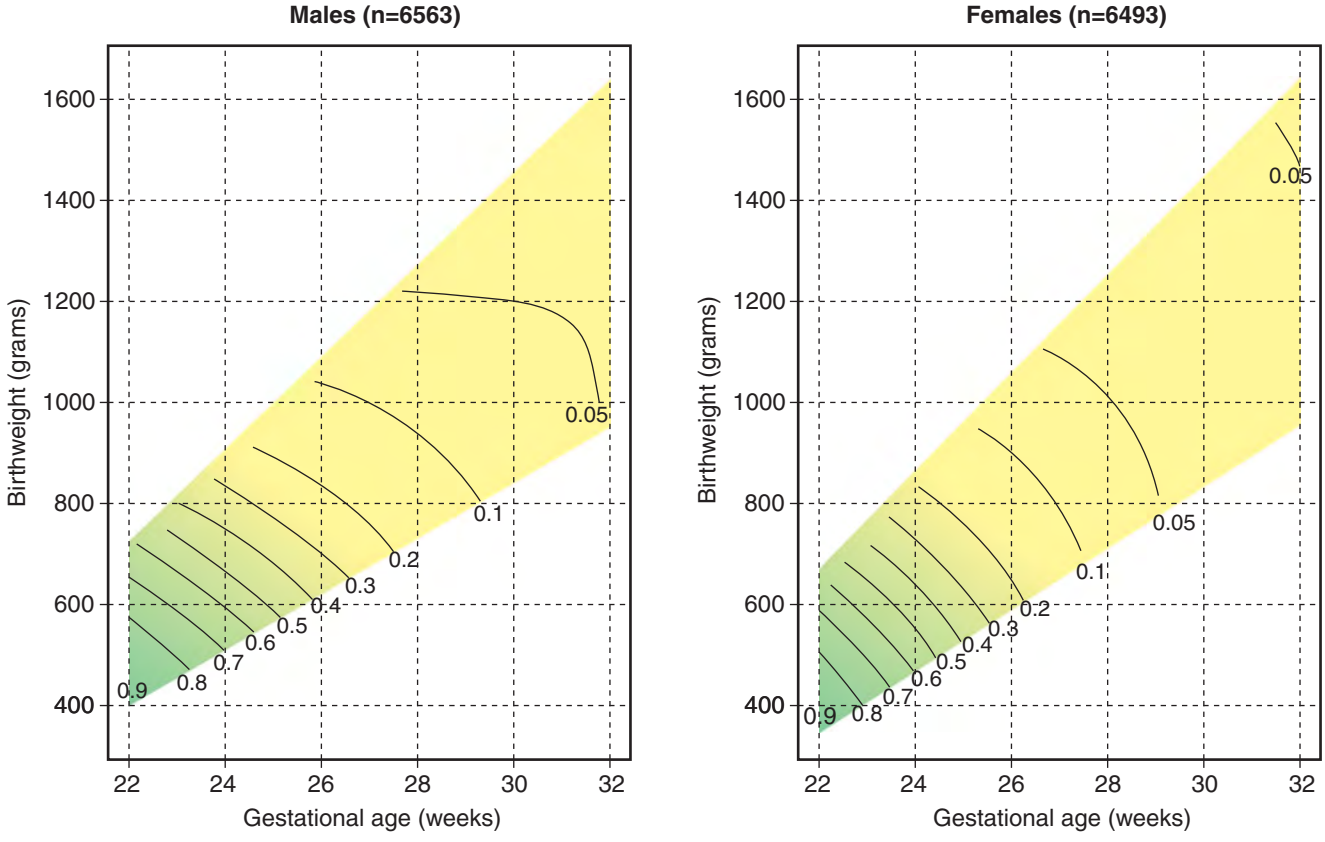

FIGURE 36-2 Mortality rates by birthweight, gestational age, and gender. The limits of the colored area indicate the upper 95th and lower 5th percentiles of birthweight for each gestational age. The curved lines indicate combinations of birthweight and gestational age with the same estimated probability of mortality from 10 to 90 percent. The gradation of color denotes the change in estimated probability of death—green indicates infants of lower gestational age and birthweight who are more likely to die; yellow indicates infants of higher gestational ages and birthweights who are less likely to die. The methods used underestimate mortality rates in those at 22 and 23 weeks with a birthweight up to 600 g. (From Fanaroff and associates, 2007, with permission.)

TABLE 36-3. Overall Survival and Survival with Selected Complications among Very-Low-Birthweight Infants

	Birthweight Groups			
Outcome	501–750 g (n = 4046)	751–1000 g (n = 4266)	1001–1250 g (n = 4557)	1251–1500 g (n = 5284)
Overall survival (percent)	55	88	94	96
Survival with complications (percent)	65	43	22	11
Bronchopulmonary dysplasia alone	42	25	11	4
Severe intraventricular hemorrhage alone	5	6	5	4
Necrotizing enterocolitis alone	3	3	3	2
Bronchopulmonary dysplasia and severe intraventricular hemorrhage	10	4	2	<1

Data from National Institute of Child Health and Human Development Neonatal Research Network, 1997 to 2002. From Fanaroff and colleagues (2007) as adapted by Eichenwald and Stark (2008), with permission.

with extrauterine survival. This has resulted in continual reassessment of the *threshold of viability*.

Threshold of Viability

It appears generally accepted that births before 26 weeks, especially those weighing less than 750 g, are at the current threshold of viability and that these preterm infants pose a variety of complex medical, social, and ethical considerations (American College of Obstetricians and Gynecologists, 2002, 2008c). For example, Sidney Miller is a child who was born at 23 weeks, weighed 615 g, and survived but developed severe physical and mental impairment (Annas, 2004). At age 7 years, she was described as a child who "could not walk, talk, feed herself, or sit up on her own . . . was legally blind, suffered from severe mental retardation, cerebral palsy, seizures and spastic quadriparesis in her limbs." An important issue for her family was the need for a lifetime of medical care estimated to cost tens of millions of dollars.

According to current guidelines developed by the American Academy of Pediatrics (Braner and co-workers, 2000), it is considered appropriate not to initiate resuscitation for infants younger than 23 weeks or those whose birthweight is less than 400 g. The involvement of the family is considered critical to the decision-making process with regard to resuscitation. Thus, infants now considered to be at the threshold of viability are those born at 22, 23, 24, or 25 weeks. These infants have been described as fragile and vulnerable because of their immature organ systems (Vohr and Allen, 2005). Moreover, they are at high risk for brain injury from hypoxic-ischemia injury and sepsis (Stoll and associates, 2004). In this setting, hypoxia and sepsis start a cascade of events that lead to brain hemorrhage, white-matter injury that causes periventricular leukomalacia, and poor subsequent brain growth eventuating in neurodevelopmental impairment (see Chap. 29, p. 610). It is thought that because active brain development normally occurs throughout the second and third trimesters, those infants born at 22 to 25 weeks are especially vulnerable to brain injury because of their extreme immaturity.

Considerable outcome data for preterm live births between 22 and 25 weeks have become available since the last edition of this textbook. Shown in Table 36-3 are rates of overall survival as well as survival with selected complications in 250-g birthweight increments for very-low-birthweight infants. Of those with birthweights 500 to 750 g, only 55 percent survived, and most had severe complications. Survival, even with no complications apparent at initial hospital discharge, does not preclude serious developmental impairment at age 8 to 9 years (Fig. 36-3). Importantly, survival of very low-birthweight infants with and without complications of prematurity was not substantially improved when two epochs—1997 to 2002 and 1995 to 1996 are compared (Eichenwald and Stark, 2008). Saigal and Doyle (2008) collated 16 reports based on geographically defined cohorts from Australia and several European countries. Survival increased progressively from 1.7 percent at 22 weeks to 54 percent at 25 weeks. Overall, 25 percent of infants born at 22 to 25 weeks had severe neurological disabilities, and 72 percent of those with birthweights < 750 g experienced difficulty in school. Marlow and colleagues (2005) identified all infants born between 22 and 25 weeks in the United Kingdom and Ireland between March and December 1995 and examined the children at age 6 years. As shown in Table 36-4, survival was

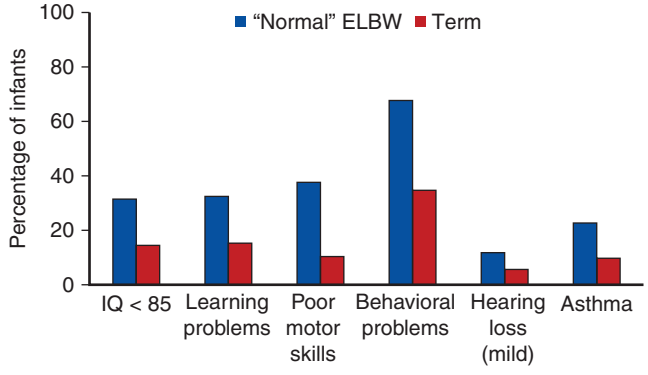

FIGURE 36-3 Selected neurodevelopmental and medical complications at age 8 to 9 years in children with extremely low birthweight (ELBW) but with no apparent neurosensory abnormalities at initial hospital discharge. IQ = intelligence quotient. (Data from Hack and colleagues, 2005, as adapted by Eichenwald and Stark, 2008, with permission.)

TABLE 36-4. 6-Year Outcomes of Surviving Infants Born from 22 to 25 Weeks in the United Kingdom in 1995

	Gestational Age (weeks)			
Outcomes	**22**	**23**	**24**	**25**
Live births	138	241	382	424
Surviving infants	2 (1)	25 (10)	98 (26)	183 (43)
Without moderate to severe disability at age 6 years	1 (0.7)	8 (3)	36 (9)	86 (20)

Data shown as number (percent).
Adapted from Marlow and colleagues (2005).

rare at 22 weeks—only 2 of 138 infants lived. This rate increased to 10 percent, 26 percent, and 43 percent, at 23, 24 and 25 weeks, respectively. Moderate to severe disability at age 6 years was identified in more than 90 percent of infants surviving following birth at 22 to 24 weeks. As shown in **Figure 36-4**, cognitive scores were much lower for infants born at 22 to 25 weeks compared with those of normal term births.

The reported results from the Neonatal Research Network were made available by Tyson and associates (2008). A total of 4192 infants born at 22 to 25 weeks and undergoing neurodevelopmental testing at age 18 to 22 months were studied prospectively. A total of 61 percent died or had profound impairment. Interestingly, only 23 percent of infants born at 22 weeks received intensive care compared with 99 percent at 25 weeks. Importantly, female gender, singleton pregnancy, corticosteroids given for lung maturation, and higher gestational age improved the prognosis for these infants born at the threshold of viability.

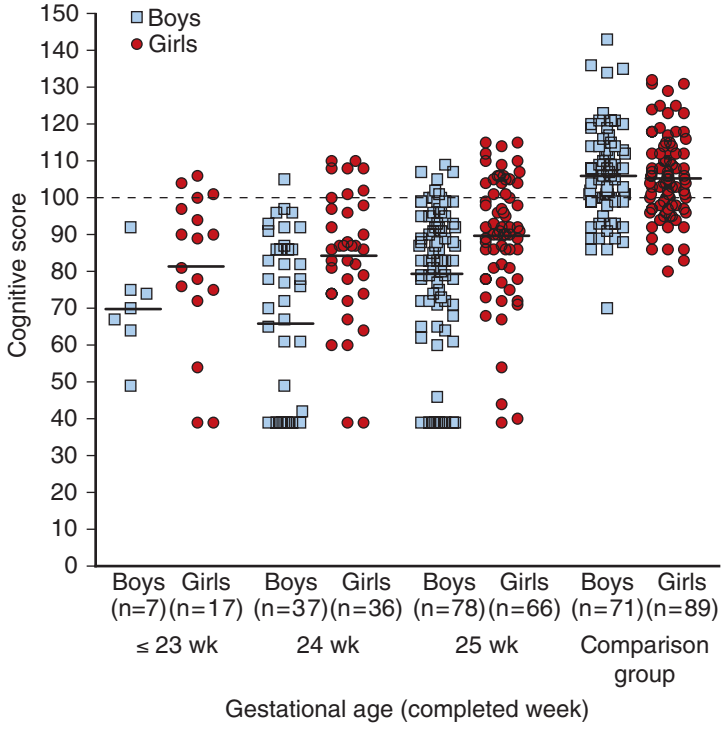

FIGURE 36-4 Cognitive scores for infants born at 22 to 23 weeks, 24 weeks, and 25 weeks compared with those for normal infants delivered at term. (From Marlow and colleagues, 2005, with permission).

Cesarean delivery at the threshold of viability is controversial. For example, if the fetus-infant is perceived to be too immature for aggressive support, then cesarean delivery for common indications such as breech presentation or nonreassuring fetal heart rate patterns might be preempted. This aside, national data clearly show a high frequency of cesarean delivery for the smallest infants (**Fig. 36-5**). Moreover, neonatal mortality rates in the very smallest infants—500 to 700 g—are approximately half if cesarean delivery is used compared with vaginal birth (**Fig. 36-6**). But this apparent advantage of cesarean delivery vis-à-vis survival is not the whole story. Louis and colleagues (2004) compared outcomes by route of delivery for infants born at 23 to 26 weeks during two epochs. Deliveries from 1990 through 1995 were compared with births between 1996 and 2001. There were 31 percent cesarean deliveries in the first epoch for malpresentation or nonreassuring fetal heart rate, and this increased significantly to 47 percent in the later epoch. Although this increase in cesarean use was associated with increased survival, it was not associated with a reduction in the short-term serious morbidities in infants born at the threshold of viability. Cazan-London and co-workers (2005) analyzed willingness or unwillingness to perform cesarean delivery at 24 weeks. They found that although survival increased with willingness, so too did survival with major morbidity. They stressed that both absolute survival and long-term handicaps must be considered when proceeding with aggressive intervention in extremely preterm pregnancies.

Policy for Threshold of Viability at Parkland Hospital

Policies were developed in conjunction with the Neonatology Service. We must emphasize that the decision not to perform cesarean delivery does not necessarily imply

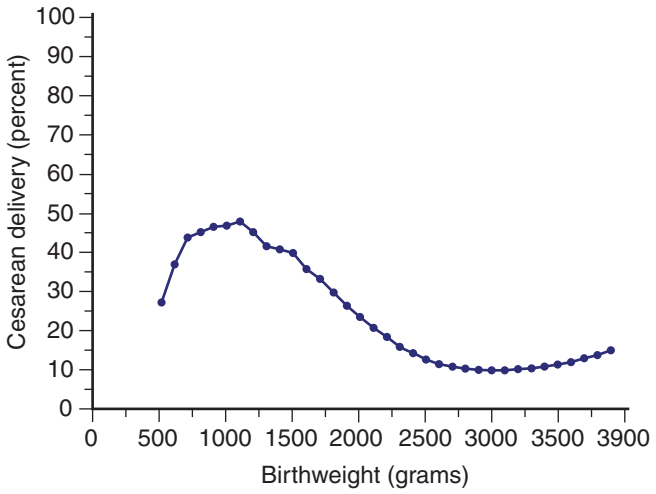

FIGURE 36-5 U.S. cesarean delivery rates by birthweight from 1999 to 2000. (Reprinted from Lee HC, Gould JB: Survival advantage associated with cesarean delivery in very low birth weight vertex neonates, *Obstetrics & Gynecology,* 2006, vol. 107, no. 1, pp. 97–105, with permission.)

that the fetus is "nonviable" or "written off." Neonatologists are consulted before delivery, and there is discussion of survival and morbidity with the woman and her family. A neonatologist attends each delivery and determines subsequent management.

From an obstetrical standpoint, all fetal indications for cesarean delivery in more advanced pregnancies are practiced in women at 25 weeks. Cesarean delivery is not offered for fetal indications at 23 weeks. At 24 weeks, cesarean delivery is not offered unless fetal weight is estimated at 750 g or greater. Aggressive obstetrical management is practiced in cases of growth restriction.

Late Preterm Birth

Infants between 34 and 36 weeks account for approximately 75 percent of all preterm births, as shown in **Figure 36-7**, and are the fastest increasing and largest proportion of singleton preterm births in the United States (Raju and colleagues, 2006).

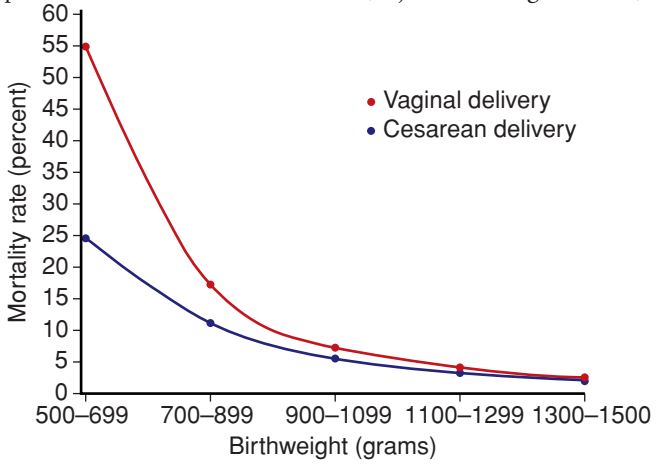

FIGURE 36-6 Birthweight-specific neonatal mortality rate by mode of delivery in the United States from 1999 to 2000. (Reprinted from Lee HC, Gould JB: Survival advantage associated with cesarean delivery in very low birth weight vertex neonates, *Obstetrics & Gynecology,* 2006, vol. 107, no. 1, pp. 97–105, with permission.)

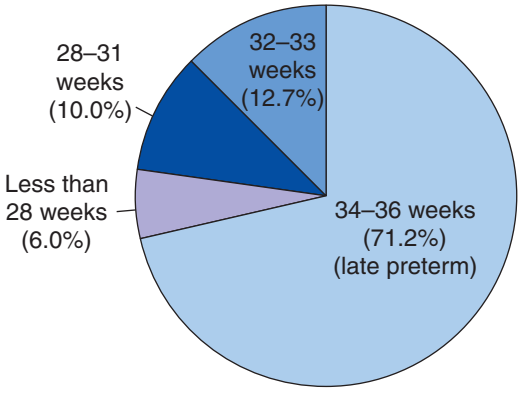

FIGURE 36-7 Percent distribution of preterm births in the United States for 2004. (From Martin and colleagues, 2006.)

As such, late preterm birth is receiving increased attention as to optimal obstetrical and neonatal management.

To estimate the risks associated with late preterm births, we analyzed neonatal mortality and morbidity rates at 34, 35, and 36 weeks compared with those of births at term between 1988 and 2005 at Parkland Hospital (McIntire and Leveno, 2008). We were particularly interested in obstetrical complications during this time, because if modified, rates of late preterm birth can possibly be decreased. Approximately 3 percent of births during the study period occurred between 24 and 32 weeks, and 9 percent were during the late preterm weeks. Thus, late preterm births accounted for three fourths of all preterm births. Approximately 80 percent of late preterm births were due to idiopathic spontaneous preterm labor or prematurely ruptured membranes (**Fig. 36-8**). Complications such as hypertension or placental accidents were implicated in approximately 20 percent of cases.

Neonatal mortality rates were significantly increased in each late preterm week compared with those at 39 weeks as the referent and as shown in **Figure 36-9**. Similarly, Tomashek and coworkers (2007) analyzed all United States births between 1995 and 2002 and also found increased neonatal mortality rates for late preterm infants. Importantly, indices of neonatal morbidity shown in **Table 36-5** are increased in late preterm infants born

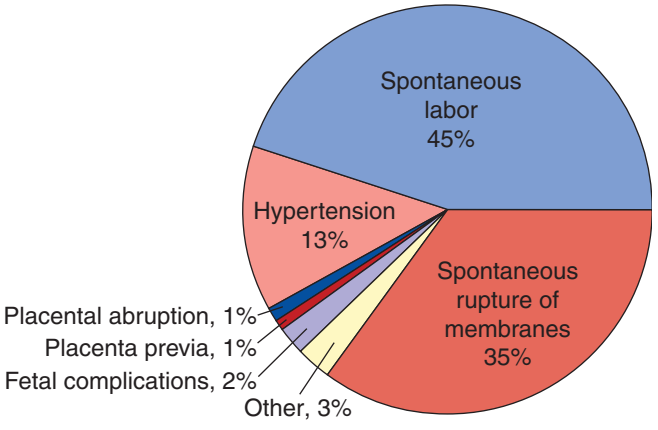

FIGURE 36-8 Obstetrical complications associated with 21,771 late preterm births at Parkland Hospital. (Adapted from McIntire and Leveno, 2008.)

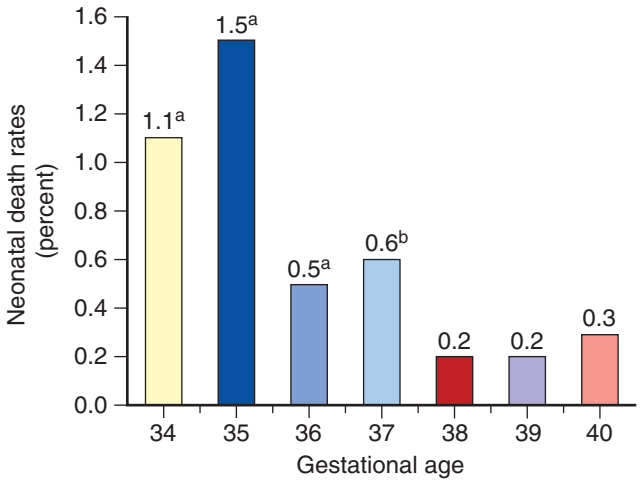

FIGURE 36-9 Neonatal death rates at Parkland Hospital from 34 to 40 weeks' gestation in singleton infants without malformations. [a]$p < .001$ compared with 39 weeks as the referent. [b]$p = .02$ compared with 39 weeks as the referent. (Reprinted from McIntire DD, Leveno KJ: Neonatal mortality and morbidity rates in late preterm births compared with births at term, *Obstetrics & Gynecology,* 2008, vol. 111, no. 1, pp. 35–41, with permission.)

at Parkland. Fuchs and colleagues (2009) reported similar results regarding respiratory morbidity in 722 infants. Specifically, the frequency of respiratory morbidity decreased by approximately 50 percent per week from 34 to 37 completed weeks. Increased rates of adverse neurodevelopment have also been found in late preterm infants compared with term newborns (Petrini and co-workers, 2009).

These findings from Parkland Hospital suggest that the healthcare focus on prematurity should be expanded to include late preterm births. Even so, because approximately 80 percent of these women begin labor spontaneously—similar to births before 32 weeks—attempts to interrupt preterm labor have not been satisfactory. Specifically, the Institute of Medicine report *Preterm Birth: Causes, Consequences, and Prevention* (2006) acknowledges that treatment of preterm labor has not prevented preterm birth. Thus, we are of the view that a national strategy aimed at prevention of late preterm births is unlikely to provide discernible benefit without new developments in the prevention and management of preterm labor. In the meantime, the Maternal-Fetal Medicine Units Network is preparing a study of corticosteroid efficacy in late preterm births. The American College of Obstetricians and Gynecologists (2008a) has emphasized that late preterm deliveries should occur only when an accepted maternal or fetal indication for delivery exists.

REASONS FOR PRETERM DELIVERY

There are four main direct reasons for preterm births in the United States:

1. Delivery for maternal or fetal indications in which labor is induced or the infant is delivered by prelabor cesarean delivery
2. Spontaneous unexplained preterm labor with intact membranes

TABLE 36-5. Neonatal Morbidity Rates at Parkland Hospital in Live Births Delivered Late Preterm Compared with 39 Weeks

	Preterm Births			Term Births
Morbidity[a]	34 weeks (n = 3498)	35 weeks (n = 6571)	36 weeks (n = 11,702)	39 Weeks (n = 84,747)

3. Idiopathic preterm premature rupture of membranes (PPROM)
4. Twins and higher-order multifetal births.

Of preterm births, 30 to 35 percent are indicated, 40 to 45 percent are due to spontaneous preterm labor, and 30 to 35 percent follow preterm rupture of membranes (Goldenberg and colleagues, 2008b). Indeed, much of the increase in the singleton preterm birth rate in the United States is explained by rising numbers of indicated preterm births (Ananth and colleagues, 2005).

Reasons for preterm birth have multiple, often interacting, antecedents and contributing factors. This complexity has greatly confounded efforts to prevent and manage this complication. This is particularly true for preterm ruptured membranes and spontaneous preterm labor, which together lead to 70 to 80 percent of preterm births. Lastly, according to data from Martin and co-workers (2006), approximately one in six preterm births in the United States are from twins or higher-order multifetal pregnancies (see Chap. 39, p. 859). For example, in 2004, there were 508,356 preterm births, and of these, 86,116 or 17 percent were from multifetal pregnancies. Many of these pregnancies were achieved using ovulation-inducing drugs and assisted reproductive technologies.

Medical and Obstetrical Indications

Ananth and Vintzileos (2006) used Missouri birth data from 1989 to 1997 to analyze factors leading to indicated birth before 35 weeks. Preeclampsia, fetal distress, small for gestational age, and placental abruption were the most common indications for medical intervention resulting in preterm birth. Other less common causes were chronic hypertension, placenta previa, unexplained bleeding, diabetes, renal disease, Rh isoimmunization, and congenital malformations.

Preterm Prematurely Ruptured Membranes

Defined as rupture of the membranes before labor and prior to 37 weeks, preterm premature rupture of membranes can result from a wide array of pathological mechanisms, including intraamnionic infection. Other factors implicated include low socioeconomic status, low body mass index—less than 19.8, nutritional deficiencies, and cigarette smoking. Women with prior preterm ruptured membranes are at increased risk for recurrence during a subsequent pregnancy (Bloom and associates, 2001). Most cases of preterm rupture, however, occur without risk factors.

Spontaneous Preterm Labor

Most commonly, preterm birth—up to 45 percent of cases—follows spontaneous labor. Goldenberg and colleagues (2008b) reviewed the pathogenesis of preterm labor and implicated: (1) progesterone withdrawal, (2) oxytocin initiation, and (3) decidual activation. Deviations from normal fetal growth have also been noted in spontaneous preterm labor and suggest a fetal role (Morken and co-workers, 2006).

The progesterone withdrawal theory stems from studies in sheep. As parturition nears, the fetal-adrenal axis becomes more sensitive to adrenocorticotropic hormone, increasing the secretion of cortisol (see Chap. 6, p. 157). Fetal cortisol stimulates placental 17-α-hydroxylase activity, which decreases progesterone secretion and increases estrogen production. The reversal in the estrogen/progesterone ratio results in increased prostaglandin formation, which initiates a cascade that culminates in labor. In human beings, serum progesterone concentrations do not fall as labor approaches. Even so, because progesterone antagonists such as RU486 initiate preterm labor and progestational agents prevent preterm labor, decreased local progesterone concentrations may play a role.

Because intravenous oxytocin increases the frequency and intensity of uterine contractions, oxytocin is assumed to play a part in labor initiation. But serum concentrations of oxytocin do not rise before labor, and the clearance of oxytocin remains constant. Accordingly, oxytocin is an unlikely initiator.

An important pathway leading to labor initiation implicates inflammatory decidual activation. At term, such activation seems to be mediated at least in part by the fetal-decidual paracrine system and perhaps through localized decreases in progesterone concentration. In many cases of early preterm labor, however, decidual activation seems to arise in the context of intrauterine bleeding or occult intrauterine infection.

ANTECEDENTS AND CONTRIBUTING FACTORS

Threatened Abortion

Vaginal bleeding in early pregnancy is associated with increased adverse outcomes later. Weiss and associates (2004) reported outcomes with vaginal bleeding at 6 to 13 weeks in nearly 14,000 women. Both light and heavy bleeding were associated with subsequent preterm labor, placental abruption, and subsequent pregnancy loss prior to 24 weeks.

Lifestyle Factors

Cigarette smoking, inadequate maternal weight gain, and illicit drug use have important roles in both the incidence and outcome of low-birthweight neonates (see Chap. 14, p. 329). In addition, Ehrenberg and colleagues (2009) found that overweight women at risk for preterm birth had lower rates of preterm delivery before 35 weeks than at-risk women with normal weight. Some of these effects are undoubtedly due to restricted fetal growth, but Hickey and colleagues (1995) linked prenatal weight gain specifically with preterm birth. Other maternal factors implicated include young or advanced maternal age, poverty, short stature, vitamin C deficiency, and occupational factors such as prolonged walking or standing, strenuous working conditions, and long weekly work hours (Casanueva, 2005; Gielchinsky, 2002; Kramer, 1995; Luke, 1995; Meis, 1995; Satin, 1994, and all their colleagues).

Psychological factors such as depression, anxiety, and chronic stress have been reported in association with preterm birth (Copper, 1996; Li, 2008; Littleton, 2007; Mercer, 2002, and all their associates). Neggers and co-workers (2004) found

a significant link between low birthweight and preterm birth in women injured by physical abuse (see Chap. 42, p. 936).

Racial and Ethnic Disparity

In the United States and in the United Kingdom, women classified as black, African-American, and Afro-Caribbean are consistently reported to be at higher risk of preterm birth (Goldenberg and colleagues, 2008b). Other associations include low socioeconomic status and educational status. Lu and Chen (2004) used the federal-state cooperative survey, *Pregnancy Risk Assessment Monitoring System (PRAMS)*, to study stressful life events in minority populations of pregnant women and found these to be unrelated to preterm birth. Kistka and colleagues (2007) used Missouri state data to analyze racial disparity independent of medical and socioeconomic risk factors and found black women to have an increased risk of recurrent preterm birth. The authors implied evidence of an intrinsic increased risk of preterm birth in this population.

Work During Pregnancy

Studies of work and physical activity related to preterm birth have produced conflicting results (Goldenberg and colleagues, 2008b). There is some evidence, however, that working long hours and hard physical labor are probably associated with increased risk of preterm birth.

Genetic Factors

The recurrent, familial, and racial nature of preterm birth has led to the suggestion that genetics may play a causal role (Anum, 2009; Lie, 2006; Ward, 2005, and all their co-workers). There is an accumulating literature on genetic variants that buttresses this concept (Gibson, 2007; Hampton, 2006; Li, 2004; Macones, 2004, and all their associates). Several such studies have also implicated immunoregulatory genes in potentiating chorioamnionitis in cases of preterm delivery due to infection (Varner and Esplin, 2005).

Periodontal Disease

Gum inflammation is a chronic anaerobic inflammation that affects as many as 50 percent of pregnant women in the United States (Goepfert and co-workers, 2004). Vergnes and Sixou (2007) performed a meta-analysis of 17 studies and concluded that periodontal disease was significantly associated with preterm birth—odds ratio 2.83 (CI 1.95–4.10). In an accompanying editorial, Stamilio and colleagues (2007) concluded that the data used were not robust enough to recommend screening and treatment of pregnant women.

To better study the relationship with periodontitis, Michalowicz and associates (2006) randomly assigned 813 pregnant women between 13 and 17 weeks with periodontal disease to treatment during pregnancy or postpartum. They found that treatment during pregnancy improved periodontal disease and that it is safe, but it did not significantly alter rates of preterm birth.

Birth Defects

In a secondary analysis of data from the First- and Second-Trimester Evaluation of Risk (FASTER) Trial, Dolan and colleagues (2007) found after controlling for multiple confounding factors that birth defects were associated with preterm birth and low birthweight.

TABLE 36-6. Recurrent Spontaneous Preterm Births According to Prior Outcome

Birth Outcome[a]	Second Birth ≤ 34 Weeks Percent
First birth ≥ 35 weeks	5
First birth ≤ 34 weeks	16
First and second birth ≤ 34 weeks	41

[a]Data from 15,863 women delivering their first and subsequent pregnancies at Parkland Hospital.
Adapted from Bloom and associates (2001) with permission.

Interval between Pregnancies and Preterm Birth

Short intervals between pregnancies have been known for some time to be associated with adverse perinatal outcomes. In a recent meta-analysis, Conde-Agudelo and co-workers (2006) reported that intervals shorter than 18 months and longer than 59 months were associated with increased risks for both preterm birth and small-for-gestational age infants.

Prior Preterm Birth

A major risk factor for preterm labor is prior preterm delivery (Spong, 2007). Shown in Table 36-6 is the incidence of recurrent preterm birth in nearly 16,000 women delivered at Parkland Hospital (Bloom and associates, 2001). The risk of recurrent preterm delivery for women whose first delivery was preterm was increased threefold compared with that of women whose first neonate was born at term. More than a third of women whose first two newborns were preterm subsequently delivered a third preterm newborn. Most—70 percent—of the recurrent births in this study occurred within 2 weeks of the gestational age of the prior preterm delivery. Importantly, the causes of prior preterm delivery also recurred.

Although women with prior preterm births are clearly at risk for recurrence, they contributed only 10 percent of the total preterm births in this study. Expressed another way, 90 percent of the preterm births at Parkland Hospital cannot be predicted based on a history of preterm birth. Extrapolating data from the new United States birth certificate, which was updated in 2003, it is estimated that approximately 2.5 percent of women delivered in 2004 had a history of prior preterm birth (Martin and Menacker, 2007). Self-reported coitus during early pregnancy was not associated with an increased risk of recurrent preterm birth (Yost and co-workers, 2006).

Infection

Goldenberg and colleagues (2008b) have reviewed the role of infection in preterm birth. It is hypothesized that intrauterine

infections trigger preterm labor by activation of the innate immune system. In this hypothesis, microorganisms elicit release of inflammatory cytokines such as interleukins and tumor necrosis factor (TNF), which in turn stimulate the production of prostaglandin and/or matrix-degrading enzymes. Prostaglandins stimulate uterine contractions, whereas degradation of extracellular matrix in the fetal membranes leads to preterm rupture of membranes. It is estimated that 25 to 40 percent of preterm births result from intrauterine infection. Potential routes of intrauterine infection are shown in **Figure 36-10**.

Two microorganisms, *Ureaplasma urealyticum* and *Mycoplasma hominis*, have emerged as important perinatal pathogens. Goldenberg and colleagues (2008a) reported that 23 percent of neonates born between 23 and 32 weeks have positive umbilical blood cultures for these genital mycoplasmas. Similar results were reported earlier by the research group at the Perinatology Research Branch of the National Institute of Child Health and Human Development (NICHD). In one study, amnionic fluid was aspirated by amniocentesis from 219 Korean women with prematurely ruptured membranes before 25 weeks. A positive culture result, primarily for *U. urealyticum*, was found in 23 percent (Shim and associates, 2004). Similarly, Gomez and co-workers (2005) performed amniocentesis in 401 Chilean women and found microbial invasion in 7 percent—the most common organism was *U. urealyticum*. A sonographically measured short cervix was associated with microbial invasion suggesting ascent from the lower genital tract (see Fig. 36-10).

There have been several studies in which antimicrobial treatment was given to prevent preterm labor due to microbial invasion. Because of the above-cited data, these strategies especially targeted mycoplasma species. Morency and Bujold (2007) performed a meta-analysis of 61 articles and suggested that antimicrobials given in the second trimester may prevent subsequent preterm birth. Andrews and colleagues (2006) reported results of a double-blind interconceptional trial from the University of Alabama in Birmingham. A course of azithromycin plus metronidazole was given every 4 months to 241 nonpregnant women whose last pregnancy resulted in spontaneous delivery before 34 weeks. Approximately 80 percent of the women with subsequent pregnancies had received study drug within 6 months of their subsequent conception. Such interconceptional antimicrobial treatment did not reduce the rate of recurrent preterm birth. Tita and co-workers (2007) performed a subgroup analysis of these same data and concluded that such use of antimicrobials may be harmful. In another study, Goldenberg and colleagues (2006) randomized 2661 women at four African sites to placebo or metronidazole plus erythromycin between 20 and 24 weeks followed by ampicillin plus metronidazole during labor. This antimicrobial regimen did not reduce the rate of preterm birth nor that of histological chorioamnionitis.

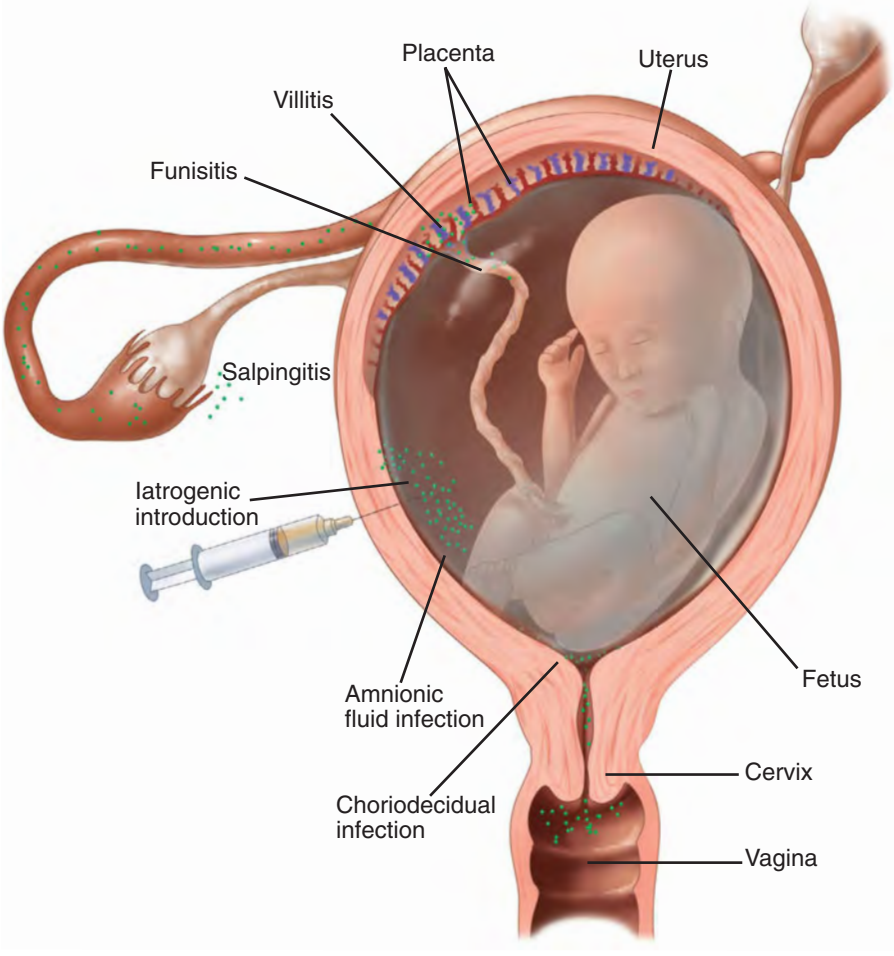

FIGURE 36-10 Potential routes of intrauterine infection.

Bacterial Vaginosis

In this condition, normal, hydrogen peroxide-producing, lactobacillus-predominant vaginal flora is replaced with anaerobes that include *Gardnerella vaginalis, Mobiluncus* species, and *Mycoplasma hominis* (Hillier and colleagues, 1995; Nugent and co-workers, 1991). Its diagnosis and management are discussed in Chapter 59 (see p. 1246). Using Gram staining, relative concentrations of the bacterial morphotypes characteristic of bacterial vaginosis are determined and graded as the *Nugent score*.

Bacterial vaginosis has been associated with spontaneous abortion, preterm labor, preterm rupture of membranes, chorioamnionitis, and amnionic fluid infection (Hillier, 1995; Kurki, 1992; Leitich, 2003a, b, and all their colleagues). Environmental factors appear to be important in the development of bacterial vaginosis. Exposure

to chronic stress, ethnic differences, and frequent or recent douching have all been associated with increased rates of the condition (Culhane and co-workers, 2002; Ness and associates, 2002). A gene-environment interaction was identified by Macones and colleagues (2004). Women with bacterial vaginosis and a susceptible TNF-α genotype had a ninefold increased incidence of preterm birth.

From all of these studies, there seems no doubt that adverse vaginal flora is associated in some way with spontaneous preterm birth. Unfortunately, to date, screening and treatment have not been shown to prevent preterm birth. Indeed, microbial resistance or antimicrobial-induced change in the vaginal flora has been reported as a result of regimens intended to eliminate bacterial vaginosis (Beigi and colleagues, 2004; Carey and Klebanoff, 2005). Okun and associates (2005) performed a systematic review of reports on the use of antibiotics given for bacterial vaginosis and for *Trichomonas vaginalis*. They found no evidence to support such use for the prevention of preterm birth in either low-risk or high-risk women.

Screening Methods for Prevention of Preterm Birth

Risk-Scoring Systems

There has been considerable interest in risk-scoring systems to identify women at greatest risk for preterm birth. In their review, Hueston and associates (1995) found no benefits of this programmatic approach. Mercer and colleagues (1996) concluded that risk assessment failed to identify most women who deliver preterm neonates. In another study, Klerman and coworkers (2001) randomly assigned 619 women with a modified risk assessment score for preterm delivery of 10 or higher to receive augmented or customary prenatal care. Mean birthweight and incidences of preterm delivery and low birthweight were similar in both groups and in the general obstetrical population. Recommendations from the American College of Obstetricians and Gynecologists (2008a) are listed in Table 36-7.

TABLE 36-7. Recommended Screening Strategies to Prevent Preterm Birth

- No current data support use of home uterine-activity monitoring or bacterial vaginosis screening.
- Screening for risk of preterm labor, other than historical risk factors, is not beneficial in the general obstetrical population.
- Sonography to determine cervical length and/or fetal fibronectin level measurement may be useful in determining women at risk for preterm labor. However, their value may rest primarily with their negative-predictive value given the lack of proven treatment options.

Compiled from American College of Obstetricians and Gynecologists (2001, 2008a).

DIAGNOSIS

Patient Symptoms

Early differentiation between true and false labor is difficult before there is demonstrable cervical effacement and dilatation. Uterine activity alone can be misleading because of *Braxton Hicks contractions,* which are discussed in detail in Chapter 18 (p. 437). These contractions, described as irregular, nonrhythmical, and either painful or painless, can cause considerable confusion in the diagnosis of true preterm labor. Not infrequently, women who deliver before term have uterine activity that is attributed to Braxton Hicks contractions, prompting an incorrect diagnosis of false labor. Because uterine contractions alone may be misleading, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (1997) had earlier proposed the following criteria to document preterm labor:

1. Contractions of four in 20 minutes or eight in 60 minutes plus progressive change in the cervix
2. Cervical dilatation greater than 1 cm
3. Cervical effacement of 80 percent or greater.

Currently, however, such clinical findings are now considered inaccurate predictors of preterm delivery (American College of Obstetricians and Gynecologists, 2003). Thus, such explicit criteria do not appear in more recent guidelines (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2008).

In addition to painful or painless uterine contractions, symptoms such as pelvic pressure, menstrual-like cramps, watery vaginal discharge, and lower back pain have been empirically associated with impending preterm birth. Such complaints are thought by some to be common in normal pregnancy and are therefore often dismissed by patients, clinicians, and nurses. The importance of these symptoms as a harbinger of labor has been emphasized by some but not all investigators (Copper and colleagues, 1990; Iams and associates, 1990; Kragt and Keirse, 1990). Iams and colleagues (1994) found that the signs and symptoms signaling preterm labor, including uterine contractions, appeared only within 24 hours of preterm labor.

Cervical Changes

Cervical Dilatation

Asymptomatic cervical dilatation after midpregnancy is suspected as a risk factor for preterm delivery, although some clinicians consider it to be a normal anatomical variant, particularly in parous women. Studies, however, have suggested that parity alone is not sufficient to explain cervical dilatation discovered early in the third trimester. Cook and Ellwood (1996) longitudinally evaluated cervical status with transvaginal sonography between 18 and 30 weeks in both nulliparous and parous women who all subsequently gave birth at term. Cervical length and diameter were identical in both groups throughout these critical weeks. At Parkland Hospital, routine cervical examinations were performed between 26 and 30 weeks in 185 women. Approximately 25 percent of women whose cervices were

dilated 2 or 3 cm delivered prior to 34 weeks. Other investigators have verified cervical dilatation as a predictor of increased preterm delivery risk (Copper and associates, 1995; Pereira and colleagues, 2007).

Although women with dilatation and effacement in the third trimester are at increased risk for preterm birth, detection does not improve pregnancy outcome. Buekens and co-workers (1994) randomly assigned 2719 women to undergo routine cervical examinations at each prenatal visit and compared them with 2721 women in whom serial examinations were not performed. Knowledge of antenatal cervical dilatation did not affect any pregnancy outcome related to preterm birth or the frequency of interventions for preterm labor. The investigators also reported that cervical examinations were not related to preterm membrane rupture. It seems, therefore, that prenatal cervical examinations are neither beneficial nor harmful.

Cervical Length

Vaginal-probe sonographic cervical assessment has been evaluated extensively over the past decade. Technique is important, and Yost and colleagues (1999) have cautioned that special expertise is needed. Iams and co-workers (1996) measured cervical length at approximately 24 weeks and again at 28 weeks in 2915 women not at risk for preterm birth. The mean cervical length at 24 weeks was approximately 35 mm, and those women with progressively shorter cervices experienced increased rates of preterm birth.

In women with a previous birth before 32 weeks, Owen and associates (2001) reported a significant correlation of cervical length at 16 to 24 weeks and subsequent preterm birth before 35 weeks. In their review, Owen and colleagues (2003) concluded that the value of cervical length to predict birth before 35 weeks is apparent only in women at high risk for preterm birth. De Carvalho and co-workers (2005) reported an interesting study of sonographic examination of the cervix in 1958 women attending a routine prenatal clinic at the University of São Paulo. These investigators correlated sonographic cervical length, funneling, and prior history of preterm birth with delivery before 35 weeks. Funneling was defined as bulging of the membranes into the endocervical canal and protruding at least 25 percent of the entire cervical length (**Fig. 36-11**). As shown in **Figure 36-12**, a short cervix by itself was the poorest predictor of preterm birth, whereas funneling plus a history of prior preterm birth was highly predictive.

Incompetent Cervix

Cervical incompetence is a clinical diagnosis characterized by recurrent, painless cervical dilatation and spontaneous midtrimester birth in the absence of spontaneous membrane rupture, bleeding, or infection. It is considered in detail in Chapter 9 (see p. 218).

Ambulatory Uterine Monitoring

An external tocodynamometer belted around the abdomen and connected to an electronic waist recorder allows a woman to ambulate while uterine activity is recorded. Results are transmitted via telephone daily. Women are educated concerning signs and symptoms of preterm labor, and clinicians are kept apprised of their progress. The 1985 approval of this monitor by the Food and Drug Administration prompted its widespread clinical use. Subsequently, the American College of Obstetricians and Gynecologists (1995) concluded that the use of this expensive, bulky, and time-consuming system does not reduce preterm birth rates. Studies that followed confirmed this conclusion. In the Collaborative Home Uterine Monitoring Study Group (1995), sham transducers were used in 655 women and outcomes compared with those of 637 women with functioning monitors. The rate of preterm birth was similar in both groups.

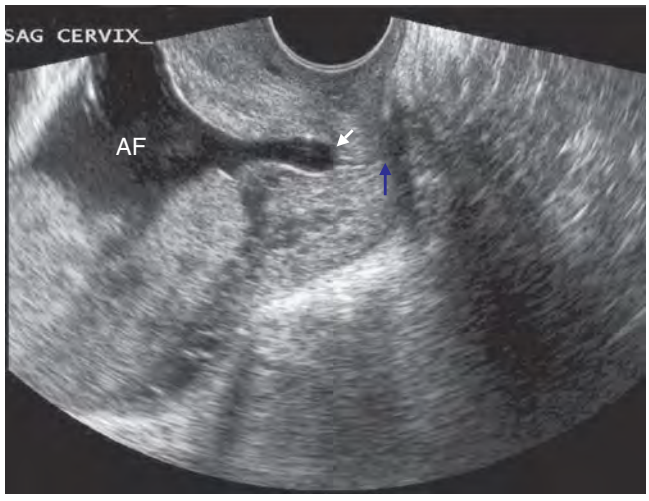

FIGURE 36-11 Transvaginal sonogram of a cervix and funneling. The amnionic sac is seen to bulge into the endocervical canal (*white arrow*). The cervix is markedly shortened. Its length is measured between the leading edge of the protruding amnionic sac and the ectocervix. The ectocervix is marked by a blue arrow. AF = amnionic fluid. (Courtesy of Dr. Irene Stafford.)

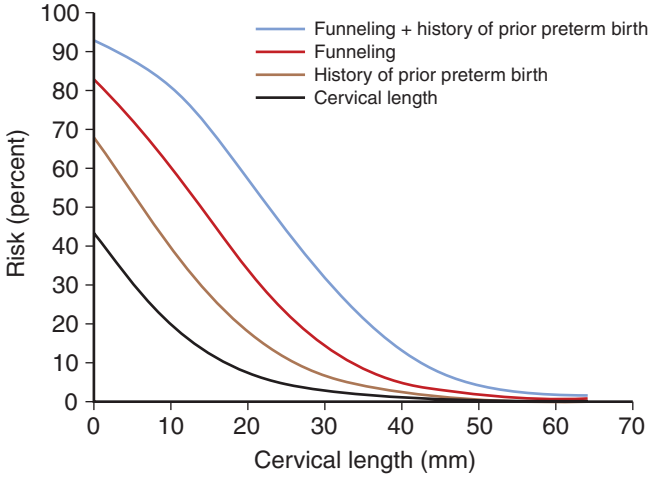

FIGURE 36-12 The probability of delivery at or before 34 weeks' gestation according to cervical length, presence of funneling, previous history of prematurity, and presence of funneling combined with a previous history of prematurity. (Modified from de Carvalho and colleagues, 2005, with permission.)

Iams and colleagues (2002) analyzed data from almost 35,000 hours of daily home monitoring from 306 women. They verified that contraction frequency increased with gestational age but that no pattern efficiently predicted preterm birth.

In a study by Dyson and associates (1998), women were randomly assigned to receive weekly contact with a nurse or to use home contraction monitoring. There were no differences in the rates of preterm delivery before 35 weeks or in the incidence of birthweights less than 1500 g or less than 2500 g. Moreover, women who used home monitoring had a significant increase in the number of unscheduled visits, and women with twins had increased use of tocolytic therapy.

Fetal Fibronectin

This glycoprotein is produced in 20 different molecular forms by a variety of cell types, including hepatocytes, fibroblasts, endothelial cells, and fetal amnion. Present in high concentrations in maternal blood and in amnionic fluid, it is thought to play a role in intercellular adhesion during implantation and in the maintenance of placental adhesion to uterine decidua (Leeson and colleagues, 1996). Fetal fibronectin is detected in cervicovaginal secretions in women who have normal pregnancies with intact membranes at term. It appears to reflect stromal remodeling of the cervix prior to labor.

Lockwood and co-workers (1991) reported that fibronectin detection in cervicovaginal secretions prior to membrane rupture was a possible marker for impending preterm labor. Fetal fibronectin is measured using an enzyme-linked immunosorbent assay, and values exceeding 50 ng/mL are considered positive. Sample contamination by amnionic fluid and maternal blood should be avoided.

A positive value for cervical or vaginal fetal fibronectin assay, even as early as 8 to 22 weeks, has been found to be a powerful predictor of subsequent preterm birth (Goldenberg and coworkers, 2000). In a randomized trial, a negative fibronectin assay in women with threatened preterm labor was associated with fewer admissions and decreased hospital stay (Lowe and associates, 2004). In contrast, Grobman and colleagues (2004) in a randomized trial of open versus blinded fetal fibronectin test results in 100 women found that this test did not affect physician behavior or healthcare costs associated with preterm contractions.

Andrews and associates (2003) studied the effectiveness of antimicrobial treatment to reduce the incidence of preterm birth in women with positive cervicovaginal fetal fibronectin tests. Of 16,317 women screened between 21 and 26 weeks, 6.6 percent had a positive result. In women given antimicrobial treatment or placebo, no differences were observed in rates of spontaneous preterm birth before 37 weeks—14.4 versus 12.4 percent; before 35 weeks—6.9 versus 7.5 percent; or before 32 weeks—4.3 versus 2.2 percent.

PREVENTION OF PRETERM BIRTH

Prevention of preterm birth has been an elusive goal. Recent reports, however, suggest that prevention in selected populations may be achievable.

Progesterone

Maternal plasma progesterone levels increase throughout pregnancy (see Chap. 3, p. 67). Accordingly, the use of progesterone to maintain uterine quiescence and "block" labor initiation, as espoused by Csapo (1956), has stimulated several studies. A pivotal study was done in the NICHD Maternal-Fetal Medicine Units Network (Meis and colleagues, 2003). In this trial, 310 women with prior preterm births were randomized to receive 17-hydroxyprogesterone caproate, while another 153 received placebo. Weekly intramuscular injections of either inert oil or 17-hydroxyprogesterone caproate were given from 16 through 36 weeks. Rates of delivery before 37, 35, and 32 weeks were all significantly reduced by progestin therapy. But similar studies of 17-hydroxyprogesterone caproate in both twins and triplets done by the Network showed no improvement in preterm birth rates (Caritis and associates, 2009; Rouse and coworkers, 2007).

There have also been two large studies by da Fonseca and colleagues (2003, 2007) of vaginal progesterone suppositories. In the first study, 142 women with a prior preterm birth, prophylactic cervical cerclage, or uterine malformation were randomly assigned to daily 100-mg progesterone or placebo suppositories. Progesterone suppositories were associated with a significant reduction in births before 34 weeks. In the second study, 413 women with sonographically short cervices—15 mm or less—were identified during routine prenatal care. They were randomly assigned to be given nightly 200-mg progesterone vaginal suppositories or placebo from 24 to 34 weeks. Spontaneous delivery before 34 weeks was significantly reduced by progesterone therapy. In contrast, O'Brien and colleagues (2007) randomized 659 women with a prior preterm birth to treatment with vaginal progesterone gel (90 mg) or placebo, and they found no differences in preterm birth rates. A study of the efficacy of 17-hydroxyprogesterone caproate in nulliparous women with sonographically short cervices is under way in the Maternal-Fetal Medicine Units Network.

Recommendations for Progesterone Use

Given the conflicting results surrounding progesterone use for prevention of preterm birth, there have been several meta-analyses of published studies. All investigators identified evidence of some benefits in terms of reducing preterm birth in specific populations. At the same time, all also called for more study, primarily because there was insufficient information regarding potential harms (Dodd, 2008; Mackenzie, 2006; Sanchez-Ramos, 2005; Tita and Rouse, 2009, and all their associates). At this time, the American College of Obstetricians and Gynecologists (2008c) has concluded that progesterone therapy should be limited to women with a documented history of a previous spontaneous birth at less than 37 weeks. Further studies are needed as to optimal preparation, dosage, and route of administration.

Cervical Cerclage

There are at least three circumstances when cerclage placement may be used to prevent preterm birth. First, cerclage may be used in women who have a history of recurrent midtrimester losses and who are diagnosed with an incompetent cervix

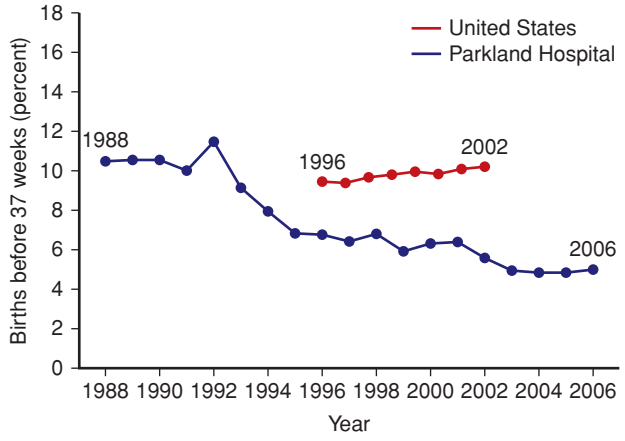

FIGURE 36-13 Number of births before 37 weeks' gestation at Parkland Hospital from 1988 to 2006 compared with that in the United States from 1995 to 2002. Analysis in both cohorts was limited to singleton live births ≥ 500 g who received prenatal care. (Reprinted from Leveno KJ, McIntire DD, Bloom SL, et al: Decreased preterm births in an inner-city public hospital, *Obstetrics & Gynecology*, 2009, vol. 113, no. 3, pp. 578–584, with permission.)

(see Chap. 9, p. 218). A second circumstance is in women identified during sonographic examination to have a short cervix. The third indication is "rescue" cerclage, done emergently when cervical incompetence is recognized in the women with threatened preterm labor (see p. 822).

Regarding the second indication, Berghella and colleagues (2005) reviewed several small trials of cerclage in this group and concluded that cerclage may reduce preterm birth rates in those women with a prior preterm birth. Owen and co-workers (2009) randomly assigned 302 women with prior preterm birth from 16 centers with a short cervix—defined as length < 25 mm—to cerclage or no procedure. Women with a cervical length < 15 mm delivered before 35 weeks significantly less often following cerclage compared with women with no cerclage—30 versus 65 percent. This study suggests that recurrent preterm birth can be prevented in a subset of women who have a history of prior preterm births.

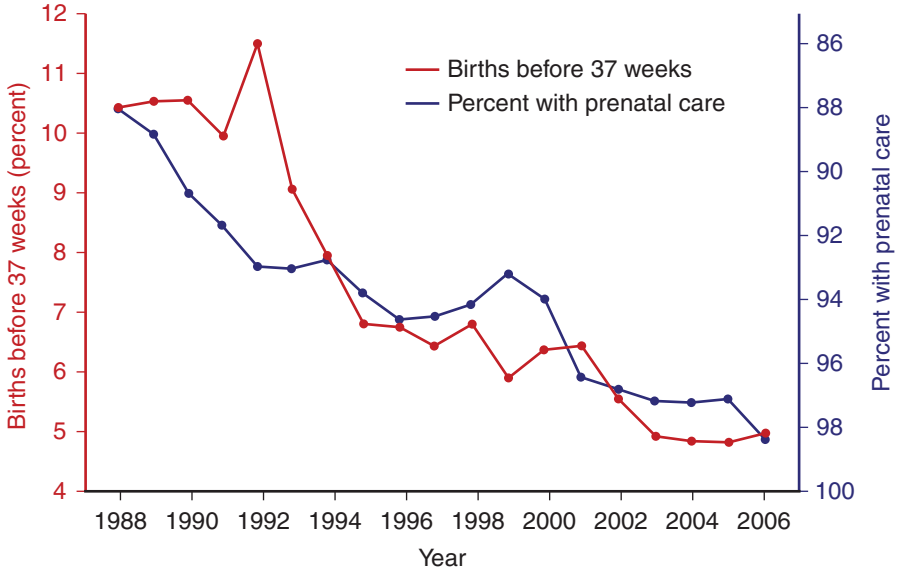

FIGURE 36-14 Relationship of increased prenatal care rates to decreased preterm birth rates at Parkland Hospital from 1988 to 2006. (Reprinted from Leveno KJ, McIntire DD, Bloom SL, et al: Decreased preterm births in an inner-city public hospital, *Obstetrics & Gynecology,* 2009, vol. 113, no. 3, pp. 578–584, with permission.)

Geographic-Based Public Healthcare Program

The decreasing rate of preterm births at Parkland Hospital between 1988 and 2006 shown in **Figure 36-13** coincided with a substantial increase in prenatal care utilization as shown in **Figure 36-14**. In the early 1990s, a concerted effort was made to improve access to and use of prenatal care. The intention was to develop a program of seamless care beginning with enrollment during the prenatal period and extending through delivery and into the puerperium. Prenatal clinics are placed strategically throughout Dallas County to provide convenient access for indigent women. When possible, these clinics were co-located with comprehensive medical and pediatric clinics that enhance patient use. Because the entire clinic system is operated by Parkland Hospital, administrative and medical oversight is seamless. For example, prenatal protocols are used by nurse practitioners at all clinic sites to guarantee homogeneous care. Women with high-risk pregnancy complications are referred to the hospital-based central clinic system. Here, high-risk pregnancy clinics operate each weekday, with specialty clinics for women with prior preterm birth, gestational diabetes, infectious diseases, multifetal pregnancy, and hypertensive disorders. Clinics are staffed by residents and midwives supervised by maternal-fetal medicine fellows and faculty. Because Parkland Hospital has a closed medical staff, all attending physicians are employed by the University of Texas Southwestern Department of Obstetrics and Gynecology. These faculty members adhere to agreed-upon practice guidelines using an evidence-based outcomes approach. Thus, prenatal care is considered one component of a comprehensive and orchestrated public health care system that is community-based. Putting this together, we hypothesize that the decrease in preterm births experienced at our inner-city hospital was attributable to a geographically based public healthcare program specifically targeting minority populations of pregnant women.

MANAGEMENT OF PRETERM RUPTURE OF MEMBRANES AND PRETERM LABOR

Women identified as being at risk for preterm birth and those who present with signs and symptoms of preterm labor have become candidates for a number of interventions intended to improve neonatal outcomes. In the absence of maternal or fetal indications warranting intentional delivery, interventions are intended to forestall preterm birth. Although many of these interventions are described in the following sections, they are not necessarily recommended. Some may produce borderline improvement at best, and others are unproven. For example, the American College of

Obstetricians and Gynecologists (2003, 2008b), in its review of preterm labor management, has concluded: "Despite the numerous management methods proposed, the incidence of preterm birth has changed little over the past 40 years. Uncertainty persists about the best strategies for managing preterm labor."

Diagnosis of Preterm Prematurely Ruptured Membranes

Diagnosis of ruptured membranes is detailed in Chapter 17 (see p. 392). A history of vaginal leakage of fluid, either as a continuous stream or as a gush, should prompt a speculum examination to visualize gross vaginal pooling of amnionic fluid, clear fluid from the cervical canal, or both. Confirmation of ruptured membranes is usually accompanied by sonographic examination to assess amnionic fluid volume, to identify the presenting part, and if not previously determined, to estimate gestational age. Amnionic fluid is slightly alkaline (pH 7.1–7.3) compared with vaginal secretions (pH 4.5–6.0), and this is the basis of frequently used pH testing for ruptured membranes. Blood, semen, antiseptics, or bacterial vaginosis, however, are all also alkaline and can give false-positive results.

Natural History of Preterm Ruptured Membranes

Cox and associates (1988) described pregnancy outcomes of 298 consecutive women who gave birth following spontaneously ruptured membranes between 24 and 34 weeks. Although this complication was identified in only 1.7 percent of pregnancies, it contributed to 20 percent of all perinatal deaths. By the time they presented, 75 percent of the women were already in labor, 5 percent were delivered for other complications, and another 10 percent were delivered within 48 hours. In only 7 percent was delivery delayed 48 hours or more after membrane rupture. This latter subgroup, however, appeared to benefit from delayed delivery, because there were no neonatal deaths. This contrasted with a neonatal death rate of 80 per 1000 in preterm newborns delivered within 48 hours of membrane rupture. Nelson and co-workers (1994) reported similar results.

The time from preterm ruptured membranes to delivery is inversely proportional to the gestational age when rupture occurs (Carroll and associates, 1995). As shown in **Figure 36-15**, very few days were gained when membranes ruptured during the third trimester compared with midpregnancy.

Hospitalization

Most clinicians hospitalize women with preterm ruptured membranes. Concerns about the costs of lengthy hospitalizations are usually moot, because most women enter labor within a week or less after membrane rupture. Carlan and co-workers (1993) randomly assigned 67 women with ruptured membranes to home or hospital management. No benefits were found for hospitalization, and maternal hospital stays were reduced by 50 percent in those sent home—14 versus 7 days. Importantly, the investigators emphasized that this study was too small to conclude that home management was safe.

Intentional Delivery

Prior to the mid-1970s, labor was usually induced in women with preterm ruptured membranes because of fears of sepsis. Two randomized trials compared labor induction with expectant management in such pregnancies. Mercer and colleagues (1993) randomly assigned 93 women with pregnancies between 32 and 36 weeks to undergo delivery or expectant management. Fetal lung maturity, as evidenced by mature surfactant profiles, was present in all cases. Intentional delivery reduced the length of maternal hospitalization and also reduced infection rates in both mothers and neonates. Cox and Leveno (1995) similarly apportioned 129 women between 30 and 34 weeks. Fetal lung maturity was not assessed. One fetal death resulted from sepsis in the pregnancies managed expectantly. Among those intentionally delivered, there were three neonatal deaths—two from sepsis and one from pulmonary hypoplasia. Thus, neither management approach proved to be superior.

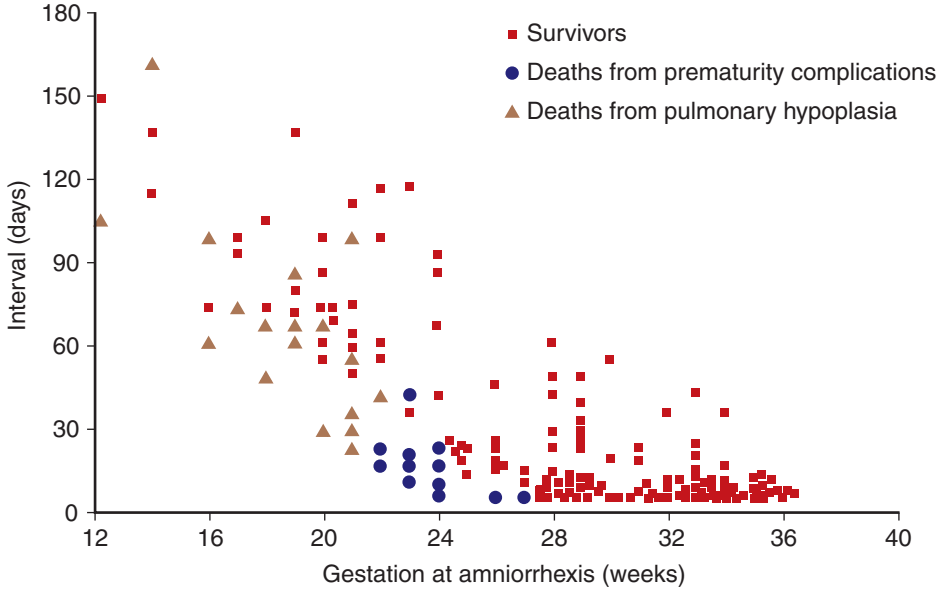

FIGURE 36-15 Relationship of time between preterm membrane rupture and delivery in 172 singleton pregnancies. (Reprinted from Carroll SG, Blott M, Nicolaides KH: Preterm prelabor amniorrhexis: Outcome of live births, *Obstetrics & Gynecology,* 1995, vol. 86, no. 1, pp. 18–25, with permission.)

Expectant Management

Despite extensive literature concerning expectant management of preterm ruptured membranes, tocolysis has been used in few studies. In randomized studies, women were assigned to receive either tocolysis or expectant management. The investigators concluded that active interventions did not improve perinatal outcomes (Garite and associates, 1981, 1987; Nelson and co-workers, 1985).

Other considerations with expectant management involve the use of digital cervical examination and cerclage. Alexander and colleagues (2000) analyzed findings in women expectantly managed between 24 and 32 weeks. They compared those who had one or two digital cervical examinations with women who were not examined digitally. Women who were examined had a rupture-to-delivery interval of 3 days compared with 5 days in those who were not examined. This difference did not worsen maternal or neonatal outcomes. McElrath and associates (2002) studied 114 women with cerclage in place who later had ruptured membranes prior to 34 weeks. They were compared with 288 controls who had not received a cerclage. Pregnancy outcomes were equivalent in both groups. As discussed in Chapter 9 (see p. 219), such management is controversial.

Risks of Expectant Management

Maternal and fetal risks vary with the gestational age at membrane rupture. Morales and Talley (1993b) expectantly managed 94 singleton pregnancies with ruptured membranes prior to 25 weeks. The average time gained was 11 days. *Although 41 percent of infants survived to age 1 year, only 27 percent were neurologically normal.* Similar results were reported by Farooqi (1998) and Winn (2000) and their associates. Lieman and colleagues (2005) found no improved neonatal outcomes with expectant management beyond 33 weeks. In contrast, McElrath and co-workers (2003) found that prolonged latency after membrane rupture was not associated with an increased incidence of fetal neurological damage.

The volume of amnionic fluid remaining after rupture appears to have prognostic importance in pregnancies before 26 weeks. Hadi and associates (1994) described 178 pregnancies with ruptured membranes between 20 and 25 weeks. Forty percent of women developed oligohydramnios defined by the absence of fluid pockets 2 cm or larger. Virtually all women with oligohydramnios delivered before 25 weeks, whereas 85 percent with adequate amnionic fluid volume were delivered in the third trimester. Carroll and colleagues (1995) observed no cases of pulmonary hypoplasia in fetuses born after membrane rupture at 24 weeks or beyond. This suggests that 23 weeks or less is the threshold for development of lung hypoplasia. Further, when contemplating early expectant management, consideration is also given to oligohydramnios and resultant limb compression deformities (see Chap. 21, p. 495).

Other risk factors have also been evaluated. In neonates born to women with active herpetic lesions who were expectantly managed, the infectious morbidity risk appeared to be outweighed by risks associated with preterm delivery (Major and associates, 2003). Lewis and colleagues (2007) found that expectant management of women with preterm ruptured membranes and noncephalic presentation had an increased rate of umbilical cord prolapse, especially before 26 weeks.

Clinical Chorioamnionitis

Most authors report that prolonged membrane rupture is associated with increased fetal and maternal sepsis (Ho and colleagues, 2003). If chorioamnionitis is diagnosed, prompt efforts to effect delivery, preferably vaginally, are initiated. Fever is the only reliable indicator for this diagnosis, and temperature of 38°C (100.4°F) or higher accompanying ruptured membranes implies infection. Maternal leukocytosis alone has not been found to be reliable. During expectant management, monitoring for sustained maternal or fetal tachycardia, for uterine tenderness, and for a malodorous vaginal discharge is warranted.

With chorioamnionitis, fetal and neonatal morbidity is substantively increased. Alexander and co-workers (1998) studied 1367 very-low-birthweight neonates delivered at Parkland Hospital. Approximately 7 percent were born to women with overt chorioamnionitis, and their outcomes were compared with similar newborns without clinical infection. Those in the infected group had a higher incidence of sepsis, respiratory distress syndrome, early-onset seizures, intraventricular hemorrhage, and periventricular leukomalacia. The investigators concluded that these very-low-birthweight neonates were vulnerable to neurological injury attributable to chorioamnionitis.

Although Locatelli and colleagues (2005) have challenged this finding, there is other evidence that very small newborns are at increased risk for sepsis. Yoon and associates (2000) found that intra-amnionic infection in preterm neonates was related to increased rates of cerebral palsy at 3 years. Petrova and coworkers (2001) studied more than 11 million singleton live births from 1995 to 1997 who were in the database of the National Center for Health Statistics. During labor, 1.6 percent of all women had fever, and this was a strong predictor of infection-related death in both term and preterm neonates. Bullard and associates (2002) reported similar results.

Accelerated Pulmonary Maturation

A variety of clinical events—some well defined—were once proposed to accelerate fetal surfactant production (Gluck, 1979). These included chronic renal or cardiovascular disease, hypertensive disorders, heroin addiction, fetal-growth restriction, placental infarction, chorioamnionitis, and preterm ruptured membranes. Although this view was widely held for many years, subsequent observations do not support this association (Hallak and Bottoms, 1993; Owen and associates, 1990).

Antimicrobial Therapy

The proposed microbial pathogenesis for spontaneous preterm labor or ruptured membranes has prompted investigators to give various antimicrobials in an attempt to forestall delivery. Mercer and Arheart (1995) reviewed 13 randomized trials performed before 35 weeks. Meta-analysis indicated that only three of 10 outcomes were *possibly* benefited: (1) fewer women developed chorioamnionitis, (2) fewer newborns developed sepsis, and (3) pregnancy was more often prolonged 7 days in women given antimicrobials. Neonatal survival, however, was unaffected, as was the incidence of necrotizing enterocolitis, respiratory distress, or intracranial hemorrhage.

To further address this issue, the Maternal-Fetal Medicine Units Network designed a trial to study expectant management combined with a 7-day treatment of ampicillin, amoxicillin plus erythromycin, or placebo. The women had membrane rupture between 24 and 32 weeks. Neither tocolytics nor corticosteroids were given. Antimicrobial-treated women had significantly fewer

newborns with respiratory distress syndrome, necrotizing enterocolitis, and composite adverse outcomes (Mercer and colleagues, 1997). The latency period was significantly longer. Specifically, 50 percent of women given an antimicrobial regimen remained undelivered after 7 days of treatment compared with only 25 percent of those given placebo. There was also significant prolongation of pregnancy at 14 and 21 days. Cervicovaginal group B streptococcal colonization did not alter these results.

More recent studies have examined the efficacy of shorter treatment lengths and other antimicrobial combinations. Three-day treatment compared with 7-day regimens using either ampicillin or ampicillin-sulbactam appeared equally effective in regard to perinatal outcomes (Lewis and associates, 2003; Segel and co-workers, 2003). Similarly, erythromycin compared with placebo offered a range of significant neonatal benefits. The amoxicillin-clavulanate regimen was not recommended, however, because of its association with an increased incidence of necrotizing enterocolitis (Kenyon and colleagues, 2004).

Some predicted that prolonged antimicrobial therapy in such pregnancies might have unwanted consequences. Carroll and co-workers (1996) and Mercer and associates (1999) cautioned that such therapy potentially increased the risk for resistant bacteria. Stoll and colleagues (2002) studied 4337 neonates weighing from 400 to 1500 g and born from 1998 to 2000 at centers of the Neonatal Research Network. Their outcomes were compared with those of 7606 neonates of similar birthweight born from 1991 to 1993. The overall rate of early-onset sepsis did not change between these two epochs. But the rate of group B streptococcal sepsis decreased from 5.9 per 1000 births in the 1991 to 1993 group to 1.7 per 1000 births in the 1998 to 2000 group. Comparing these same epochs, the rate of *Escherichia coli* sepsis increased—from 3.2 to 6.8 per 1000 births. Almost 85 percent of coliform isolates from the more recent cohort were ampicillin resistant. Neonates with early-onset sepsis were more likely to die, especially if they were infected with coliforms. Kenyon and co-workers (2008a) found that the prescription of antimicrobials for women with preterm rupture of membranes had no effect on the health of the children at age 7 years.

Corticosteroids

The National Institutes of Health Consensus Development Conference (2000) recommended a single course of antenatal corticosteroids for women with preterm membrane rupture before 32 weeks and in whom there was no evidence of chorioamnionitis. Since then, a number of meta-analyses have addressed this issue, and according to the American College of Obstetricians and Gynecologists (2007), single-dose therapy is recommended from 24 to 32 weeks. There is no consensus regarding treatment between 32 and 34 weeks. They are not recommended prior to 24 weeks.

Membrane Repair

Tissue sealants have been used for a variety of purposes in medicine and have become important in maintaining surgical hemostasis and stimulating wound healing. Devlieger and colleagues (2006) have reviewed the efficacy of sealants in the repair of fetal membrane defects such as in preterm ruptured membranes.

Recommended Management

The management scheme recommended by the American College of Obstetricians and Gynecologists (2007) is summarized in **Table 36-8**. This management is similar to that practiced at Parkland Hospital and the University of Alabama Hospital at Birmingham.

TABLE 36-8. Recommended Management of Preterm Ruptured Membranes

Gestational Age	Management
34 weeks or more	• Proceed to delivery, usually by induction of labor • Group B streptococcal prophylaxis is recommended
32 weeks to 33 completed weeks	• Expectant management unless fetal pulmonary maturity is documented • Group B streptococcal prophylaxis is recommended • Corticosteroids—no consensus, but some experts recommend • Antimicrobials to prolong latency if no contraindications
24 weeks to 31 completed weeks	• Expectant management • Group B streptococcal prophylaxis is recommended • Single-course corticosteroids use is recommended • Tocolytics—no consensus • Antimicrobials to prolong latency if no contraindications
Before 24 weeks[a]	• Patient counseling • Expectant management or induction of labor • Group B streptococcal prophylaxis is not recommended • Corticosteroids are not recommended • Antimicrobials—there are incomplete data on use in prolonging latency

[a]The combination of birthweight, gestational age, and sex provide the best estimate of chances of survival and should be considered in individual cases.

PRETERM LABOR WITH INTACT MEMBRANES

Women with signs and symptoms of preterm labor with intact membranes are managed much the same as described above for those with preterm ruptured membranes. The cornerstone of treatment is to avoid delivery prior to 34 weeks, if possible. Drugs used to abate or suppress preterm uterine contractions are subsequently discussed.

Amniocentesis to Detect Infection

Several tests have been used to diagnose intra-amnionic infection. Romero and co-workers (1993) evaluated the diagnostic value of amnionic fluid containing an elevated leukocyte count, a low glucose level, a high interleukin-6 concentration, or a positive Gram stain result in 120 women with preterm labor and intact membranes. Women with positive amnionic fluid culture results were considered infected. These investigators found that a negative Gram stain result was 99-percent specific to exclude amnionic fluid bacteria. A high interleukin-6 level was 82-percent sensitive for detection of amnionic fluids containing bacteria. Other investigators have also found good correlation between amnionic fluid interleukin-6 or leukocyte levels and chorioamnionic infection (Andrews and colleagues, 1995; Yoon and associates, 1996). Despite these associations, it has not been shown that amniocentesis to diagnose infection is associated with improved pregnancy outcomes in women with or without membrane rupture (Feinstein and colleagues, 1986). The American College of Obstetricians and Gynecologists (2003) has concluded that there is no evidence to support routine amniocentesis to identify infection.

Corticosteroid Therapy to Enhance Fetal Lung Maturation

Glucosteroids will accelerate lung maturation in preterm sheep fetuses, and thus Liggins and Howie (1972) evaluated them to treat women. Corticosteroid therapy was effective in lowering the incidence of respiratory distress and neonatal mortality rates if birth was delayed for at least 24 hours after *initiation* of betamethasone. Remarkably, infants exposed to corticosteroids in these early studies have been now followed to age 31 years with no ill effects detected. The work by Liggins and Howie (1972) has stimulated more than 35 years of fetal lung research. In 1995, a National Institutes of Health Consensus Development Panel recommended corticosteroids for fetal lung maturation in threatened preterm birth.

In a follow-up meeting, the National Institutes of Health Consensus Development Conference (2000) concluded that data were insufficient to assess the effectiveness of corticosteroids in pregnancies complicated by hypertension, diabetes, multifetal gestation, fetal-growth restriction, and fetal hydrops. It concluded, however, that it was reasonable to administer corticosteroids for these complications. Roberts and Dalziel (2006) reviewed antenatal corticosteroids for accelerating fetal lung maturation.

The issue of the fetal and infant safety with single versus repeat courses of corticosteroids for lung maturation has been the topic of two major trials. Although both found repeated courses to be beneficial in reducing neonatal respiratory morbidity rates, the long-term consequences were much different. Specifically, Crowther and colleagues (2007) studied outcomes in 982 women from the Australian Collaborative Study. These women were given a single weekly dose of 11.4 mg of betamethasone. These investigators found no adverse effects in the infants followed to age 2 years. Wapner and colleagues (2007) studied infants born to 495 women in a Network study who were randomized to receive two weekly 12-mg betamethasone doses given 24 hours apart. They were concerned by their finding of a nonsignificant increase in cerebral palsy rates in infants exposed to repeated courses. The twice-as-large betamethasone dose in the Network study was worrisome because there is some experimental evidence to support the view that adverse corticosteroid effects are dose dependent. Bruschettini and colleagues (2006) studied the equivalent of 12-mg versus 6-mg betamethasone given to pregnant cats. They reported that the lower dose had less severe effects on somatic growth without affecting cell proliferation in the fetal brain.

Stiles (2007) summarized the Australian and American studies as "early gain, long-term questions." We agree, and at Parkland Hospital, we follow the recommendation for single-course therapy by the American College of Obstetricians and Gynecologists (2008a).

"Rescue" Therapy

This refers to administration of a repeated corticosteroid dose when delivery becomes imminent and more than 7 days have elapsed since the initial dose. The 2000 Consensus Development Conference recommended that rescue therapy should not be routinely used and that it should be reserved for clinical trials. The first randomized trial reported by Peltoniemi and colleagues (2007) allocated 326 women to placebo or 12-mg betamethasone single-dose rescue regimens. Paradoxically, they found that the rescue dose of betamethasone increased the risk of respiratory distress syndrome! Subsequently, the American College of Obstetricians and Gynecologists (2008a) also recommended such therapy for trials. Most recently, in a multicenter study of 437 women < 33 weeks who were randomized to rescue therapy or placebo, Kurtzman and associates (2009) reported significantly decreased rates of respiratory complications and neonatal composite morbidity with rescue corticosteroids. There were, however, no differences in perinatal mortality rates and other morbidities. In another trial, McEvoy and co-workers (2009) showed that treated infants had improved respiratory compliance.

Which Corticosteroid?

As summarized by Murphy (2007), there is a 10-year question as to whether betamethasone is superior to dexamethasone for fetal lung maturation. Elimian and co-workers (2007) randomized 299 women between 24 and 33 weeks in a double-blinded trial of betamethasone versus dexamethasone. These two drugs were comparable in reducing the rates of major neonatal morbidities in preterm infants.

Antimicrobials

As with preterm ruptured membranes, antimicrobials have been given to arrest preterm labor. Here too, results have been disappointing. A Cochrane meta-analysis by King and Flenady (2000) of 10 randomized trials found no difference in the rates of newborn respiratory distress syndrome or of sepsis between placebo- and antimicrobial-treated groups. They did find, however, increased perinatal morbidity in the antimicrobial-treated group. Kenyon and associates (2001) reported the ORACLE Collaborative Group study of 6295 women with spontaneous preterm labor, intact membranes, and without evidence of infection. Women were randomly assigned to receive antimicrobial or placebo therapy. The primary outcomes of neonatal death, chronic lung disease, and major cerebral abnormality were similar in both groups. In his review, Goldenberg (2002) also concluded that antimicrobial treatment of women with preterm labor for the sole purpose of preventing delivery is generally not recommended. In a recent follow-up of the ORACLE II trial, Kenyon and colleagues (2008b) reported that fetal exposure to antimicrobials in this clinical setting was associated with an increased cerebral palsy rate at age 7 years compared with that of nonexposed infants.

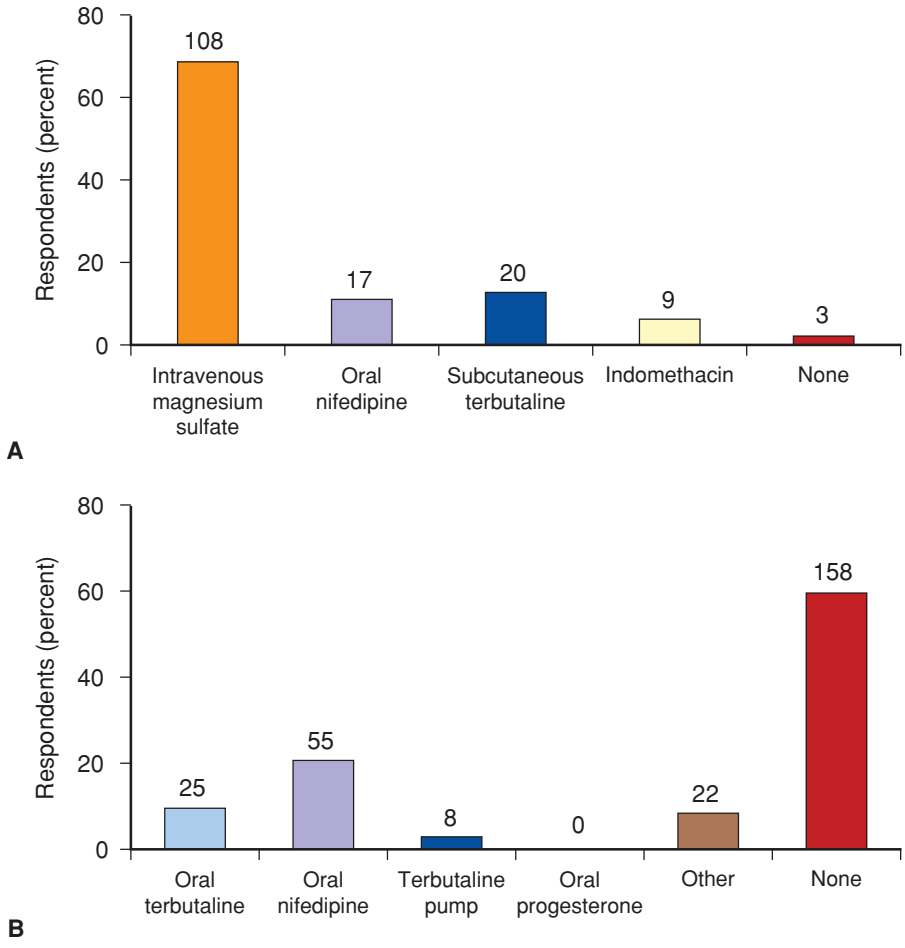

FIGURE 36-16 Results from an interactive questionnaire that surveyed use of tocolytic therapy for preterm labor. **A.** Tocolytic agent used by 157 respondents for initial treatment of a woman in preterm labor at 31 weeks 2 days of gestation. **B.** Maintenance tocolytic agent chosen by 268 respondents for this same woman when discharged 2 days later with no further contractions or cervical change. (From Norwitz and associates, 2004, with permission.)

Emergency or Rescue Cerclage

There is support for the concept that cervical incompetence and preterm labor are part of a spectrum leading to preterm delivery. Consequently, investigators have evaluated the role of cerclage done after preterm labor begins to manifest clinically. Harger (1983) concluded that if cervical incompetence is recognized with threatened preterm labor, emergency cerclage can be attempted, albeit with an appreciable risk of infection and pregnancy loss. Althuisius and associates (2003) randomly assigned 23 women with cervical incompetence prior to 27 weeks to bed rest, with or without emergency McDonald cerclage. Delivery delay was significantly greater in the cerclage group compared with that of bed rest alone—54 versus 24 days. Terkildsen and co-workers (2003) studied 116 women who underwent second-trimester emergency cerclage. Nulliparity, membranes extending beyond the external cervical os, and cerclage prior to 22 weeks were associated with a significantly decreased chance of pregnancy continuation to 28 weeks or beyond. Cerclage is discussed further on page 816 as well as in Chapter 9 (p. 218).

Inhibition of Preterm Labor

Although a number of drugs and other interventions have been used to prevent or inhibit preterm labor, none has been shown to be completely effective. The American College of Obstetricians and Gynecologists (2007) has concluded that tocolytic agents do not markedly prolong gestation, but may delay delivery in some women for at least 48 hours. This may facilitate transport to a regional obstetrical center and allow time for administration of corticosteroid therapy. It is estimated that 72,733 women giving birth in the United States in 2006 received tocolytic drugs (Martin and colleagues, 2009). The rate of tocolysis use was 1.7 percent in 2006, a rate that has fluctuated only slightly since 1996. Norwitz and co-workers (2004) performed an interactive survey of tocolytic treatment at the 2004 Annual Meeting of the Society of Maternal-Fetal Medicine. As shown in Figure 36-16, intravenous magnesium sulfate was the most commonly used tocolytic—about 70 percent of respondents. Approximately the same proportion of respondents would not prescribe *maintenance* therapy.

Bed Rest

This is one of the most often prescribed interventions during pregnancy, yet one of the least studied. In 1994, Goldenberg and colleagues reviewed the available literature on bed rest in pregnancy and concluded that they could find no evidence supporting or refuting the benefit of either bed rest or hospitalization in women threatening preterm delivery. More recently, Sosa and associates (2004) searched the Cochrane Database for randomized trials done to assess the efficacy of bed rest at home or with hospitalization. They concluded that the available evidence neither supported nor refuted the use of bed rest to prevent preterm birth.

Goulet and colleagues (2001) randomized 250 Canadian women to either home care or hospitalization after treatment of an acute episode of preterm labor and also found no benefits. Yost and colleagues (2005) attempted a randomized study at Parkland Hospital but terminated the study after 6 years due to low recruitment. In this study, bed rest in the hospital compared with bed rest at home had no effect on pregnancy duration in women with threatened preterm labor before 34 weeks. Bed rest was not enforced—that is, women were permitted ambulation *ad lib* either in the hospital or at home. Kovacevich and associates (2000) reported that bed rest for 3 days or more increased thromboembolic complications to 16 per 1000 women compared with only 1 per 1000 with normal ambulation. Promislow and co-workers (2004) observed significant bone loss in pregnant women prescribed outpatient bed rest.

Hydration and Sedation

Helfgott and associates (1994) compared hydration and sedation with bed rest in a randomized trial of 119 women with threatened preterm labor. Women who were randomly selected to receive 500 mL of crystalloid over 30 minutes and 8 to 12 mg of intramuscular morphine sulfate had outcomes similar to those prescribed bed rest. Although women with preterm contractions treated with 0.25-mg subcutaneous terbutaline may have contractions that cease more quickly and may be discharged significantly earlier compared with women not treated, pregnancy outcomes are similar (Guinn and co-workers, 1997).

β-Adrenergic Receptor Agonists

A number of compounds react with β-adrenergic receptors to reduce intracellular ionized calcium levels and prevent activation of myometrial contractile proteins (see Chap. 6, p. 148). In the United States, ritodrine and terbutaline have been used in obstetrics, but only ritodrine had been approved for preterm labor by the Food and Drug Administration.

Ritodrine. In a multicenter trial, neonates whose mothers were treated with ritodrine for threatened preterm labor had lower rates of death and respiratory distress. They also achieved a gestational age of 36 weeks or a birthweight of 2500 g more often than did those of untreated mothers (Merkatz and colleagues, 1980). In a randomized trial at Parkland Hospital, Leveno and associates (1986) allocated 106 women between 24 and 33 weeks to receive either intravenous ritodrine or no tocolysis. Although drug treatment delayed delivery for 24 hours, there were no other benefits. The transient tocolytic effects of ritodrine and its ultimate failure to arrest labor may be due to β-adrenergic receptor desensitization (Hausdorff and co-workers, 1990).

The infusion of β-agonists has resulted in frequent and at times, serious and fatal side effects. Pulmonary edema is a special concern, and its contribution to morbidity is discussed in Chapter 42 (see p. 929). Tocolysis was the third most common cause of acute respiratory distress and death in pregnant women during a 14-year period in Mississippi (Perry and associates, 1996). *The cause of pulmonary edema is multifactorial, and risk factors include tocolytic therapy with β-agonists, multifetal gestation, concurrent corticosteroid therapy, tocolysis for more than 24 hours, and large intravenous crystalloid volume infusion.* Because β-agonists cause retention of sodium and water, with time—usually 24 to 48 hours, these can cause volume overload (Hankins and colleagues, 1988). The drugs have been implicated as a cause of increased capillary permeability, disturbance of cardiac rhythm, and myocardial ischemia. Finally, maternal sepsis—a relatively common occurrence with preterm labor—appreciably increases this risk (see Chap. 42, p. 932).

Schiff and co-workers (1993) challenged the efficacy of oral ritodrine on pharmacokinetic grounds, and its manufacturer discontinued distribution of tablets in 1995. According to the *Federal Register*, ritodrine was withdrawn voluntarily in 2003 by its manufacturer and is not available in the United States.

Terbutaline. This β-agonist is commonly used to forestall preterm labor. Like ritodrine, it can cause pulmonary edema (Angel and associates, 1988). Long-term low-dose terbutaline given by subcutaneous pump in nine pregnancies was described by Lam and colleagues (1988). The Tokos Corporation promptly marketed this approach, and between 1987 and 1993, these pumps were used in nearly 25,000 women with suspected preterm labor (Perry and co-workers, 1995). Adverse reports concerning terbutaline pumps describe a sudden maternal death and a newborn with myocardial necrosis after the mother used the pump for 12 weeks (Fletcher and colleagues, 1991; Hudgens and Conradi, 1993). Elliott and co-workers (2004) have used continuous terbutaline subcutaneous infusion in 9359 patients and reported that only 12 women experienced severe adverse events—primarily pulmonary edema.

Two randomized trials found no benefit for terbutaline pump therapy. In one, Wenstrom and colleagues (1997) randomly assigned 42 women with preterm labor to a terbutaline pump, to a saline pump, or to oral terbutaline. In the other, Guinn and associates (1998) randomly treated 52 women with terbutaline or with saline pump therapy. Terbutaline did not significantly prolong pregnancy, prevent preterm delivery, or improve neonatal outcomes in either of these studies.

Oral terbutaline therapy to prevent preterm delivery has also not been effective (How and associates, 1995; Parilla and coworkers, 1993). In a double-blind trial, Lewis and colleagues (1996) studied 203 women with arrested preterm labor at 24 to 34 weeks. They were randomly assigned to receive 5-mg terbutaline tablets or placebo every 4 hours. Delivery rates at 1 week were similar in both groups, as was median latency, mean gestational age at delivery, and the incidence of recurrent preterm labor.

Overview of Beta-Adrenergic Drugs to Inhibit Preterm Labor. Analyses of *parenteral* β-agonists to prevent preterm birth have confirmed a delay of delivery for at least 48 hours (Canadian Preterm Labor Investigators Group, 1992). Unfortunately, this delay has not proven to be beneficial. Macones and colleagues (1995) used meta-analysis to assess the efficacy of *oral* β-agonist therapy and found no benefits. Keirse (1995b) suggests that this brief delay may aid maternal transport to tertiary care or effect fetal lung maturation with corticosteroids. Although this intuitive reasoning is logical, there are no data to support this viewpoint.

Magnesium Sulfate

Ionic magnesium in a sufficiently high concentration can alter myometrial contractility. Its role is presumably that of a calcium antagonist. Clinically, magnesium in pharmacological doses may inhibit labor. Steer and Petrie (1977) concluded that intravenously administered magnesium sulfate—a 4-g loading dose followed by a continuous infusion of 2 g/hr—usually arrests labor. Women given magnesium sulfate must be monitored closely for evidence of hypermagnesemia. The pharmacology and toxicology of magnesium are considered in more detail in Chapter 34 (p. 738). Samol and Lambers (2005) found 67 cases—8.5 percent—of pulmonary edema among 789 women given tocolysis with magnesium sulfate at their hospital.

There have been only two randomized placebo-controlled studies of tocolysis with magnesium sulfate. Cotton and associates (1984) compared magnesium sulfate, ritodrine, and placebo in 54 women in preterm labor. They identified few differences in outcomes. Cox and co-workers (1990) randomly assigned 156 women to receive magnesium sulfate or normal saline infusions. These women were at appreciable risk, and few reached 33 weeks. Magnesium-treated women and their fetuses had identical outcomes compared with those given placebo. Because of these findings, this method of tocolysis was abandoned at Parkland Hospital. Grimes and Nanda (2006) reviewed the use of magnesium sulfate for tocolysis and concluded it was "Time to Quit" on the basis that this therapy was ineffective and potentially harmful to infants.

Neonatal Effects of Magnesium. In intriguing reports, very-low-birthweight neonates whose mothers were treated with magnesium sulfate for preterm labor or preeclampsia were found to have a reduced incidence of cerebral palsy at 3 years (Grether and associates, 2000; Nelson and Grether, 1995). This was logical, as magnesium has been shown in adults to stabilize intracranial tone, minimize fluctuations in cerebral blood flow, reduce reperfusion injury, and block calcium-mediated intracellular damage (Aslanyan and colleagues, 2007; Marret and associates, 1995). Magnesium reduces synthesis of cytokines and bacterial endotoxins and thus, also may minimize the inflammatory effects of infection (Nelson and Grether, 1997).

Because epidemiological evidence suggested that maternal magnesium sulfate therapy had a fetal neuroprotective effect, randomized trials were designed to investigate this hypothesis. An Australian randomized trial by Crowther and colleagues (2003) included 1063 women at imminent risk of delivery before 30 weeks and who were given magnesium sulfate or placebo. These investigators showed that magnesium exposure improved some perinatal outcomes. Rates of both neonatal death and cerebral palsy were lower in the magnesium-treated group—but the study was not sufficiently powered. The multicenter French trial reported by Marret and associates (2008) had similar problems. This trial included 573 pregnancies at <33 weeks, and the investigators showed improvements of magnesium-treated infants at 2 years compared with infants not exposed to magnesium.

More convincing evidence for magnesium neuroprotection then came from the NICHD Maternal-Fetal Medicine Units Network study reported by Rouse and colleagues (2008). The *Beneficial Effects of Antenatal Magnesium Sulfate—BEAM—Study* was a placebo- controlled trial in 2241 women at imminent risk for preterm birth between 24 and 31 weeks. Almost 87 percent had preterm ruptured membranes, and almost a fifth had previously received magnesium sulfate for tocolysis. Women randomized to magnesium sulfate were given a 6-g bolus over 20 to 30 minutes followed by a maintenance infusion of 2 g per hour. A 2-year follow-up was available for 96 percent of the children. Selected results are shown in Table 36-9. This

TABLE 36-9. Magnesium Sulfate for the Prevention of Cerebral Palsy[a]

	Treatment		
	Magnesium Sulfate	Placebo	Relative Risk
Perinatal Outcome[a]	No. (%)	No. (%)	(95% CI)
Infants with 2-year follow-up	1041 (100)	1095 (100)	—
Fetal or infant death	99 (9.5)	93 (8.5)	1.12 (0.85–1.47)
Moderate or severe cerebral palsy:			
Overall	20/1041 (1.9)	3/1095 (3.4)	0.55 (0.32–0.95)
<28–31 weeks[b]	12/442 (2.7)	30/496 (6)	0.45 (0.23–0.87)
≥24–27 weeks[b]	8/599 (1.3)	8/599 (1.3)	1.00 (0.38–2.65)

[b]Weeks' gestation at randomization.
Data from Rouse and colleagues (2008).

trial was interpreted differently depending upon statistical philosophy. Those who disdain subgroup analysis opted to interpret these findings to mean that magnesium sulfate infusion prevents cerebral palsy regardless of the gestational age at which the therapy is given. Those with a differing view concluded that this trial only supports use of magnesium sulfate for prevention of cerebral palsy before 28 weeks. What is certain, however, is that maternally administered magnesium sulfate infusions cannot be implicated in increased perinatal deaths as reported by Mittendorf and colleagues (1997).

Subsequent to these studies, Doyle and co-workers (2009) performed a Cochrane review of the five randomized trials dose to assess neuroprotective effects of magnesium sulfate. A total of 6145 infants were available, and as expected, the vast majority came from larger Australian, French, and Network multicenter studies. These reviewers reported that magnesium exposure compared with no exposure significantly decreased risks for cerebral palsy—RR 0.68 (0.54 to 0.87) and substantial gross motor function—RR 0.61 (0.44 to 0.85). There were no significant effects on rates of pediatric mortality or other neurological impairments or disabilities. These reviewers calculated that treatment given to 63 women would prevent one case of cerebral palsy.

Because of these findings, at Parkland Hospital, our policy is to give magnesium sulfate for threatened preterm delivery from 24 to 28 completed weeks. At the University of Alabama at Birmingham Hospital, we administer neuroprotection magnesium from 23 to 32 completed weeks. In both, a 6-g loading dose is followed by an infusion of 2 g per hour for at least 12 hours.

Prostaglandin Inhibitors

Drugs that inhibit prostaglandins have been of considerable interest because prostaglandins are intimately involved in contractions of normal labor (see Chap. 6, p. 153). Antagonists act by inhibiting prostaglandin synthesis or by blocking their action on target organs. A group of enzymes collectively termed *prostaglandin synthase* is responsible for the conversion of free arachidonic acid to prostaglandins. A number of drugs block this system, including acetylsalicylate and indomethacin.

Indomethacin was first used as a tocolytic for 50 women by Zuckerman and associates (1974). Studies that followed reported the efficacy of indomethacin in halting contractions and delaying preterm birth (Muench and colleagues, 2003; Niebyl and associates, 1980). Morales and co-workers (1989, 1993a), however, compared indomethacin with either ritodrine or magnesium sulfate and found no difference in their efficacy to forestall preterm delivery. Berghella and colleagues (2006) reviewed four trials of indomethacin given to women with sonographically short cervices and found such therapy to be ineffective.

Indomethacin is administered orally or rectally. A dose of 50 to 100 mg is followed at 8-hour intervals not to exceed a total 24-hour dose of 200 mg. Serum concentrations usually peak 1 to 2 hours after oral administration, whereas levels after rectal administration peak slightly sooner. Most studies have limited indomethacin use to 24 to 48 hours because of concerns of oligohydramnios, which can develop with these doses. If amnionic fluid is monitored, oligohydramnios can be detected early, and it is reversible with discontinuation of indomethacin.

Case-control studies have been performed to assess neonatal effects of indomethacin exposure given for preterm labor. In a study of neonates born before 30 weeks, Norton and associates (1993) identified necrotizing enterocolitis in 30 percent of 37 indomethacin-exposed newborns compared with 8 percent of 37 control newborns. Higher incidences of intraventricular hemorrhage and patent ductus arteriosus were also documented in the indomethacin group. The impact of treatment duration and its timing in relation to delivery were not reported. In contrast, several investigators have challenged the association between indomethacin exposure and necrotizing enterocolitis (Muench and co-workers, 2001; Parilla and colleagues, 2000). Finally, Gardner and associates (1996) and Abbasi and co-workers (2003) showed no link between indomethacin use and intraventricular hemorrhage, patent ductus arteriosus, sepsis, necrotizing enterocolitis, or neonatal death.

Schmidt and colleagues (2001) followed 574 newborns who were randomly assigned to receive either indomethacin or placebo to prevent pulmonary hypertension from patent ductus arteriosus. The infants, who weighed 500 to 1000 g, were followed to a corrected age of 18 months. Those given indomethacin had a significantly *reduced* incidence of both patent ductus as well as severe intraventricular hemorrhage. Survival without impairment, however, was similar in both groups. Peck and Lutheran (2003) reported that indomethacin therapy for 7 or more days prior to 33 weeks does not increase the risk of neonatal or childhood medical problems. There have been two meta-analyses of the effects of antenatal indomethacin on neonatal outcomes with conflicting findings (Amin and colleagues, 2007; Loe and associates, 2005).

Calcium-Channel Blockers

Myometrial activity is directly related to cytoplasmic free calcium, and a reduction in its concentration inhibits contractions. Calcium-channel blockers act to inhibit, by a variety of mechanisms, the entry of calcium through channels in the cell membrane. Although they were developed to treat hypertension, their use to arrest preterm labor has been the subject of research since the late 1970s.

Using the Cochrane Database, Keirse (1995a) compared nifedipine and β-agonists and concluded that although nifedipine treatment reduced births of neonates weighing less than 2500 g, significantly more of these were admitted for intensive care. Other investigators have also concluded that calcium-channel blockers, especially nifedipine, are safer and more effective tocolytic agents than are β-agonists (King and colleagues, 2003; Papatsonis and co-workers, 1997). Lyell and colleagues (2007) randomized 192 women at 24 to 33 weeks to either magnesium sulfate or nifedipine and found no substantial differences in efficacy or adverse effects. Finally, oral nifedipine does not significantly prolong pregnancy in women initially treated with intravenous magnesium sulfate for preterm labor (Carr and colleagues, 1999).

The combination of nifedipine with magnesium for tocolysis is potentially dangerous. Ben-Ami and co-workers (1994) and

Kurtzman and associates (1993) reported that nifedipine enhances neuromuscular blocking effects of magnesium that can interfere with pulmonary and cardiac function. How and colleagues (2006) randomized 54 women between $32^{0/7}$ and $34^{6/7}$ weeks to magnesium sulfate plus nifedipine or no tocolytic and found neither benefit nor harm.

Atosiban

This nonapeptide oxytocin analog is a competitive antagonist of oxytocin-induced contractions. Goodwin and colleagues (1995) described its pharmacokinetics in pregnant women. In randomized clinical trials, however, atosiban failed to improve relevant neonatal outcomes and was linked with significant neonatal morbidity (Moutquin and co-workers, 2000; Romero and associates, 2000). The Food and Drug Administration has denied approval of atosiban because of concerns regarding efficacy and fetal-newborn safety. Goodwin (2004) has reviewed the history of atosiban both in the United States and in Europe, where this drug is approved for use and is widely used as a tocolytic.

Nitric Oxide Donors

These potent smooth-muscle relaxants affect the vasculature, gut, and uterus. In randomized clinical trials, nitroglycerin administered orally, transdermally, or intravenously was not effective or showed no superiority to other tocolytics. In addition, maternal hypotension was a common side effect (Bisits, 2004; Buhimschi, 2002; Clavin, 1996; El-Sayed, 1999; Lees, 1999, and all their colleagues).

Summary of Tocolytic Use for Preterm Labor

In many women, tocolytics stop contractions temporarily but rarely prevent preterm birth. In a meta-analysis of tocolytic therapy, Gyetvai and colleagues (1999) concluded that although delivery may be delayed long enough for administration of corticosteroids, treatment does not result in improved perinatal outcome. Berkman and associates (2003) reviewed 60 reports and concluded that tocolytic therapy can prolong gestation, but that β-agonists are not better than other drugs and pose potential maternal danger. They also concluded that there are no benefits of maintenance tocolytic therapy.

As a general rule, if tocolytics are given, they should be given concomitantly with corticosteroids. The gestational age range for their use is debatable, but because corticosteroids are not generally used after 33 weeks and because the perinatal outcomes in preterm neonates are generally good after this time, most practitioners do not recommend use of tocolytics at or after 33 weeks (Goldenberg, 2002).

Recommended Management of Preterm Labor

The following considerations should be given to women in preterm labor:

1. Confirmation of preterm labor as detailed on p. 814
2. For pregnancies less than 34 weeks in women with no maternal or fetal indications for delivery, close observation with monitoring of uterine contractions and fetal heart rate is appropriate. Serial examinations are done to assess cervical changes
3. For pregnancies less than 34 weeks, corticosteroids are given for enhancement of fetal lung maturation
4. Consideration is given for maternal magnesium sulfate infusion for 12 to 24 hours to afford fetal neuroprotection
5. For pregnancies less than 34 weeks in women who are not in advanced labor, some practitioners believe it is reasonable to attempt inhibition of contractions to delay delivery while the women are given corticosteroid therapy and group B streptococcal prophylaxis. Although tocolytic drugs are not used at Parkland Hospital, they are given at University of Alabama at Birmingham Hospital
6. For pregnancies at 34 weeks or beyond, women with preterm labor are monitored for labor progression and fetal well-being
7. For active labor, an antimicrobial is given for prevention of neonatal group B streptococcal infection.

Intrapartum Management

In general, the more immature the fetus, the greater the risks of labor and delivery.

Labor

Whether labor is induced or spontaneous, abnormalities of fetal heart rate and uterine contractions should be sought. We prefer continuous electronic monitoring. Fetal tachycardia, especially with ruptured membranes, is suggestive of sepsis. There is some evidence that intrapartum acidemia may intensify some of the neonatal complications usually attributed to preterm delivery. For example, Low and colleagues (1995) observed that intrapartum acidosis—umbilical artery blood pH less than 7.0—had an important role in neonatal complications (see Chap. 29, p. 614). Similarly, Kimberlin and colleagues (1996) found that increasing umbilical artery blood acidemia was related to more severe respiratory disease in preterm neonates. Despite this, no effects were found in short-term neurological outcomes that included intracranial hemorrhages.

Group B streptococcal infections are common and dangerous in the preterm neonate. Accordingly, as discussed in Chapter 58 (see p. 1220), prophylaxis should be provided.

Delivery

In the absence of a relaxed vaginal outlet, an episiotomy for delivery may be necessary once the fetal head reaches the perineum. Perinatal outcome data do not support routine forceps delivery to protect the "fragile preterm fetal head." Staff proficient in resuscitative techniques commensurate with the gestational age and fully oriented to any specific problems should be present at delivery. Principles of resuscitation described in Chapter 28 are applicable. The importance of the availability of specialized personnel and facilities in the care of preterm newborns is underscored by the improved survival of these neonates when they are delivered in tertiary care centers.

Prevention of Neonatal Intracranial Hemorrhage

Preterm newborns frequently have intracranial germinal matrix bleeding that can extend to more serious intraventricular hemorrhage (see Chap. 29, p. 607). It was hypothesized that cesarean delivery to obviate trauma from labor and vaginal delivery might prevent these complications. This has not been validated by most subsequent studies. Malloy and colleagues (1991) analyzed 1765 newborns with birthweights less than 1500 g and found that cesarean delivery did not lower the risk of mortality or intracranial hemorrhage. Anderson and coworkers (1988), however, made an interesting observation regarding the role of cesarean delivery in the prevention of neonatal intracranial hemorrhages. These hemorrhages related to whether or not the fetus had been subjected to the active phase of labor. They emphasized that avoidance of active-phase labor is impossible in most preterm births because the route of delivery cannot be decided until the active phase of labor is firmly established.

CHAPTER 37

Postterm Pregnancy

ESTIMATED GESTATIONAL AGE USING MENSTRUAL DATES 832
INCIDENCE 833
PERINATAL MORTALITY 833
PATHOPHYSIOLOGY 834
COMPLICATIONS 836
MANAGEMENT 837
INTRAPARTUM MANAGEMENT 840

The adjectives *postterm, prolonged, postdates*, and *postmature* are often loosely used interchangeably to describe pregnancies that have exceeded a duration considered to be the upper limit of normal. We do not use the term *postdates* because the real issue in many postterm pregnancies is "post-*what* dates?" *Postmature* is reserved for the relatively uncommon specific clinical fetal syndrome in which the infant has recognizable clinical features indicating a pathologically prolonged pregnancy. Therefore, *postterm* or *prolonged* pregnancy is our preferred expression for an extended pregnancy.

The international definition of prolonged pregnancy, endorsed by the American College of Obstetricians and Gynecologists (2004), is 42 completed weeks (294 days) or more from the first day of the last menstrual period. It is important to emphasize the phrase "42 completed weeks." Pregnancies between 41 weeks 1 day and 41 weeks 6 days, although in the 42nd week, do not complete 42 weeks until the seventh day has elapsed. Thus, technically speaking, prolonged pregnancy could begin either on day 294 or on day 295 following the onset of the last menses. Which is it? Day 294 or 295? We cannot resolve this question, and emphasize this dilemma only to ensure that litigators and others understand that some imprecision is inevitable when there is biological variation such as with prolonged pregnancy. Amersi and Grimes (1998) have cautioned against use of ordinal numbers such as "42nd week" because of imprecision. For example, "42nd week" refers to 41 weeks and 1 through 6 days, whereas the cardinal number "42 weeks" refers to precisely 42 completed weeks.

ESTIMATED GESTATIONAL AGE USING MENSTRUAL DATES

The definition of postterm pregnancy as one that persists for 42 weeks or more from the onset of a menstrual period assumes that the last menses was followed by ovulation 2 weeks later. This said, some pregnancies may not actually be postterm, but rather are the result of an error in gestational age estimation because of faulty recall of menstrual dates or delayed ovulation. Thus, there are two categories of pregnancies that reach 42 completed weeks: (1) those truly 40 weeks past conception, and (2) those of less advanced gestation but with inaccurately estimated gestational age.

Even with precisely recalled menstrual dates, there is still not precision. Specifically, Munster and associates (1992) reported that large variations in menstrual cycle lengths are common in normal women. Boyce and associates (1976) studied 317 French women with periconceptional basal body temperature profiles. They found that 70 percent who completed 42 postmenstrual weeks had a less advanced gestation based on ovulation dates. These variations in menstrual cycle may partially explain why a relatively small proportion of fetuses delivered postterm have evidence of *postmaturity*. Even so, because there is no accurate method to identify the truly prolonged pregnancy, all those judged to be 42 completed weeks should be managed as if abnormally prolonged.

Sonographic evaluation of gestational age during pregnancy has been used to add precision. Blondel and colleagues (2002) studied 44,623 women delivered at the Royal Victoria Hospital in

Montreal. They analyzed postterm pregnancy rates according to six algorithms for gestational age estimates based on either the last menstrual period, sonographic evaluation at 16 to 18 weeks, or both. The proportion of births at 42 weeks or longer was 6.4 percent when based on the last menstrual period alone, but was 1.9 percent when based on sonographic measurements alone. Sonographic pregnancy dating at 12 weeks or less resulted in a 2.7-percent incidence of postterm gestation compared with 3.7 percent in a group assessed at 13 to 24 weeks (Caughey and co-workers, 2008). These findings suggest that menstrual dates are frequently inaccurate in predicting postterm pregnancy. Subsequent clinical studies have confirmed these observations (Bennett, 2004; Joseph, 2007; Wingate, 2007, and all their colleagues).

INCIDENCE

From their review, Divon and Feldman-Leidner (2008) report that the incidence of postterm pregnancy ranges from 4 to 19 percent. Using criteria that likely overestimate the incidence, approximately 6 percent of 4 million infants born in the United States during 2006 were estimated to have been delivered at 42 weeks or more (Martin and colleagues, 2009). The trend toward fewer births at 42 weeks suggests earlier intervention. Specifically, in 2000, 7.2 percent of births in this country were 42 weeks or beyond, compared with 5.6 percent in 2006.

There are contradictory findings concerning the significance of maternal demographic factors such as parity, prior postterm birth, socioeconomic class, and age. Olesen and colleagues (2006) analyzed a variety of risk factors in 3392 participants in the 1998 to 2001 Danish Birth Cohort. They reported that only prepregnancy body mass index (BMI) ≥ 25 and nulliparity were significantly associated with prolonged pregnancy. Denison (2008) and Caughey (2009) and their co-workers also reported similar associations.

The tendency for some mothers to have repeated postterm births suggests that some prolonged pregnancies are biologically determined. In 27,677 births in Norway, Bakketeig and Bergsjø (1991) reported that the incidence of a subsequent postterm birth increased from 10 to 27 percent if the first birth was postterm. This was increased to 39 percent if there had been two previous, successive postterm deliveries. Similar results were reported from Missouri by Kistka and colleagues (2007). And Mogren and colleagues (1999) reported that prolonged pregnancy recurred across generations in Swedish women. When mother and daughter had a prolonged pregnancy, the risk for the daughter to have a subsequent postterm pregnancy was increased two- to threefold. In another Swedish study, Laursen and associates (2004) found that maternal, but not paternal, genes influenced prolonged pregnancy. Rare fetal–placental factors that have been reported as predisposing to postterm pregnancy include anencephaly, adrenal hypoplasia, and X-linked placental sulfatase deficiency (MacDonald and Siiteri, 1965; Naeye, 1978; Rabe and colleagues, 1983).

PERINATAL MORTALITY

The historical basis for the concept of an upper limit of human pregnancy duration was the observation that perinatal mortality

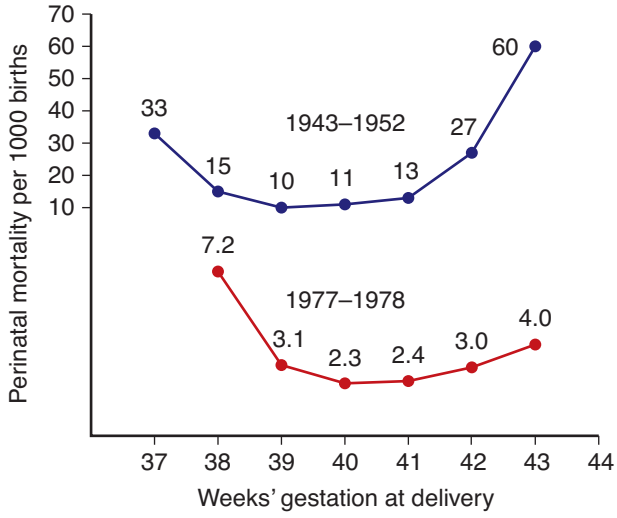

FIGURE 37-1 Perinatal mortality rates in late pregnancy according to gestational age in Sweden of all births during 1943–1952 compared with those during 1977–1978. The logarithmic scale is used for convenience in depiction. (Adapted from Bakketeig and Bergsjø, 1991, and Lindell, 1956.)

rates increased after the expected due date was passed. This is best seen when perinatal mortality rates are analyzed from times before widespread intervention for postterm pregnancies. In two large Swedish studies shown in **Figure 37-1**, after reaching a nadir at 39 to 40 weeks, the perinatal mortality rate increased as pregnancy exceeded 41 weeks. More recently, MacDorman and Kirmeyer (2009) noted this trend also in the U.S. Similar observations were recently reported by Cheng and associates (2008), who described more than 2.5 million births in the United States in 2003. The major causes of death included gestational hypertension, prolonged labor with cephalopelvic disproportion, "unexplained anoxia," and malformations. Similar outcomes were reported by Olesen and colleagues (2003) in their analysis of 78,022 women with postterm pregnancies delivered before routine labor induction was adopted in Denmark. Lindstrom and colleagues (2005) performed developmental tests at age 4 to 5½ years in 354 consecutive infants born at 42 weeks or more in a Swedish hospital in 1991. Children born postterm had more developmental abnormalities compared with those born before 42 weeks.

Alexander and colleagues (2000a) reviewed 56,317 consecutive singleton pregnancies delivered at 40 or more weeks between 1988 and 1998 at Parkland Hospital. As shown in **Table 37-1**, labor was induced in 35 percent of pregnancies completing 42 weeks. The rate of cesarean delivery for dystocia and fetal distress was significantly increased at 42 weeks compared with earlier deliveries. More infants of postterm pregnancies were admitted to intensive care units. Finally, the incidence of neonatal seizures and deaths doubled at 42 weeks. Tita and co-workers (2009) evaluated outcomes in women undergoing elective repeat cesarean delivery. They reported a 19.5-percent incidence of adverse neonatal outcomes in pregnancies ≥ 42 weeks. Caughey and colleagues (2007) compared 119,254 low-risk pregnancies delivered at 39 weeks versus 40, 41, and 42 weeks. They reported a continuum of increasing risk in successive epochs for cesarean delivery as well as maternal complications of labor and delivery.

TABLE 37-1. Pregnancy Outcomes in 56,317 Consecutive Singleton Pregnancies Delivered at or Beyond 40 Weeks at Parkland Hospital from 1988 through 1998

	Weeks' Gestation			
Outcome	40 (n = 29,136)	41 (n = 16,386)	42 (n = 10,795)	*p* value[a]
Maternal Outcomes (percent)				
Labor induction	2	7	35	<.001
Cesarean delivery				
Dystocia	7	6	9	<.001
Fetal distress	2	3	4	<.001
Perinatal outcomes (per 1000)				
Neonatal ICU	4	5	6	<.001
Neonatal seizures	1	1	2	.12
Stillbirth	2	1	2	.84
Neonatal death	0.2	0.2	0.6	.17

[a]*p* value is for the trend using 42 weeks as the referent.
ICU = intensive care unit.
Adapted from Alexander and colleagues (2000a).

Smith (2001) has challenged analyses such as these because the population at risk for perinatal mortality rate in a given week consists of all ongoing pregnancies rather than just the births in a given week. Figure 37-2 shows perinatal mortality rates calculated using only births in a given week of gestation from 37 to 43 completed weeks compared with the cumulative probability—the perinatal index—of death when all ongoing pregnancies are included in the denominator. As shown, delivery at 38 weeks had the lowest risk index for perinatal death.

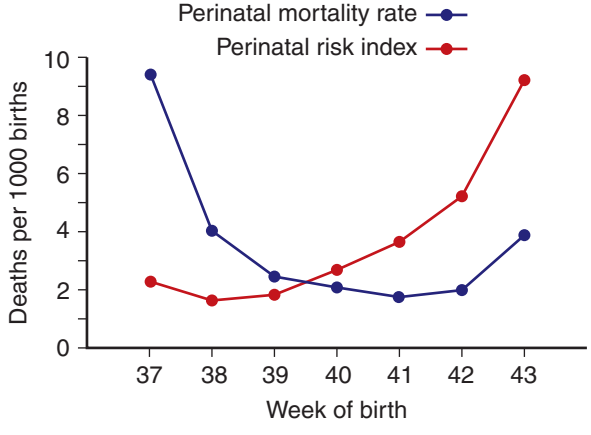

FIGURE 37-2 Perinatal risk index and perinatal mortality rate for births between 37 and 43 weeks in Scotland from 1985 through 1996, and expressed as deaths per 1000 births. The perinatal risk index is the cumulative probability of perinatal death multiplied by 1000. The perinatal mortality rate is the number of perinatal deaths with delivery in a given gestational week divided by the total number of births in that week multiplied by 1000. (Modified from *American Journal of Obstetrics & Gynecology*, Vol. 184, No. 3, GCS Smith, Life-table analysis of the risk of perinatal death at term and post term in singleton pregnancies, pp. 489–496, Copyright 2001, with permission from Elsevier.)

PATHOPHYSIOLOGY

Clifford (1954) described a recognizable clinical syndrome that did much to dispel the prevailing obstetrical opinion that prolonged human pregnancy did not exist (Calkins, 1948). Infants, either live or stillborn, demonstrating these clinical characteristics are now diagnosed to be pathologically *postmature,* or to have the *postmaturity syndrome.* Many of the postmature infants described by Clifford died, and many were seriously ill due to birth asphyxia and meconium aspiration. Several survivors were brain damaged. Interestingly, Ballantyne (1902) had reported this postmature syndrome more than 50 years before Clifford did.

Postmaturity Syndrome

The postmature infant presents a unique and characteristic appearance such as shown in Figure 37-3. Features include wrinkled, patchy, peeling skin; a long, thin body suggesting wasting; and advanced maturity because the infant is open-eyed, unusually alert, and appears old and worried. Skin wrinkling can be particularly prominent on the palms and soles. The nails are typically long. Most such postmature infants are not technically growth restricted because their birthweight seldom falls below the 10th percentile for gestational age. On the other hand, severe growth restriction—which logically must have preceded completion of 42 weeks—may be present.

The incidence of postmaturity syndrome in infants at 41, 42, or 43 weeks, respectively, has not been conclusively determined. In one of the rare contemporary reports that chronicle postmaturity, Shime and colleagues (1984) found this syndrome in approximately 10 percent of pregnancies between 41 and 43 weeks. The incidence increased to 33 percent at 44 weeks. Associated oligohydramnios substantially increases the

FIGURE 37-3 Postmature infant delivered at 43 weeks' gestation. Thick, viscous meconium coated the desquamating skin. Note the long, thin appearance and wrinkling of the hands.

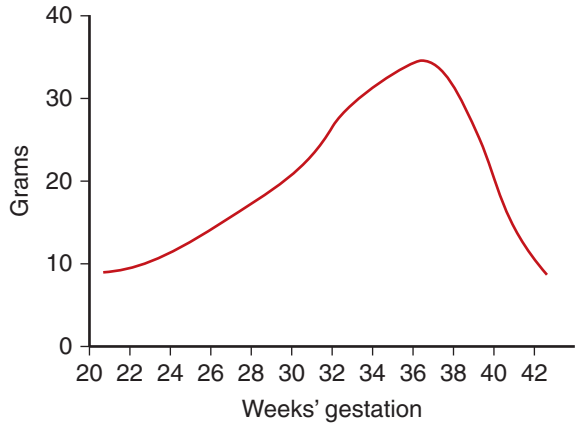

FIGURE 37-4 Mean daily fetal growth during previous week of gestation. (From Jazayeri and co-workers, 1998, with permission.)

likelihood of postmaturity. Trimmer and colleagues (1990) diagnosed oligohydramnios when the sonographic maximum-vertical amnionic fluid pocket measured 1 cm or less at 42 weeks, and 88 percent of the infants were postmature.

Placental Dysfunction

Clifford (1954) proposed that the skin changes of postmaturity were due to loss of the protective effects of vernix caseosa. He also attributed the postmaturity syndrome to placental senescence, although he did not find placental degeneration histologically. Still, the concept that postmaturity is due to placental insufficiency has persisted despite an absence of morphological or significant quantitative findings (Larsen and co-workers, 1995; Rushton, 1991). Of interest, Smith and Baker (1999) reported that placental apoptosis—programmed cell death—was significantly increased at 41 to 42 completed weeks compared with that at 36 to 39 weeks. The clinical significance of such apoptosis is currently unclear.

Jazayeri and co-workers (1998) investigated cord blood erythropoietin levels in 124 appropriately grown newborns delivered from 37 to 43 weeks. The only known stimulator of erythropoietin is decreased partial oxygen pressure. Thus, they sought to assess whether fetal oxygenation was compromised due to placental aging in postterm pregnancies. All women had an uncomplicated labor and delivery. These investigators reported that cord blood erythropoietin levels were significantly increased in pregnancies reaching 41 weeks or more. Although Apgar scores and acid-base studies were normal, these researchers concluded that there was decreased fetal oxygenation in some postterm gestations.

Another scenario is that the postterm fetus may continue to gain weight and thus be unusually large at birth. This at least suggests that placental function is not severely compromised. Indeed, continued fetal growth—albeit at a slower rate—is characteristic beginning at 37 completed weeks (**Fig. 37-4**). Nahum and colleagues (1995) confirmed that fetal growth continues until at least 42 weeks. Despite this, Link and associates (2007) showed that umbilical blood flow did not increase concomitantly.

Fetal Distress and Oligohydramnios

The principal reasons for increased risks for postterm fetuses were described by Leveno and associates (1984). They reported that both antepartum fetal jeopardy and intrapartum fetal distress were the consequence of cord compression associated with oligohydramnios. In their analysis of 727 postterm pregnancies, intrapartum fetal distress detected with electronic monitoring was not associated with late decelerations characteristic of uteroplacental insufficiency. Instead, one or more prolonged decelerations such as shown in **Figure 37-5** preceded three fourths of emergency cesarean deliveries for nonreassuring fetal heart rate tracings. In all but two cases, there were also variable decelerations (**Fig. 37-6**). Another common fetal heart rate pattern, although not ominous by itself, was the saltatory baseline shown in **Figure 37-7**. As described in Chapter 18 (p. 423), these findings are consistent with cord occlusion as the proximate cause of the nonreassuring tracings. Other correlates found were oligohydramnios and viscous meconium. Schaffer and colleagues (2005) implicated a nuchal cord in abnormal intrapartum fetal heart rate patterns, meconium, and compromised newborn condition in prolonged pregnancies.

The volume of amnionic fluid normally continues to decrease after 38 weeks and may become problematic (**Fig. 37-8**). Moreover, meconium release into an already reduced amnionic fluid volume causes thick, viscous meconium that may cause *meconium aspiration syndrome* (see Chap. 29, p. 628).

Trimmer and co-workers (1990) sonographically measured hourly fetal urine production using sequential bladder volume

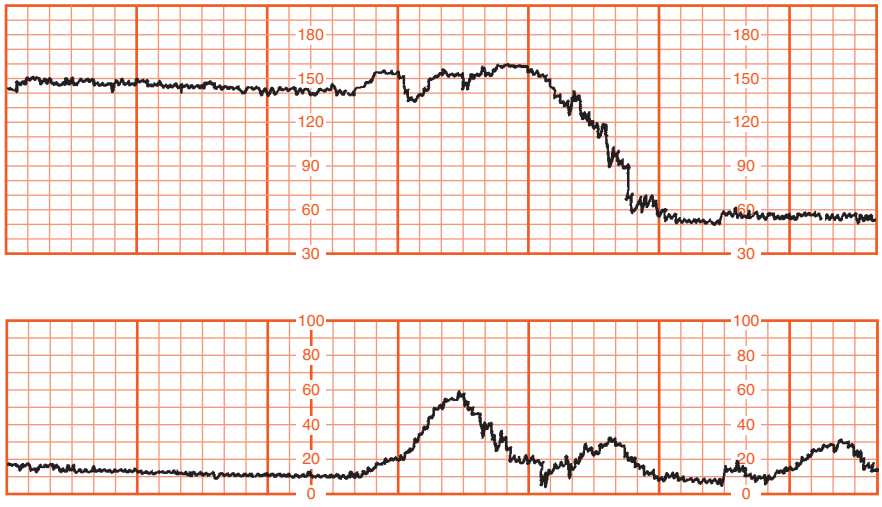

FIGURE 37-5 Upper panel: Prolonged fetal heart rate deceleration prior to emergency cesarean delivery in a postterm pregnancy with oligohydramnios. (This figure was published in *American Journal of Obstetrics & Gynecology*, Vol. 150, No. 5, pt. 1, KJ Leveno, JG Quirk, Jr., FG Cunningham, et al., Prolonged pregnancy. I. Observations concerning the causes of fetal distress, pp. 465–473, Copyright Elsevier 1984.)

measurements in 38 pregnancies of 42 weeks or more. Diminished urine production was found to be associated with oligohydramnios. They hypothesized, however, that decreased fetal urine flow was likely the result of preexisting oligohydramnios that limited fetal swallowing. Oz and co-workers (2002), using Doppler waveforms, concluded that fetal renal blood flow is reduced in those postterm pregnancies complicated by oligohydramnios. Mentioned above was the study by Link and associates (2007), which showed that umbilical blood flow did not increase past term.

Fetal-Growth Restriction

It was not until the late 1990s that the clinical significance of fetal-growth restriction in the otherwise uncomplicated pregnancy became more fully appreciated. Divon and associates (1998) and Clausson and co-workers (1999) analyzed births between 1991 and 1995 in the National Swedish Medical Birth Registry. As shown in **Table 37-2**, stillbirths were more common among growth-restricted infants who were delivered after 42 weeks. Indeed, a third of postterm stillborn infants were growth restricted. During this time in Sweden, labor induction and antenatal fetal testing usually commenced at 42 weeks.

In a study from Parkland Hospital, Alexander and colleagues (2000d) analyzed outcomes for 355 infants who were 42 weeks or greater and whose birthweights were at or below the 3rd percentile. They compared these with outcomes of 14,520 similarly aged infants above the 3rd percentile and found that morbidity and mortality rates were significantly increased in the growth-restricted infants. Notably, a fourth of all stillbirths associated with prolonged pregnancy were in this comparatively small number of growth-restricted infants.

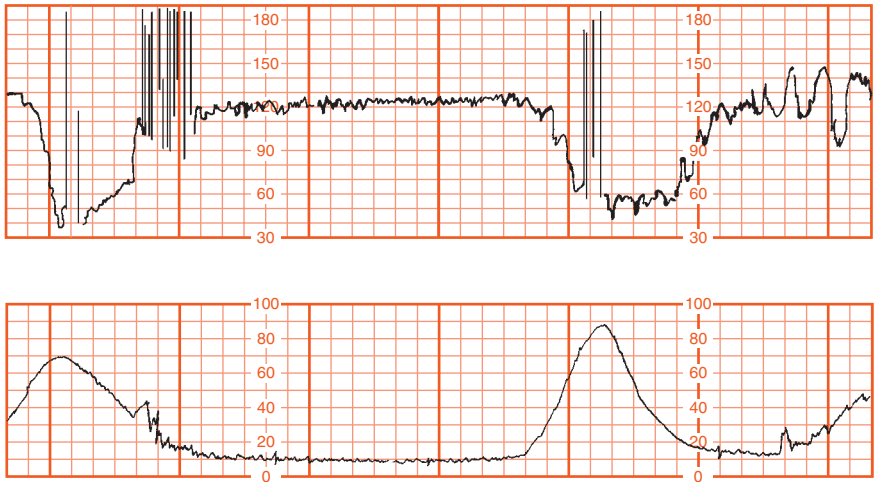

FIGURE 37-6 Upper panel: Severe—less than 70 bpm for 60 seconds or longer—variable decelerations in a postterm pregnancy with oligohydramnios. (This figure was published in *American Journal of Obstetrics & Gynecology*, Vol. 150, No. 5, pt. 1, KJ Leveno, JG Quirk, Jr., FG Cunningham, et al., Prolonged pregnancy. I. Observations concerning the causes of fetal distress, pp. 465–473, Copyright Elsevier 1984.)

COMPLICATIONS

Oligohydramnios

The aggregate of most clinical studies is consistent with the view that diminished amnionic fluid determined by various sonographic methods identifies a postterm fetus with increased risks. Indeed, decreased amnionic fluid in any pregnancy signifies increased fetal risk (see Chap. 21, p. 496). Unfortunately, lack of an exact quantification method to define "decreased amnionic fluid" has limited investigators, and many different criteria for sonographic diagnosis have been proposed. Fischer and colleagues (1993) attempted to determine which criteria were most predictive of normal versus abnormal outcomes in postterm pregnancies. As shown in **Figure 37-9**, the smaller the amnionic fluid pocket, the greater the likelihood that there was clinically significant oligohydramnios. Importantly, normal amnionic fluid volume did not preclude abnormal outcomes. Alfirevic and co-workers (1997) randomly assigned 500 women with postterm pregnancies to assessment of amnionic fluid volume using either the amnionic fluid index (AFI) or the deepest vertical pocket (see Chap. 21, p. 490). They concluded that the AFI overestimated the number of abnormal outcomes in postterm pregnancies.

Regardless of the criteria used to diagnose oligohydramnios in postterm pregnancies, most investigators have found an

increased incidence of "fetal distress" during labor. Thus, oligohydramnios by most definitions is a clinically meaningful finding. Conversely, reassurance of continued fetal well-being in the presence of "normal" amnionic fluid volume is tenuous. This may be related to how quickly pathological oligohydramnios develops. For example, Clement and coworkers (1987) described six postterm pregnancies in which amnionic fluid volume diminished abruptly over 24 hours—in one of these, the fetus died.

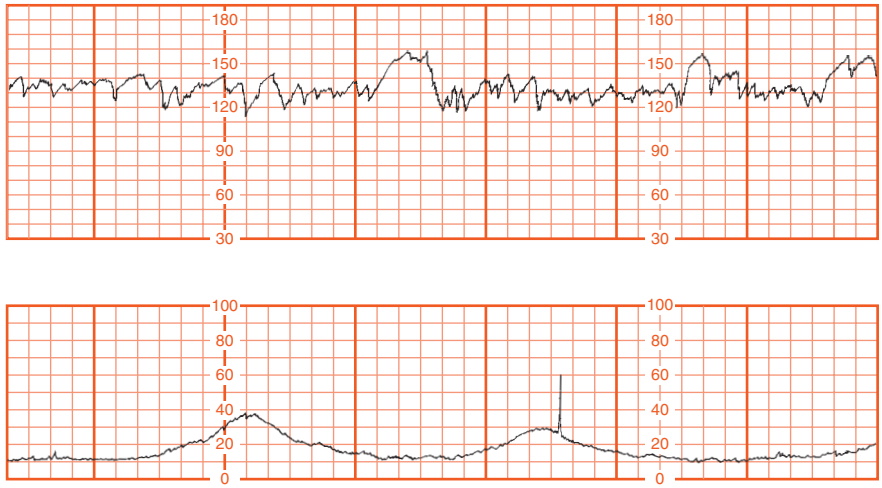

FIGURE 37-7 Saltatory baseline fetal heart rate showing oscillations exceeding 20 bpm and associated with oligohydramnios in a postterm pregnancy. (This figure was published in *American Journal of Obstetrics & Gynecology,* Vol. 150, No. 5, pt. 1, KJ Leveno, JG Quirk, Jr., FG Cunningham, et al., Prolonged pregnancy. I. Observations concerning the causes of fetal distress, pp. 465–473, Copyright Elsevier 1984.)

Macrosomia

The velocity of fetal weight gain peaks at approximately 37 weeks as shown in Figure 37-4. Although growth velocity slows at that time, most fetuses continue to gain weight. For example, the percentage of fetuses born in 2006 whose birthweight exceeded 4000 g was 8.5 percent at 37 to 41 weeks and increased to 11.2 percent at 42 weeks or more (Martin and colleagues, 2009). Intuitively at least, it seems that both maternal and fetal morbidity associated with macrosomia would be mitigated with timely induction to preempt further growth. This does not appear to be the case, however, and the American College of Obstetricians and Gynecologists (2000) has concluded that current evidence does not support such a practice in women at term with suspected fetal macrosomia. Moreover, the College concluded that in the absence of diabetes, vaginal delivery is not contraindicated for women with an estimated fetal weight up to 5000 g. Cesarean delivery was recommended for estimated fetal weights greater than 4500 g if there is prolonged second-stage labor or arrest of descent. Obvious problems with all such recommendations are substantive normal variations of fetal weight estimation (see Chap. 38, p. 854).

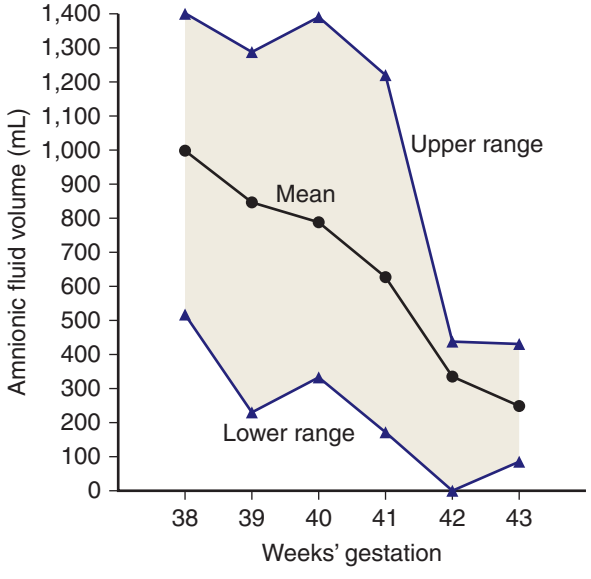

FIGURE 37-8 Volume of amnionic fluid during the last weeks of pregnancy. (Adapted from *The Lancet*, Vol. 278, PM Elliott and WHW Inman, Volume of liquor amnii in normal and abnormal pregnancy, pp. 835–840, Copyright 1961, with permission from Elsevier.)

Medical or Obstetrical Complications

In the event of a medical or other obstetrical complication, it is generally unwise to allow a pregnancy to continue past 42 weeks. Indeed, in many such instances, *earlier* delivery is indicated. Common examples include gestational hypertensive disorders, prior cesarean delivery, and diabetes.

MANAGEMENT

It is generally accepted that some form of intervention is indicated for prolonged pregnancies. The types of interventions and timing of their use, however, are not unanimous (Divon and Feldman-Leidner, 2008). After this decision is reached, the second issue is whether labor induction is warranted or if expectant management with fetal surveillance is best. Although hindered by the biases of surveys, Cleary-Goldman and colleagues (2006) reported that 73 percent of members of the American College of Obstetricians and Gynecologists responding to a 2004 poll routinely induced women at 41 weeks. Most of the remainder performed twice weekly fetal testing until 42 weeks.

Prognostic Factors for Successful Induction

Unfavorable Cervix

Although all obstetricians know what an "unfavorable cervix" is, the term unfortunately defies precise definition. Thus, various investigators have used different criteria for studies of prolonged pregnancies. For example, Harris and colleagues (1983) defined an unfavorable cervix by a Bishop score of less than 7 and reported this in 92 percent of women at 42 weeks. Hannah and

TABLE 37-2. Effects of Fetal-Growth Restriction on Stillbirth Rates in 537,029 Swedish Women Delivered before and after 42 Weeks

	Pregnancy Duration	
Outcome	**37–41 Weeks**	**≥ 42 Weeks**
Births (number)	469,056	40,973
Fetal-growth restriction[a] (%)	10,312 (2)	1,558 (4)
Stillbirths (per 1000)		
Appropriate growth	650 (1.4)	69 (1.8)

colleagues (1992) found that only 40 percent of 3407 women with a 41-week pregnancy had an undilated cervix. Alexander and associates (2000b) evaluated 800 women undergoing induction for postterm pregnancy at Parkland Hospital. Women in whom there was no cervical dilatation had a twofold increased cesarean delivery rate for "dystocia." Yang and co-workers (2004) found that cervical length of 3 cm or less measured with transvaginal ultrasonography was predictive of successful induction. In a similar study, Vankayalapati and associates (2008) found that cervical length of 25 mm or less was predictive of spontaneous labor or successful induction.

Cervical Ripening. A number of investigators have evaluated prostaglandin E_2 (PGE_2) for induction in women with an unfavorable cervix and prolonged pregnancies. The National Institute of Child Health and Human Development Network of Maternal-Fetal Medicine Units (1994) reported that PGE_2 gel was not more effective than placebo. Alexander and associates (2000c) treated 393 women with a postterm pregnancy with PGE_2, even if the cervix was "favorable." They reported that almost half of the 84 women with cervical dilatation of 2 to 4 cm entered labor with prostaglandin E_2 use alone. The American College of Obstetricians and Gynecologists (2004) has concluded that prostaglandin gel can be used safely in postterm pregnancies. Fasset and Wing (2008) reported that mifepristone increased uterine activity without uterotonic agents in women beyond 41 weeks. Prostaglandins and other agents used for cervical ripening are discussed in Chapter 22 (p. 502).

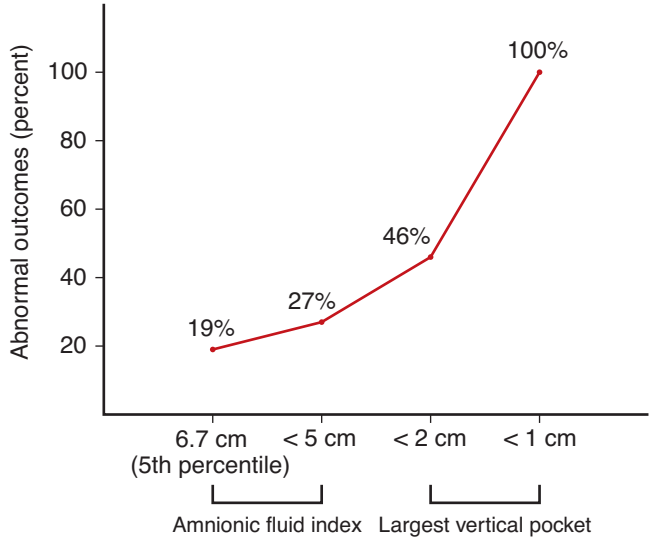

FIGURE 37-9 Comparison of the prognostic value of various sonographic estimates of amnionic fluid volume in prolonged pregnancies. Abnormal outcomes include cesarean or operative vaginal delivery for fetal jeopardy, 5-minute Apgar score of 6 or less, umbilical arterial blood pH less than 7.1, or admission to the neonatal intensive care unit. (Adapted from Fischer RL, McDonnell M, Bianculli KW, et al: Amniotic fluid volume estimation in the postdate pregnancy: A comparison of techniques, *Obstetrics & Gynecology,* 1993, vol. 81, no. 5, part 1, pp. 698–704, with permission.)

Sweeping or stripping of the membranes to induce labor and thereby prevent postterm pregnancy was studied in 15 randomized trials during the 1990s. Boulvain and co-workers (1999) performed a meta-analysis of these and found that membrane stripping at 38 to 40 weeks decreased the frequency of postterm pregnancy. This, however, did not modify the risk for cesarean delivery. They also found that maternal and neonatal infection rates were not increased by cervical manipulation. Since then, randomized trials by Wong (2002), Kashanian (2006), Hill (2008), and their colleagues found that sweeping membranes did not reduce the need to induce labor (see Chap. 22, p. 504). Drawbacks of membrane stripping included pain, vaginal bleeding, and irregular contractions without labor.

Station of Vertex

The station of fetal head in the pelvis is another important predictor of successful postterm pregnancy induction. Shin and colleagues (2004) studied 484 nulliparas who underwent induction after 41 weeks. The cesarean delivery rate was directly related to station. It was 6 percent if the vertex prior to induction was at −1 station; 20 percent at −2; 43 percent at −3; and 77 percent at −4.

Induction versus Fetal Testing

Because of marginal benefits for induction with an unfavorable cervix as discussed above, some clinicians prefer to use the alternative strategy of fetal testing beginning at 41 completed weeks.

There now have been a number of quality studies designed to resolve these important questions.

Hannah and colleagues (1992) randomly assigned 3407 Canadian women at 41 or more weeks to induction or to fetal testing. In the latter group, evaluation included: (1) counting fetal movements during a 2-hour period each day, (2) nonstress testing three times weekly, and (3) amnionic fluid volume assessment two to three times weekly with pockets less than 3 cm considered abnormal. Labor induction resulted in a small, albeit significantly lower, cesarean delivery rate compared with fetal testing—21 versus 24 percent, respectively. This difference was due to fewer procedures for fetal distress. Importantly, the only two stillbirths were in the fetal testing group.

The Maternal–Fetal Medicine Network performed a randomized trial of induction versus fetal testing beginning at 41 weeks (Gardner and associates, 1996). Fetal surveillance included nonstress testing and sonographic estimation of amnionic fluid volume performed twice weekly in 175 women. Their perinatal outcomes were compared with those of 265 women randomized to induction with or without cervical ripening. There were no perinatal deaths, and the cesarean delivery rate was not different between management groups. Thus, this study supported the validity of these management schemes, and similar results were subsequently reported from a Norwegian randomized trial of 508 women (Heimstad and colleagues, 2007).

These and similar findings caused Menticoglou and Hall (2002) to lament that labor induction at 41 weeks had become the standard of care in Canada. They termed this a *nonsensus consensus* resulting in "ritual induction at 41 weeks." They opined that this practice is based on seriously flawed evidence and that it constituted "an abuse of biological norms." They called for its discontinuation because it had potential to do more harm than good, and with staggering resource implications.

In an analysis of 19 trials in the Cochrane Pregnancy and Childbirth Trials Registry, Gulmezoglu and colleagues (2006) found that induction after 41 weeks was associated with fewer perinatal deaths without significantly increasing the cesarean delivery rate. Similar findings were reported by Mozurkewich and co-workers (2009) in their review of 2 meta-analyses and a recent randomized controlled study.

In a study to "lower" the number of postterm pregnancies, Harrington and colleagues (2006) randomized 463 women to pregnancy dating with sonography between 8 and 12 weeks versus no first-trimester sonographic evaluation. Their primary endpoint was the labor induction rate for prolonged pregnancy, and they found no advantages to early sonographic pregnancy dating.

At 42 weeks, labor induction has a higher cesarean delivery rate compared with spontaneous labor. From Parkland Hospital, Alexander and colleagues (2001) evaluated pregnancy outcomes in 638 such women in whom labor was induced and compared them with those of 687 women who had spontaneous labor. Cesarean delivery rates were significantly increased—19 versus 14 percent—in the induced group because of failure to progress. When these investigators corrected for risk factors, however, they concluded that intrinsic maternal factors, rather than the induction itself, led to the higher rate. These factors included nulliparity, an unfavorable cervix, and epidural analgesia.

Evidence to substantiate intervention—whether induction or fetal testing—commencing at 41 versus 42 weeks is limited. Most evidence used to justify intervention at 41 weeks is from the randomized Canadian and American investigations cited earlier. No randomized studies have specifically assessed intervention at 41 weeks versus an identical intervention used at 42 weeks. But there have been observational studies. In one, Usher and colleagues (1988) analyzed outcomes in 7663 pregnancies in women determined to be 40, 41, or 42 weeks confirmed by early sonographic evaluation. After correction for malformations, perinatal death rates were 1.5, 0.7, and 3.0 per 1000 at 40, 41, and 42 weeks, respectively. These results could be used to challenge the concept of routine intervention at 41 instead of 42 weeks.

Management Recommendations

American College of Obstetricians and Gynecologists

Because of the studies discussed above, the American College of Obstetricians and Gynecologists (2004) defines postterm pregnancies as having completed 42 weeks. There is insufficient evidence to recommend a management strategy between 40 and 42 completed weeks. Thus, although not considered mandatory, initiation of fetal surveillance at 41 weeks is a reasonable option. After completing 42 weeks, recommendations are for either antenatal testing or labor induction. These are summarized in Figure 37-10.

Parkland Hospital

Based on results discussed above, we consider 41-week pregnancies without other complications to be normal. Thus, no interventions are practiced solely based on fetal age until 42

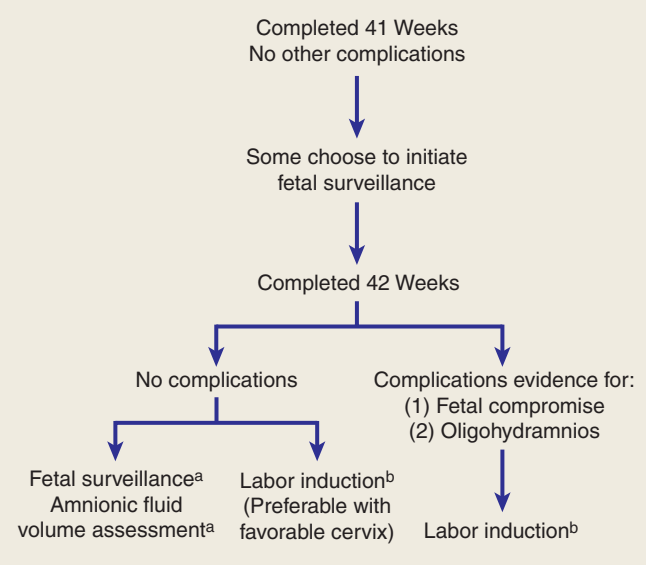

FIGURE 37-10 Management of postterm pregnancy—summary of recommendations of the American College of Obstetricians and Gynecologists (2004). [a]See text for options; [b]prostaglandins may be used for cervical ripening or induction.

completed weeks. If there are complications such as hypertension, decreased fetal movements, or oligohydramnios, then labor induction, with cervical ripening if indicated, is carried out at 41 weeks. It is our view that large, randomized trials should be performed before otherwise uncomplicated 41-week gestations are routinely considered pathologically prolonged.

In women in whom a *certain* gestational age is known, labor is induced at the completion of 42 weeks. Almost 90 percent of such women are induced successfully or enter labor within 2 days of induction. For those who do not deliver with the first induction, a second induction is performed within 3 days. Almost all women are delivered using this management plan, but in the unusual few who are not delivered, management decisions involve a third—or even more—induction versus cesarean delivery.

Women classified as having *uncertain* postterm pregnancies are managed with weekly nonstress fetal testing and assessment of amnionic fluid volume. Women with an AFI $\leq$ 5 cm or with reports of diminished fetal movement undergo labor induction.

INTRAPARTUM MANAGEMENT

Labor is a particularly dangerous time for the postterm fetus. Therefore, women whose pregnancies are known or suspected to be postterm should come to the hospital as soon as they suspect labor. While being evaluated for active labor, we recommend that fetal heart rate and uterine contractions be monitored electronically for variations consistent with fetal compromise (American College of Obstetricians and Gynecologists, 2005).

The decision to perform amniotomy is problematic. Further reduction in fluid volume following amniotomy can certainly enhance the possibility of cord compression. Conversely, amniotomy aids identification of thick meconium, which may be dangerous to the fetus if aspirated. And also, after membranes rupture, a scalp electrode and intrauterine pressure catheter can be placed. These usually provide more precise data concerning fetal heart rate and uterine contractions.

Identification of *thick meconium* in the amnionic fluid is particularly worrisome. The viscosity probably signifies the lack of liquid and thus oligohydramnios. Aspiration of thick meconium may cause severe pulmonary dysfunction and neonatal death (see Chap. 29, p. 628). Because of this, Wenstrom and Parsons (1989) proposed *amnioinfusion* during labor as a way of diluting meconium to decrease the incidence of aspiration syndrome. As discussed in Chapter 18 (p. 433), the benefits of amnioinfusion remain controversial. In a large randomized trial by Fraser and colleagues (2005), amnioinfusion did not reduce the risk of meconium aspiration syndrome or perinatal death. According to the American College of Obstetricians and Gynecologists (2005, 2006), amnioinfusion does not prevent meconium aspiration, however, it remains a reasonable treatment approach for repetitive variable decelerations, regardless of meconium status.

The likelihood of a successful vaginal delivery is reduced appreciably for the nulliparous woman who is in early labor with thick, meconium-stained amnionic fluid. Therefore, when the woman is remote from delivery, strong consideration should be given to prompt cesarean delivery, especially when cephalopelvic disproportion is suspected or either hypotonic or hypertonic dysfunctional labor is evident. Some practitioners choose to avoid oxytocin use in these cases.

Until recently, it was taught—including here—that aspiration of meconium could be minimized but not eliminated by suctioning the pharynx as soon as the head was delivered. According to the American Heart Association (2006) guidelines, there is no evidence that such practices prevent or alter the meconium aspiration syndrome. The American College of Obstetricians and Gynecologists (2007) does not recommend routine intrapartum suctioning. However, if the depressed newborn has meconium-stained fluid, then intubation is done with tracheal suctioning.

CHAPTER 38

Fetal Growth Disorders

NORMAL FETAL GROWTH 842
FETAL-GROWTH RESTRICTION 843
MACROSOMIA 853

Each year, approximately 20 percent of the almost 4 million infants in the United States are born at the low and high extremes of fetal growth. Although most low-birthweight infants are preterm, approximately 3 percent are term. In 2006, 8.3 percent of infants weighed less than 2500 g at birth, whereas 7.8 percent weighed more than 4000 g. The proportion of those < 2500 g has increased by 22 percent since 1984 and by 8 percent since 2000. At the same time, the incidence of macrosomia—defined as birthweight > 4000 g—continues to decline as the distribution has shifted toward lower weights (Martin and colleagues, 2007, 2009).

NORMAL FETAL GROWTH

Human fetal growth is characterized by sequential patterns of tissue and organ growth, differentiation, and maturation. Development is determined by maternal provision of substrate, placental transfer of these substrates, and fetal-growth potential governed by the genome. Steer (1998) has summarized the potential effects of evolutionary pressures on human fetal growth. In humans, there is an increasing conflict between the need to walk—requiring a narrow pelvis—and the need to think—requiring a large brain. Humans may be resolving this dilemma by acquiring the ability to restrict growth late in pregnancy. Thus, the ability to *growth restrict* may be adaptive rather than pathological.

Lin and Santolaya-Forgas (1998) have divided cell growth into three consecutive phases. The initial phase of hyperplasia occurs in the first 16 weeks and is characterized by a rapid increase in cell number. The second phase, which extends up to 32 weeks, includes both cellular hyperplasia and hypertrophy. After 32 weeks, fetal growth is by cellular hypertrophy, and it is during this phase that most fetal fat and glycogen deposition takes place. The corresponding fetal-growth rates during these three phases are 5 g/day at 15 weeks, 15 to 20 g/day at 24 weeks, and 30 to 35 g/day at 34 weeks (Williams and co-workers, 1982). As shown in **Figure 38-1**, there is considerable biological variation in the velocity of fetal growth.

Although many factors have been implicated, the precise cellular and molecular mechanisms by which normal fetal growth occurs are not well understood. In early fetal life, the major determinant is the fetal genome, but later in pregnancy, environmental, nutritional, and hormonal influences become increasingly important (Holmes and colleagues, 1998). For example, there is considerable evidence that insulin and insulin-like growth factor-I (IGF-I) and II (IGF-II) have a role in the regulation of fetal growth and weight gain (Chiesa and associates, 2008; Forbes and Westwood, 2008). These growth factors are produced by virtually all fetal organs beginning early in development. They are potent stimulators of cell division and differentiation.

Since the discovery of the *obesity gene* and its protein product, *leptin*, there has been interest in maternal and fetal serum leptin levels. Fetal concentrations increase during the first two trimesters, and they correlate with birthweight (Catov, 2007; Sivan, 1998; Tamura, 1998; and all their colleagues). This relationship, however, is controversial in growth-restricted fetuses (Kyriakakou, 2008; Mise, 2007; Savvidou, 2006, and all their associates). Angiogenic factors have also been studied. For example, higher levels of sFlt-1 at 10 to 14 weeks are associated with small-for-gestational age infants (Smith and co-workers, 2007).

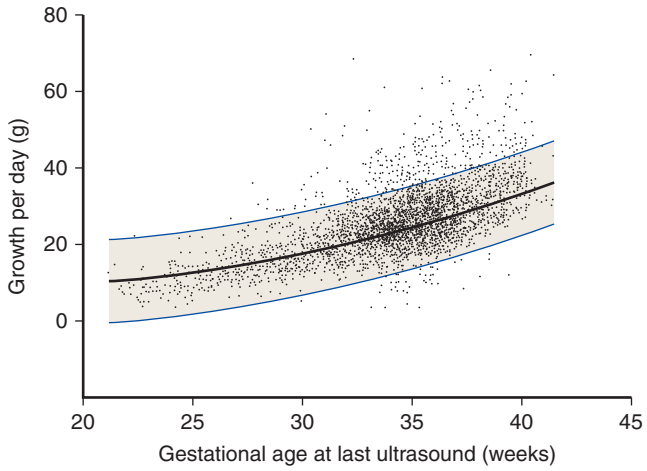

FIGURE 38-1 Increments in fetal weight gain in grams per day from 24 to 42 weeks' gestation. The black line represents the mean and the outer blue lines depict ±2 standard deviations. (Data courtesy of Dr. Don McIntire.)

Fetal growth is also dependent on an adequate supply of nutrients. As discussed in Chapter 4 (p. 87), glucose transfer has been extensively studied during pregnancy. Both excessive and diminished maternal glucose availability affect fetal growth. Excessive glycemia produces macrosomia, whereas diminished glucose levels have been associated with fetal-growth restriction. The Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) Study Cooperative Research Group (2008) found that elevated cord c-peptide levels, which reflect fetal hyperinsulinemia, have been associated with increased birthweight even in women with maternal glucose levels below the threshold for diabetes.

There is less information concerning the physiology of maternal-fetal transfer of other nutrients such as amino acids and lipids. Ronzoni and colleagues (1999) studied maternal-fetal concentrations of amino acids in 26 normal pregnancies. These investigators reported that an increase in maternal amino acid levels led to an increase in fetal levels. In growth-restricted fetuses, amino acid disturbance similar to the biochemical changes seen in postnatal protein-starvation states has also been detected (Economides and colleagues, 1989b). In a study of 38 growth-restricted infants, Jones and colleagues (1999) found impaired use of circulating triglycerides consistent with peripheral adipose depletion.

FETAL-GROWTH RESTRICTION

Low-birthweight infants who are small-for-gestational age are often designated as having *fetal-growth restriction.* The term fetal-growth retardation has been discarded because "retardation" implies abnormal mental function, which is not the intent. It is estimated that 3 to 10 percent of infants are growth restricted.

Definition

In 1963, Lubchenco and co-workers published detailed comparisons of gestational ages with birthweights in an effort to derive norms for expected fetal size at a given gestational week. Battaglia and Lubchenco (1967) then classified *small-for-gestational-age* (*SGA*) infants as those whose weights were below the 10th percentile for their gestational age. Such infants were shown to be at increased risk for neonatal death. For example, the neonatal mortality rate of SGA infants born at 38 weeks was 1 percent compared with 0.2 percent in those with appropriate birthweights.

Many infants with birthweights less than the 10th percentile, however, are not pathologically growth restricted but are small simply because of normal biological factors. Indeed, Manning and Hohler (1991) and Gardosi and colleagues (1992) concluded that 25 to 60 percent of SGA infants were in fact appropriately grown when maternal ethnic group, parity, weight, and height were considered.

Because of these disparities, other classifications have been developed. Seeds (1984) suggested a definition based on birthweight below the 5th percentile. Usher and McLean (1969) suggested that fetal-growth standards should be based on mean weights-for-age with normal limits defined by ±2 standard deviations. This definition would limit SGA infants to 3 percent of births instead of 10 percent. As demonstrated from their analysis of 122,754 pregnancies, McIntire and colleagues (1999) showed this definition to be clinically meaningful. Also, as shown in **Figure 38-2**, most adverse outcomes are in infants below the 3rd percentile. Lastly, individual fetal-growth potential has been proposed in place of a population-based cutoff. In this model, a fetus who deviates from its individual optimal size at a given gestational age is considered either overgrown or growth restricted (Bukowski and associates, 2008).

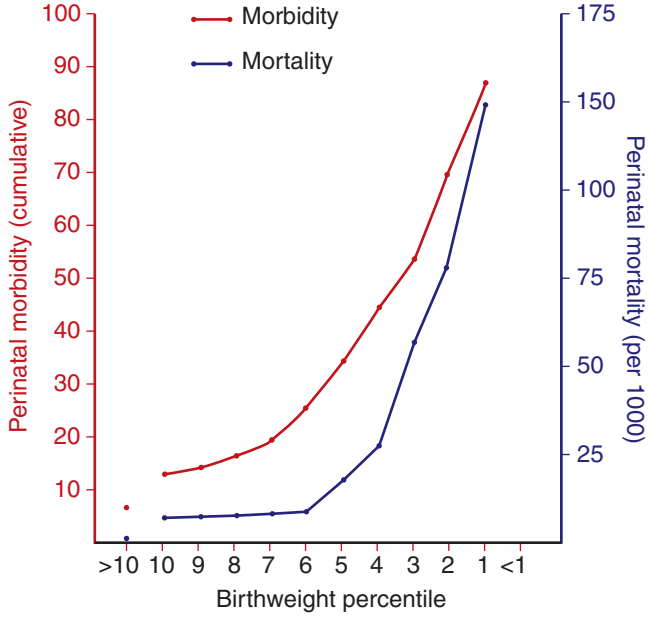

FIGURE 38-2 Relationship between birthweight percentile and perinatal mortality and morbidity rates in 1560 small-for-gestational age fetuses. A progressive increase in both mortality and morbidity rates is observed as birthweight percentile falls. (Data from Manning, 1995.)

TABLE 38-1. Smoothed Percentiles of Birthweight (g) for Gestational Age in the United States Based on 3,134,879 Singleton Live Births

	Percentile				
Age (wk)	5th	10th	50th	90th	95th
20	249	275	412	772	912
21	280	314	433	790	957

Normal Birthweight

Normative data for fetal growth based on birthweight vary with ethnic and regional differences. For example, infants born to women who reside at high altitudes are smaller than those born to women who live at sea level. Term infants average 3400 g at sea level, 3200 g at 5000 feet, and 2900 g at 10,000 feet. Accordingly, researchers have developed fetal-growth curves using various populations and geographic locations throughout the United States (Brenner and co-workers, 1976; Ott, 1993; Overpeck and colleagues, 1999; Williams, 1975). These curves are based on specific ethnic or regional groups and therefore are not representative of the entire population.

To address this, data such as those shown in Table 38-1 were derived on a nationwide basis in both the United States and Canada (Alexander and co-workers, 1996; Arbuckle and colleagues, 1993). Data from more than 3.1 million mothers with singleton liveborn infants in the United States during 1991 were used to derive the growth curve shown in Figure 38-3. In general, the previously published fetal-growth curve data underestimated birthweights compared with national data. Importantly, there are significant ethnic or racial variations in neonatal mortality rates within the national neonatal mortality rate as well as within birthweight and gestational age categories (Alexander and associates, 1999, 2003).

Birthweight versus Growth

Most of what is known about normal and abnormal human fetal growth is actually based on standards for birthweight, which is the end point of fetal growth. These standards do not define the *rate* of fetal growth. Indeed, such birthweight curves reveal compromised growth only at the extreme of impaired growth. Thus, they cannot be used to identify the fetus who fails to achieve an expected or potential size but whose birthweight is above the 10th percentile. For example, a fetus with a birthweight in the 40th percentile may not have achieved its genomic growth potential for a birthweight in the 80th percentile. The rate or *velocity* of fetal growth can be estimated by serial sonographic anthropometry. Reports suggest that a diminished growth velocity is related to perinatal morbidity (Owen and coworkers, 1997; Owen and Khan, 1998).

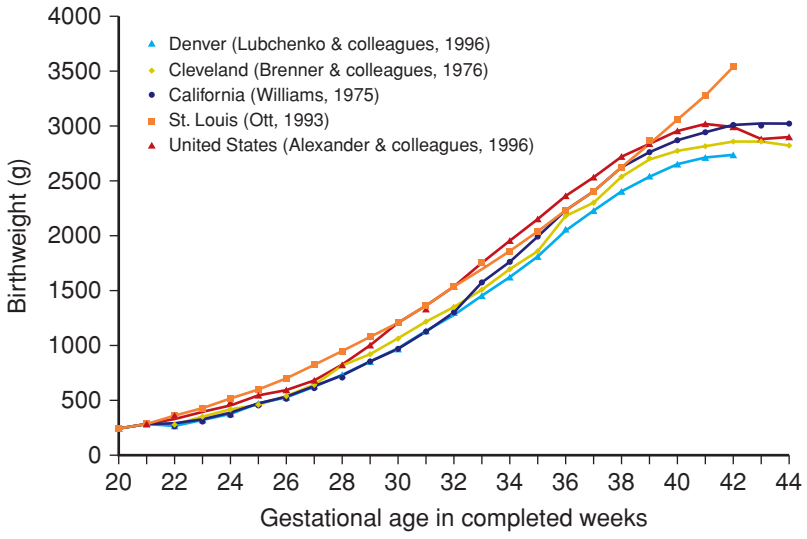

FIGURE 38-3 Comparison of fetal-growth curves for infants born in different regions of the United States and compared with those of the nation at large. (Modified from Alexander and colleagues, 1996.)

Metabolic Abnormalities

Several disturbances in fetal metabolism have been implicated in abnormal fetal growth. Economides and Nicolaides (1989a) found that the major cause of hypoglycemia in SGA fetuses was reduced supply rather than increased fetal consumption or diminished fetal glucose production. These fetuses had hypoinsulinemia along with hypoglycemia (Economides and co-workers, 1989c). The degree of fetal-growth restriction, however, did not correlate with plasma insulin levels, suggesting that glycemia is not the primary determinant of poor fetal growth.

In children with *kwashiorkor*—dietary protein malnutrition—the ratio of nonessential to essential amino acids is increased. This ratio presumably results from a decreased intake of essential amino acids. By comparison, Economides and colleagues (1989b) measured the glycine:valine ratio in cord blood from growth-restricted fetuses and found ratios similar to those observed in older children with kwashiorkor. Moreover, protein deprivation correlated with fetal hypoxemia. Economides and associates (1990) then measured plasma triglyceride concentrations in SGA fetuses and compared those with the concentrations of appropriately grown fetuses. Growth-restricted fetuses demonstrated hypertriglyceridemia that was correlated with the degree of fetal hypoxemia. They hypothesized that hypoglycemic, growth-restricted fetuses mobilize adipose tissue and that hypertriglyceridemia is the result of lipolysis of their fat stores. Beltrand and colleagues (2008) calculated growth velocity in 235 pregnancies at risk for low birthweight and found higher cord triglyceride levels, lower insulin levels, and greater insulin sensitivity in those infants with the most diminished growth velocity. They concluded that these changes represented adaptive mechanisms in fetal metabolism in response to a deleterious fetal environment.

Elevated plasma concentrations of interleukin-10, placental atrial natriuretic peptide, and endothelin-1, as well as a defect in epidermal growth factor function, have also been described in growth-restricted fetuses (Varner and colleagues, 1996). Some of these may be effect and not cause. But at the same time, these findings suggest a possible role for abnormal immune activation and abnormal placentation in the genesis of growth-restricted fetuses as well as preeclampsia syndrome (Gabriel, 1994; Heyborne, 1994; Kingdom, 1994; McQueen, 1993; Neerhof, 1995, and all their associates). These interactions are discussed further in Chapter 34 (p. 710).

In animals, chronic *reduction* in nitric oxide—an endothelium-derived, locally acting vasorelaxant—has been shown to result in diminished fetal growth (Diket and associates, 1994). Conversely, Giannubilo and co-workers (2008) showed that placenta-induced nitric oxide synthase was significantly *increased* in growth restriction, possibly representing an adaptive response to placental insufficiency.

Morbidity and Mortality

As shown in Figure 38-2, fetal-growth restriction is associated with substantive perinatal morbidity and mortality rates. Fetal demise, birth asphyxia, meconium aspiration, and neonatal hypoglycemia and hypothermia are all increased, as is the prevalence of abnormal neurological development (Jacobsson and colleagues, 2008; Paz and associates, 1995). This is true for both term and preterm growth-restricted infants (McIntire and colleagues, 1999; Minior and Divon, 1998; Wu and co-workers, 2006). Smulian and colleagues (2000) reported that growth-restricted infants had a higher 1-year infant mortality rate compared with normal infants. Boulet and associates (2006) demonstrated that for a fetus at the 10th percentile, the risk of neonatal death is increased but variably across gestational age. Risk is increased threefold at 26 weeks compared with only a 1.13-fold increased risk at 40 weeks.

Postnatal growth and development of the growth-restricted fetus depends on the cause of restriction, nutrition in infancy, and the social environment (Kliegman, 1997). Infants with growth restriction due to congenital, viral, chromosomal, or maternal size typically remain small throughout life. Fetal umbilical blood sampling for karyotyping of severely growth-restricted fetuses has permitted remarkable insights into the pathophysiology of diminished fetal growth (see Chap. 13, p. 301). If growth restriction is due to placental insufficiency, affected infants often have increased postnatal growth, and they approach their inherited growth potential.

Accelerated Maturation

There have been numerous reports describing accelerated fetal pulmonary maturation in complicated pregnancies associated

with growth restriction (Perelman and colleagues, 1985). One explanation is that the fetus responds to a stressed environment by increasing adrenal glucocorticoid secretion, which leads to earlier or accelerated fetal lung maturation (Laatikainen and associates, 1988). Although this concept pervades modern perinatal thinking, there is negligible evidence to support it (see also Chap. 29, p. 605).

To examine this hypothesis, Owen and associates (1990) analyzed perinatal outcomes in 178 women delivered because of hypertension. They compared these with outcomes in infants of 159 women delivered because of spontaneous preterm labor or ruptured membranes. They concluded that a "stressed" pregnancy did not confer an appreciable survival advantage. Similar findings were reported by Friedman and coworkers (1995) in women with severe preeclampsia. Two studies from Parkland Hospital also substantiate that the preterm infant accrues no apparent advantages from fetal-growth restriction (McIntire and associates, 1999; Tyson and colleagues, 1995).

Symmetrical Versus Asymmetrical Growth Restriction

Campbell and Thoms (1977) described the use of the sonographically determined *head-to-abdomen circumference ratio* (*HC/AC*) to differentiate growth-restricted fetuses. Those who were *symmetrical* were proportionately small, and those who were *asymmetrical* had disproportionately lagging abdominal growth.

The onset or etiology of a particular fetal insult has been hypothetically linked to either type of growth restriction. In the instance of *symmetrical growth restriction*, an early insult could result in a relative decrease in cell number and size. For example, global insults such as from chemical exposure, viral infection, or cellular maldevelopment with aneuploidy may cause a proportionate reduction of both head and body size.

Asymmetrical growth restriction might follow a late pregnancy insult such as placental insufficiency from hypertension. Resultant diminished glucose transfer and hepatic storage would primarily affect cell size and not number, and fetal abdominal circumference—which reflects liver size—would be reduced. Such somatic growth restriction is proposed to result from preferential shunting of oxygen and nutrients to the brain, which allows normal brain and head growth—so-called *brain sparing*. The fetal brain is normally relatively large and the liver relatively small. Accordingly, the ratio of brain weight to liver weight during the last 12 weeks—usually about 3 to 1—may be increased to 5 to 1 or more in severely growth-restricted infants.

Because of brain-sparing effects, asymmetrical fetuses were thought to be preferentially protected from the full effects of growth restriction. Considerable evidence has since accrued that fetal-growth patterns are much more complex. Nicolaides and co-workers (1991) found that fetuses with aneuploidy typically had disproportionately large head sizes and thus were *asymmetrically* growth restricted, which was contrary to thinking at that time. Moreover, most preterm infants with growth restriction due to preeclampsia and associated uteroplacental insufficiency were found to have symmetrical growth impairment—again, a departure from contemporaneous thinking (Salafia and associates, 1995).

More evidence was presented by Dashe and colleagues (2000), who analyzed 8722 consecutive liveborn singletons who had undergone sonographic examination within 4 weeks of delivery. Although only 20 percent of growth-restricted fetuses demonstrated sonographic head-to-abdomen asymmetry, these fetuses were at increased risk for intrapartum and neonatal complications. Symmetrically growth-restricted fetuses were not at increased risk for adverse outcomes compared with those appropriately grown. These researchers concluded that asymmetrical fetal-growth restriction represented significantly disordered growth, whereas symmetrical growth restriction more likely represented normal, genetically determined small stature.

Finally, recent data from Holland further challenges the concept of "brain sparing." Roza and associates (2008) provided follow-up of 935 toddlers enrolled between 2003 and 2007 in the Generation R Study in Rotterdam. Using the Child Behavior Checklist at 18 months of age, they found that infants with circulatory redistribution—brain sparing—had a higher incidence of behavioral problems.

Risk Factors

Constitutionally Small Mothers

It is not disputed that small women typically have smaller infants. If a woman begins pregnancy weighing less than 100 pounds, the risk of delivering an SGA infant is increased at least twofold (Simpson and colleagues, 1975). Moreover, intergenerational effects on birthweight are transmitted through the maternal line such that reduced intrauterine growth of the mother is a risk factor for reduced intrauterine growth of her offspring (Emanuel and associates, 1992; Klebanoff and co-workers, 1997).

Whether the phenomenon of a small mother giving birth to a small infant is nature or nurture is unclear. Brooks and colleagues (1995) analyzed 62 births after ovum donation to examine the relative influence of the donor versus the recipient on birthweight. They concluded that the environment provided by the recipient mother was more important than the genetic contribution to birthweight.

Poor Maternal Nutrition

In the woman of average or low body mass index (BMI), poor weight gain throughout pregnancy may be associated with fetal-growth restriction (Rode and colleagues, 2007). Lack of weight gain in the second trimester especially correlates with decreased birthweight (Abrams and Selvin, 1995). As perhaps expected, eating disorders are associated with up to a ninefold increase in fetal-growth restriction (Bansil and associates, 2008). This is discussed further in Chapter 55 (p. 1180).

Marked restriction of weight gain after midpregnancy should not be encouraged (see Chap. 43, p. 949). Even so, it appears that caloric restriction to less than 1500 kcal/day adversely affects fetal growth only minimally (Lechtig and co-workers, 1975). The best documented effect of famine on fetal growth was in the "hunger winter" of 1944 in Holland. The German

Occupation Army restricted dietary intake to 600 kcal/day for civilians, including pregnant women. The famine persisted for 28 weeks. Although this resulted in an average birthweight decrease of only 250 g, fetal mortality rates increased significantly (Stein and colleagues, 1975).

Undernourished women may benefit from micronutrient supplementation as shown in the study by the Supplementation with Multiple Micronutrients Intervention Trial (SUMMIT) Study Group (2008). Almost 32,000 Indonesian women were randomized to receive micronutrient supplementation or only iron and folate tablets. Infants of those receiving the supplement had lower risks of early infant mortality and low birthweight. A smaller trial done in West Africa was less convincing (Roberfroid and associates, 2008).

Social Deprivation

The effect of social deprivation on birthweight is interconnected to the effects of associated lifestyle factors such as smoking, alcohol or other substance abuse, and poor nutrition. In a study of 7493 British women, Wilcox and associates (1995) found that the most socially deprived mothers had the smallest infants. Similarly, Dejin-Karlsson and colleagues (2000) prospectively studied a cohort of Swedish women and found that lack of psychosocial resources increased the risk of growth-restricted infants.

Maternal and Fetal Infections

Viral, bacterial, protozoan, and spirochetal infections have been implicated in up to 5 percent of cases of fetal-growth restriction and are discussed in Chapters 58 and 59. The best known of these are infections caused by rubella and cytomegalovirus (Lin and Evans, 1984; Stagno and associates, 1977). Mechanisms affecting fetal growth appear to be different with each. *Cytomegalovirus* is associated with direct cytolysis and loss of functional cells. *Rubella* infection causes vascular insufficiency by damaging the endothelium of small vessels, and it also reduces cell division (Pollack and Divon, 1992).

Hepatitis A and B are associated with preterm delivery but may also adversely affect fetal growth (Waterson, 1979). *Listeriosis, tuberculosis,* and *syphilis* have also been reported to cause fetal-growth restriction. Paradoxically, with syphilis, the placenta is almost always increased in weight and size due to edema and perivascular inflammation (Varner and Galask, 1984). *Toxoplasmosis* is the protozoan infection most often associated with compromised fetal growth (Klein and Remington, 1995). Despite this, an analysis by Freeman and colleagues (2005) of 386 pregnant women who seroconverted due to toxoplasma infection found no association between congenital toxoplasmosis and low birthweight. *Congenital malaria* has also been implicated (Varner and Galask, 1984).

Congenital Malformations

In a study of more than 13,000 infants with major structural anomalies, 22 percent had accompanying growth restriction (Khoury and associates, 1988). In their study of 84 pregnancies complicated by fetal gastroschisis, Towers and Carr (2008) identified birthweights less than the 10th percentile in 38 percent of newborns and less than the 3rd percentile in 19 percent. As a general rule, the more severe the malformation, the more likely the fetus is to be SGA. This is especially evident in fetuses with chromosomal abnormalities or those with serious cardiovascular malformations.

Chromosomal Aneuploidies

Fetuses with *autosomal trisomies* have a placenta with reduced numbers of small muscular arteries in the tertiary stem villi (Rochelson and associates, 1990). Depending on which chromosome is extra, there may be associated growth restriction. For example, in *trisomy 21*, fetal-growth restriction is generally mild. Both shortened femur length and hypoplasia of the middle phalanx occur with increased frequency with this aneuploidy.

By contrast, fetal growth in *trisomy 18* is virtually always significantly restricted. Growth failure has been documented as early as the first trimester. Bahado-Singh (1997) and Schemmer (1997) and their colleagues found that crown-rump length in fetuses with trisomy 18 and 13, unlike that with trisomy 21, was shorter than expected. By the second trimester, long-bone measurements typically fall below the 3rd percentile for age, and the upper extremity is even more severely affected (Droste and co-workers, 1990). Visceral organ growth is also abnormal (Droste, 1992). Fetuses with *trisomy 13* and *trisomy 22* have some degree of growth restriction, but generally not as severe as those with trisomy 18 (Schwendemann and co-workers, 2009).

Trisomy 16 is the most common trisomy in spontaneous miscarriage and is usually lethal in the nonmosaic state (Lindor and associates, 1993). As discussed in Chapter 12 (p. 275), patches of trisomy 16 (or others) in the placenta—*confined placental mosaicism*—can cause placental insufficiency that may account for many cases of previously unexplained growth-restricted fetuses (Kalousek and colleagues, 1993; Towner and co-workers, 2001).

According to Droste (1992), significant fetal-growth restriction is not seen with *Turner syndrome* (45,X) or *Klinefelter syndrome* (47,XXY).

First-trimester prenatal screening programs to identify women at risk for aneuploidy may incidentally identify pregnancies at risk for fetal-growth restriction unrelated to karyotype. In their analysis of 8012 women, Krantz and associates (2004) identified an increased risk for growth restriction in those with extremely low free β-human chorionic gonadotropin (β-hCG) and pregnancy-associated plasma protein-A (PAPP-A) levels despite normal chromosomes. Similar findings have also been reported for second-trimester quad screening by the First- and Second-Trimester Evaluation of Risk (FASTER) Trial Research Consortium (Dugoff and colleagues, 2005). Abnormalities in two or more markers were more strongly associated with diminished growth than any single marker. Nuchal translucency, however, has not been shown to be predictive of fetal-growth restriction. These are discussed further in Chapter 13 (p. 292).

Disorders of Cartilage and Bone

Numerous inherited syndromes such as *osteogenesis imperfecta* and various chondrodystrophies are associated with fetal-growth restriction.

Drugs with Teratogenic and Fetal Effects

A number of drugs and chemicals are capable of adversely affecting fetal growth. Some are teratogenic and affect the fetus before organogenesis is complete. Some exert—or continue to exert—fetal effects after embryogenesis ends at 8 weeks. Many of these are considered in detail in Chapter 14, and examples include anticonvulsants and antineoplastic agents. Some antirejection immunosuppression drugs used for organ transplantation maintenance are implicated as a cause of restricted fetal growth (Mastrobattista and associates, 2008). In addition, cigarette smoking, opiates and related drugs, alcohol, and cocaine may cause growth restriction, either primarily or by decreasing maternal food intake. Finally, caffeine use throughout pregnancy has recently been linked to fetal-growth restriction. Diminished growth may be related to a phenotypic enzyme expression that slows caffeine metabolism (CARE Study Group, 2008).

Vascular Disease

Especially when complicated by superimposed preeclampsia, chronic vascular disease commonly causes growth restriction (see Chap. 34, p. 708). Preeclampsia may cause fetal-growth failure and is an indicator of its severity, especially when the onset is before 37 weeks (Gainer, 2005; Odegard, 2000; Xiong, 1999, and all their colleagues). In a study of more than 2000 women, vascular disease as evidenced by abnormal uterine artery Doppler velocimetry early in pregnancy was associated with increased rates of preeclampsia, small-for-gestational age neonates, and delivery before 34 weeks (Groom and co-workers, 2009).

Renal Disease

Chronic renal insufficiency is often associated with underlying hypertension and vascular disease (see Chap. 48, p. 1039). Chronic nephropathies are commonly accompanied by restricted fetal growth (Cunningham and colleagues, 1990; Vidaeff and associates, 2008).

Pregestational Diabetes

Fetal-growth restriction in women with diabetes may be related to congenital malformations or may follow substrate deprivation from advanced maternal vascular disease (see Chap. 52, p. 1113). As mentioned previously, the degree of growth restriction is related to malformation severity. Also, the likelihood of growth restriction increases with development of nephropathy and proliferative retinopathy—especially in combination (Haeri and co-workers, 2008).

Chronic Hypoxia

Conditions associated with chronic uteroplacental hypoxia include preeclampsia, chronic hypertension, asthma, smoking, and high altitude. When exposed to a chronically hypoxic environment, some fetuses have significantly reduced birthweight. Bahtiyar and colleagues (2007) induced growth restriction in pregnant rats using conditions of chronic hypoxia and by inhibiting nitric oxide synthase, a pathway implicated in hypertension-related growth abnormalities. They concluded that each restrictive etiology was independent but failed to demonstrate that they were synergistic. As discussed in Chapter 44 (p. 969), severe hypoxia from maternal cyanotic heart disease frequently is associated with severely growth-restricted fetuses (Patton and co-workers, 1990).

Anemia

In most cases, maternal anemia does not cause fetal-growth restriction. Exceptions include sickle-cell disease and some other inherited anemias (Chakravarty and colleagues 2008; Tongsong and associates, 2009). Conversely, curtailed maternal blood-volume expansion has been linked to fetal-growth restriction (Duvekot and colleagues, 1995). This is further discussed in Chapter 51 (p. 1079).

Placental and Cord Abnormalities

A number of placental abnormalities may cause fetal-growth restriction. These are discussed further throughout Chapter 27 and include chronic placental abruption, extensive infarction, chorioangioma, marginal or velamentous cord insertion, circumvallate placenta, placenta previa, and umbilical artery thrombosis. Growth failure in these cases is presumed to be due to *uteroplacental insufficiency.* Some pregnancies with otherwise unexplained fetal-growth restriction and a grossly normal placenta have reduced uteroplacental blood flow compared with that of normally grown fetuses (Kotini and colleagues, 2003; Lunell and Nylund, 1992; Papageorghiou and co-workers, 2001). Similar blood flow reductions have also been reported in growth-restricted fetuses with congenital malformations. These results suggest that maternal blood flow may in part be regulated by the fetus (Howard, 1987; Rankin and McLaughlin, 1979). It is interesting that the converse is likely not the case. There is no evidence that macrosomic infants have increased uteroplacental blood flow.

Abnormal placental implantation with endothelial dysfunction may also result in fetal-growth restriction (Ness and Sibai, 2006). This pathology has been implicated in pregnancies complicated by preeclampsia as discussed in Chapter 34 (p. 710) and recently reviewed by Fisher and colleagues (2009).

Infertility

Pregnancies in women with a history of infertility have an increased risk of small-for-gestational age infants with or without infertility treatments (Zhu and colleagues, 2007).

Extrauterine Pregnancy

If the placenta is implanted outside the uterus, the fetus is usually growth restricted (see Chap. 10, p. 249). Also, some uterine malformations have been linked to impaired fetal growth (see Chap. 40, p. 890).

Antiphospholipid Antibody Syndrome

Two classes of antiphospholipid antibodies—*anticardiolipin antibodies* and *lupus anticoagulant*—have been associated with fetal-growth restriction. Pathophysiological mechanisms appear to be caused by maternal platelet aggregation and placental

thrombosis. These syndromes are considered in detail in Chapter 47 (p. 1017) and Chapter 54 (p. 1151). Pregnancy outcome in women with these antibodies may be poor and include early-onset preeclampsia and fetal demise (Levine and associates, 2002; Lockwood, 2002). Not all have reported these adverse outcomes, and Infante-Rivard (2002) and Rodger (2008) and their colleagues found no association between maternal or newborn thrombophilia polymorphisms and fetal-growth restriction.

Genetics

Several studies have been done to evaluate the role of genetic polymorphisms in the mother or fetus and their relationship to growth-restricted infants. Engel and colleagues (2006) suggest a possible role for the *SHMT1(1420)T* variant in the folate metabolism pathway that affects homocysteine levels and results in SGA infants. Similarly, Stonek and associates (2007) identified *MTHFR C677T* as a marker for growth restriction. Other maternal metabolic gene polymorphisms—*CYP1A1, STT1, GSTM1*—have also been shown to modulate the risk of growth restriction in mothers who smoke (Delpisheh and co-workers, 2009). Others have evaluated microRNAs (Pineles and colleagues, 2007). Larger studies are needed to confirm and quantify the role of heredity.

Multiple Fetuses

As shown in **Figure 38-4**, pregnancy with two or more fetuses is more likely to be complicated by diminished growth of one or more fetuses compared with that of normal singletons (see Chap. 39, p. 868).

Identification of Fetal-Growth Restriction

Early establishment of gestational age, attention to maternal weight gain, and careful measurement of uterine fundal growth throughout pregnancy will identify many cases of abnormal fetal growth in low-risk women. Risk factors, including a *previous growth-restricted fetus,* increase the possibility of recurrence. Specifically, the rate of recurrence is believed to be nearly 20 percent (Berghella, 2007). In women with risk factors, consideration should be given to serial sonographic evaluation. Although frequency of examinations varies depending on indications, an initial early dating examination followed by a second examination at 32 to 34 weeks, or when otherwise clinically indicated, will identify many cases of growth restriction. Even so, *definitive diagnosis* frequently cannot be made until delivery.

Identification of the inappropriately growing fetus remains a challenge. There are, however, both simple clinical techniques and more complex technologies that may prove useful.

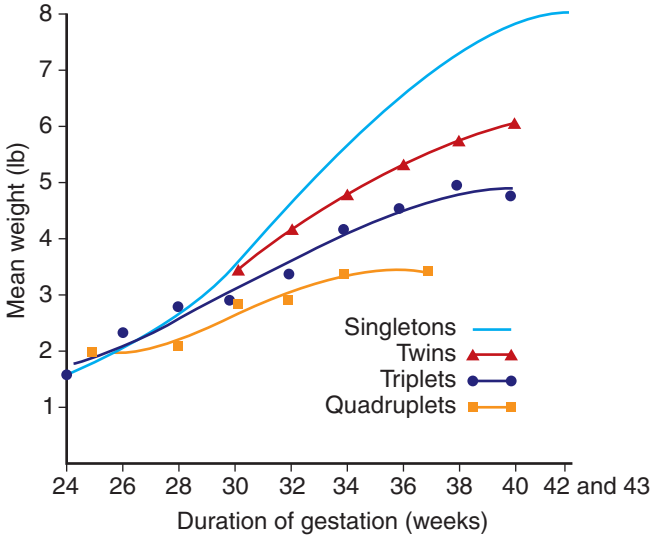

FIGURE 38-4 Birthweight and gestational age relationships in multifetal gestations. (From McKeown and Record, 1952, with permission.)

Uterine Fundal Height

Carefully performed serial fundal height measurements are a simple, safe, inexpensive, and reasonably accurate *screening* method to detect SGA fetuses (Gardosi and Francis, 1999). As a screening tool, its principal drawback is imprecision (Jelks and colleagues, 2007). For example, Jensen and Larsen (1991) and Walraven and co-workers (1995) found that this method helped to correctly identify only 40 percent of such infants. Thus, SGA fetuses were both overlooked and overdiagnosed. Despite this, these results do not diminish the importance of carefully performed fundal measurements as a simple screening technique.

Technique. The method used by most for fundal height measurement was described by Jimenez and colleagues (1983). Briefly, a tape calibrated in centimeters is applied over the abdominal curvature from the upper edge of the symphysis to the upper edge of the uterine fundus, which is identified by palpation or percussion. The tape is applied with the markings apposed to the maternal abdomen and away from the examiner's view to avoid bias. Between 18 and 30 weeks, the uterine fundal height in centimeters coincides within 2 weeks of gestational age. Thus, if the measurement is more than 2 to 3 cm from the expected height, inappropriate fetal growth may be suspected.

Sonographic Measurements

Central to the debate over whether all pregnancies should routinely undergo sonographic evaluation is the potential for diagnosis of growth restriction (Ewigman and colleagues, 1993). Typically, such routine screening incorporates an initial sonographic examination at 16 to 20 weeks to establish gestational age and identify anomalies. This is repeated at 32 to 34 weeks to evaluate fetal growth (see Chap. 16, p. 352). Ironically, Gardosi and Geirsson (1998) found that accurate gestational dating at the initial examination resulted in a lower diagnosis rate of fetal-growth restriction. In a study of 8313 pregnancies, Verburg and co-workers (2008) found that sonography prior to 24 weeks—optimally at 10 to 12 weeks—provides a better prediction of gestational age than the last menstrual period.

With sonography, the most common method for establishing the diagnosis of fetal-growth restriction is the estimation of fetal weight using multiple fetal biometric measurements. Combining head, abdomen, and femur dimensions has been

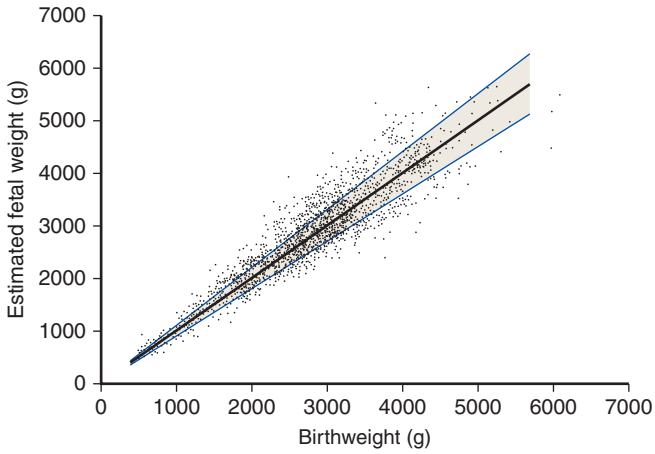

FIGURE 38-5 Correlation of sonographic fetal weight estimation using abdominal circumference (AC) with actual birthweight. (Data courtesy of Dr. Don McIntire.)

shown to optimize accuracy with little incremental improvement by addition of other biometric measurements (Platz and Newman, 2008). These are considered separately:

1. Femur length (FL) measurement is technically the easiest and the most reproducible
2. Biparietal diameter (BPD) and head circumference (HC) measurements are dependent on the plane of section and may also be affected by deformative pressures on the skull
3. Abdominal circumference (AC) measurement is more variable, but it is most commonly abnormal in cases of fetal-growth restriction because mostly soft tissue is involved (**Fig. 38-5**).

An abdominal circumference within the normal range for gestational age reliably excludes growth restriction, whereas a measurement less than the 5th percentile is highly suggestive of growth restriction (American College of Obstetricians and Gynecologists, 2000b). And as shown in **Figure 38-6**, such small circumferences are linked to decreased fetal pO_2 and pH.

Despite its accuracy, sonography used for detection of fetal-growth restriction has false-negative findings. Dashe and colleagues (2000) studied 8400 live births at Parkland Hospital in which fetal sonographic evaluation had been performed within 4 weeks of delivery. They reported that 30 percent of growth-restricted fetuses were not detected. In a study of 1000 high-risk fetuses, Larsen and associates (1992) performed serial sonographic examinations beginning at 28 weeks and then every 3 weeks. Reporting results to clinicians significantly increased the diagnosis of SGA fetuses. And although elective deliveries in this group were increased, there was no overall improvement in neonatal outcome.

Amnionic Fluid Measurement. An association between pathological fetal-growth restriction and oligohydramnios has long been recognized (see Chap. 21, p. 495). Chauhan and coworkers (2007) found oligohydramnios in less than 10 percent of pregnancies suspected of growth restriction, but this group of women was two times more likely to undergo cesarean delivery for nonreassuring fetal heart rate patterns. As shown in **Figure 38-7**, the smaller the pocket of amnionic fluid, the greater the perinatal mortality rate. One likely explanation for oligohydramnios is diminished fetal urine production caused by hypoxia and diminished renal blood flow (Nicolaides and associates, 1990).

Doppler Velocimetry

Abnormal umbilical artery Doppler velocimetry—characterized by absent or reversed end-diastolic flow—has been uniquely

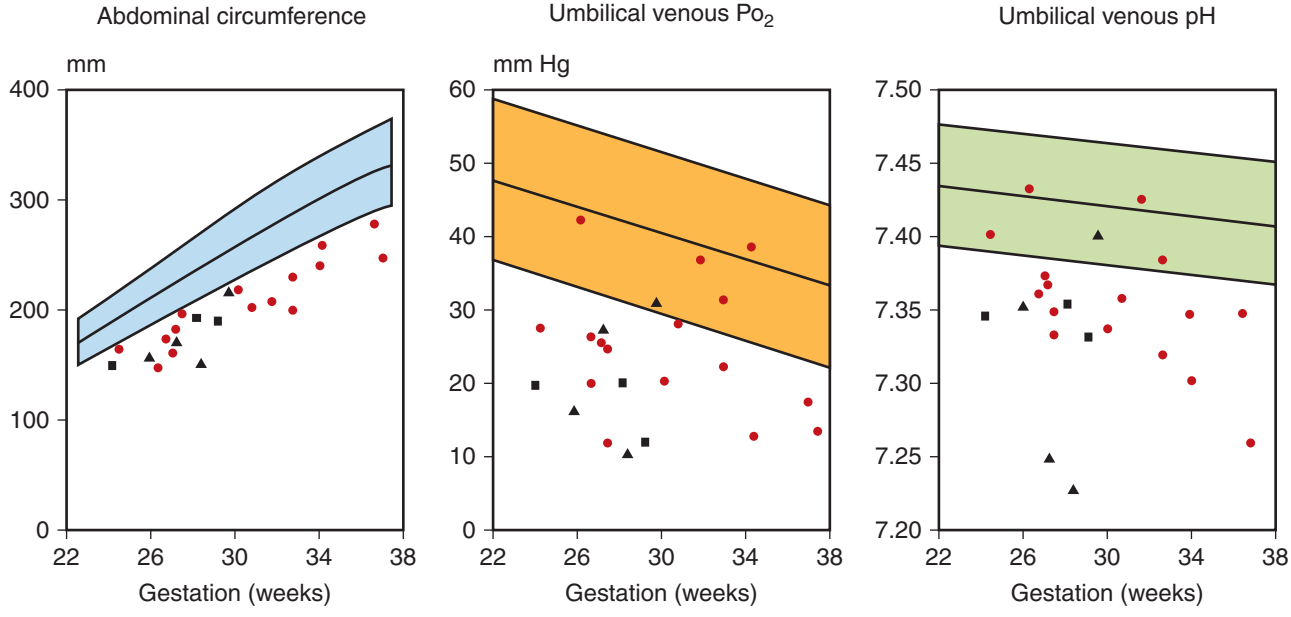

FIGURE 38-6 Abdominal circumference and umbilical venous blood pO_2 and pH in growth-restricted fetuses (red circles = liveborns; black triangles = fetal deaths; black squares = neonatal deaths). The lines within and bordering the shaded areas are the mean and the 5th and 95th percentiles, respectively, for gestational age. (From Hecher and colleagues, 1995, with permission.)

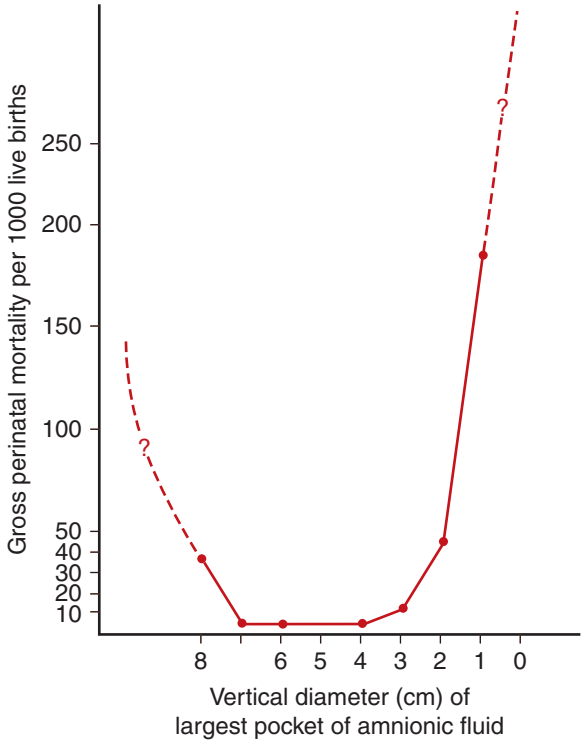

FIGURE 38-7 Relationship of amnionic fluid volume, as determined by the largest vertical pocket, to perinatal mortality rates. Mortality rates rise significantly when the largest pocket of fluid falls below 2 cm. (Data from Manning, 1995.)

associated with fetal-growth restriction (see Chap. 16, p. 363). The use of Doppler velocimetry in the management of fetal-growth restriction has been recommended as a possible adjunct to techniques such as nonstress testing or biophysical profile (American College of Obstetricians and Gynecologists, 2000b). Abnormalities in Doppler flow characterize early versus severe fetal-growth restriction and represent the transition from fetal adaptation to failure. Early changes in placenta-based growth restriction are detected in peripheral vessels such as the umbilical and middle cerebral arteries. Late changes are characterized by abnormal flow in the ductus venosus and aortic and pulmonary outflow tracts, as well as by reversal of umbilical artery flow (Pardi and Cetin, 2006). An example of this is shown in **Figure 38-8**.

In a series of 604 neonates < 33 weeks who had an abdominal circumference < 5th percentile, Baschat and colleagues (2007) found that the ductus venosus Doppler parameters were the primary cardiovascular factor in predicting neonatal outcome. These late changes are felt to reflect myocardial deterioration and acidemia, which are major contributors to adverse perinatal and neurological outcome. In their longitudinal evaluation of 46 growth-restricted fetuses, Figueras and colleagues (2009) determined that Doppler flow abnormalities at the aortic isthmus preceded those in the ductus venosus by one week. Similarly, Towers and co-workers (2008) prospectively observed 104 fetuses with abdominal circumference < 5th percentile. They broadly identified two patterns of progression of Doppler abnormalities: (1) *mild placental dysfunction*, which remained

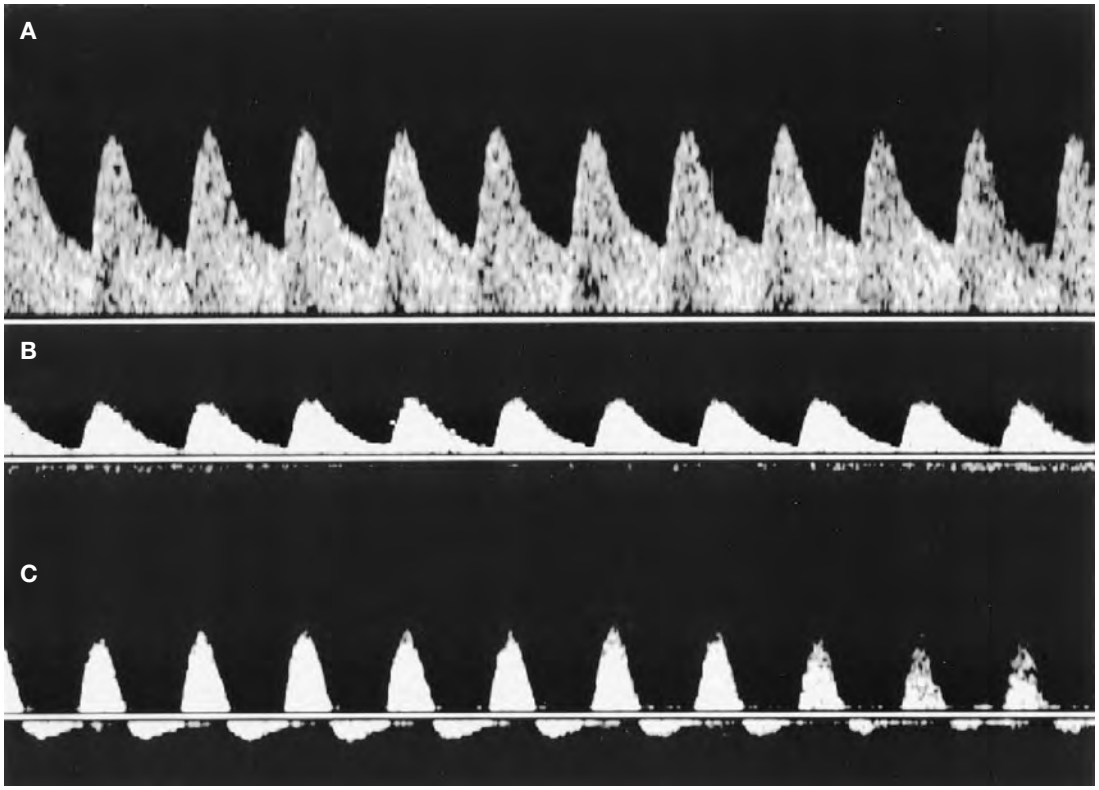

FIGURE 38-8 Umbilical arterial Doppler velocimetry studies, ranging from normal to markedly abnormal. **A.** Normal velocimetry pattern with a systolic to diastolic (S/D) ratio of < 30. **B.** The diastolic velocity approaching zero reflects increased placental vascular resistance. **C.** During diastole, arterial flow is reversed (negative S/D ratio), which is an ominous sign that may precede fetal demise.

confined to umbilical and middle cerebral arteries, and (2) *progressive placental dysfunction,* which progressed from peripheral vessels to the ductus venosus at variable intervals depending on gestational age. Both groups of investigators stressed that knowledge of these patterns of progression is critical for planning subsequent fetal surveillance and timing of delivery.

Prevention

Prevention of fetal-growth restriction ideally begins preconceptionally with optimization of maternal medical conditions, medications, and nutrition as discussed throughout Chapter 7. Smoking cessation is critical. Other risk factors should be tailored to the maternal condition, such as antimalarial prophylaxis for women living in endemic areas and correction of nutritional deficiencies. Studies have shown that treatment of mild to moderate hypertension does not reduce the incidence of SGA infants (see Chap. 45, p. 988).

During early pregnancy, accurate pregnancy dating is essential. In pregnancies at risk for fetal-growth restriction, for example, those in women with hypertension or prior fetal-growth restriction, prophylaxis with low-dose aspirin beginning early in gestation has been shown to reduce growth restriction by only 10 percent (Berghella, 2007).

Management

Once fetal-growth restriction is suspected, efforts should be made to confirm the diagnosis, assess fetal condition, and evaluate for anomalies. Growth restriction near term is easier to manage but often missed. As aptly stated by Miller and associates (2008), although growth restriction before 34 weeks is readily recognized, it presents a management challenge. Cordocentesis allows rapid karyotyping for detection of a lethal aneuploidy, which may simplify management. The American College of Obstetricians and Gynecologists (2000b) has concluded that there are not enough data to warrant routine cord blood sampling in this situation. The timing of delivery is crucial, and the risks of fetal death versus the hazards of preterm delivery must be assessed as reported in the Growth Restriction Intervention Trial (GRIT) by Thornton and colleagues (2004).

Growth Restriction Near Term

Prompt delivery is likely best for the fetus at or near term who is considered growth restricted. In fact, most clinicians recommend delivery at 34 weeks or beyond if there is clinically significant oligohydramnios. With a reassuring fetal heart rate pattern, vaginal delivery may be attempted. Some of these fetuses do not tolerate labor, and cesarean delivery is necessary.

Uncertainty about the diagnosis should preclude intervention until fetal lung maturity is assured. Expectant management can be guided using antepartum fetal surveillance techniques described in Chapter 15.

Growth Restriction Remote from Term

When growth restriction is identified in an anatomically normal fetus prior to 34 weeks, and amnionic fluid volume and fetal surveillance are normal, observation is recommended. Screening for toxoplasmosis, rubella, cytomegalovirus, herpes, and other infections is recommended by some, however, we have not found this to be productive.

As long as fetal growth continues and fetal health remains normal, pregnancy is allowed to continue until fetal maturity is reached. In some cases, amniocentesis may be helpful to assess pulmonary maturity. Although the development of oligohydramnios is highly suggestive of fetal-growth failure, it is important to recognize that normal amnionic fluid volume does not preclude growth restriction. Owen and colleagues (2001) reported that 4- and 6-week evaluation intervals were superior to 2-week intervals for predicting growth restriction. Depending on the gestational age when fetal-growth restriction is first suspected, this interval may be impractical clinically, and sonography is usually repeated more frequently.

With growth restriction remote from term, no specific treatment ameliorates the condition. For example, there is no evidence that bed rest results in accelerated growth or improved outcome. Despite this, many clinicians intuitively advise a program of modified rest. Nutrient supplementation, attempts at plasma volume expansion, oxygen therapy, antihypertensive drugs, heparin, and aspirin have all been shown to be ineffective (American College of Obstetricians and Gynecologists, 2000b).

In most cases diagnosed prior to term, neither a precise etiology nor a specific therapy is apparent. Management decisions hinge on an assessment of the relative risks of fetal death with expectant management versus the risks from preterm delivery. Although reassuring fetal testing may allow observation with continued maturation, there is concern regarding long-term neurological outcome as discussed later (Blair and Stanley, 1992; Thornton and colleagues, 2004).

Some authorities believe that various tests of fetal well-being are unnecessary to reduce risks for stillbirth. Weiner and associates (1996) performed nonstress tests, biophysical profiles, and umbilical artery velocimetry within 3 days of delivery in 135 fetuses confirmed at birth to have growth restriction. Other than metabolic acidosis at delivery, which was predicted by absent or reversed end-diastolic umbilical blood flow, morbidity and mortality were determined primarily by gestational age and birthweight and not by abnormal fetal testing. According to the American College of Obstetricians and Gynecologists (2000a), there is no convincing evidence that such testing schemes reduce the risk of long-term neurological deficits. And recently, Baschat and colleagues (2009) provided data that substantiated this opinion. Specifically, they showed that neurodevelopmental outcome at 2 years in growth-restricted fetuses was best predicted by birthweight and gestational age.

A review of the status of Doppler velocimetry to aid in delivery timing was provided by Baschat (2004). It is clear that serial changes in Doppler flow represent a new and promising frontier in the management of pregnancies complicated by growth restriction. *Nonetheless, the optimal management of the preterm growth-restricted fetus remains problematic.*

Labor and Delivery

Fetal-growth restriction is commonly the result of placental insufficiency due to faulty maternal perfusion, ablation of functional

placenta, or both. If present, these conditions are likely aggravated by labor. Equally important, diminished amnionic fluid volume increases the likelihood of cord compression during labor. For these reasons, a woman with a suspected growth-restricted fetus should undergo "high-risk" intrapartum monitoring (see Chap. 18, p. 436). For these and other reasons, the incidence of cesarean delivery is increased.

The risk of being born hypoxic or with aspirated meconium is increased. Care for the newborn should be provided immediately by an attendant who can skillfully clear the airway and ventilate the infant as needed (see Chap. 28, p. 591). The severely growth-restricted newborn is particularly susceptible to hypothermia and may also develop other metabolic derangements such as hypoglycemia, polycythemia, and hyperviscosity. In addition, low-birthweight infants are at increased risk for motor and other neurological disabilities. Risk is highest at the lowest extremes of birthweight (Baschat and colleagues, 2007, 2009; Nelson and Grether, 1997).

Long-Term Sequelae

In his book *Fetal and Infant Origins of Adult Disease,* Barker (1992) hypothesizes that adult mortality and morbidity are related to fetal and infant health. In the context of fetal-growth restriction, there are numerous reports of a relationship between suboptimal fetal nutrition and an increased risk of subsequent adult hypertension and atherosclerosis (Skilton, 2008). Low birthweight has also been implicated in subsequent development of type 2 diabetes, however, some challenge this hypothesis (Hubinette and colleagues, 2001; Huxley and co-workers, 2002). In their systematic review of 30 reports they considered relevant, Whincup and associates (2008) found that in most populations, birthweight was inversely related to type 2 diabetes risk.

Smith and colleagues (2001) found that pregnancy complications resulting in low-birthweight infants were associated with increased risk of subsequent ischemic heart disease in the mother. This suggests that common genetic risk factors might explain the link between low birthweight and risk of heart disease in both the developing fetus and the mother. In addition to risk to long-term maternal health, epidemiological studies have found that delivery of a small-for-gestational age infant increases the risk for a subsequent pregnancy complicated by stillbirth (Salihu and associates, 2006; Surkan and co-workers, 2004).

MACROSOMIA

The term *macrosomia* is used rather imprecisely to describe a very large fetus or neonate. Although there is general agreement among obstetricians that newborns weighing < 4000 g are not excessively large, a similar consensus has not been reached for the definition of macrosomia.

Newborn weight rarely exceeds 11 pounds (5000 g), and excessively large infants are a curiosity. The birth of a 16lb (7300 g) infant in the United States in 1979 was widely publicized. The largest newborn cited in the *Guinness Book of World Records* was a 23lb 12-oz (10,800 g) infant boy born to a Canadian woman, Anna Bates, in 1879 (Barnes, 1957). In the United States in 2006, of more than 4 million births, 6.7 percent weighed 4000 to 4499 g; 1 percent weighed 4500 to 4999 g; and 0.1 percent were born weighing 5000 g or more (Martin and colleagues, 2009). To be sure, the incidence of excessively large infants increased during the 20th century. According to Williams (1903), at the beginning of the 20th century, the incidence of birthweight > 5000 g was 1 to 2 per 10,000 births. This compares with 15 per 10,000 at Parkland Hospital from 1988 through 2002 and 11 per 10,000 in the United States in 2005.

The influence of increasing maternal obesity is overwhelming. The Parkland mothers with infants born weighing > 5000 g had a mean BMI of 37.8 kg/cm^2, and 20 percent were diabetic. Henriksen (2008) searched the Cochrane Database and reported that the rapid increase in prevalence of large infants was due to maternal obesity and type 2 diabetes. Importantly however, review of national vital statistics from the National Center for Health Statistics (2009a, b) indicates that the rate of birthweight ≥ 4000 g has steadily declined since 1994 from 10.4 percent to less than 9 percent in 2003. This is discussed further in Chapters 43 (p. 952) and 52 (p. 1109).

Definition

As noted, there are no precise definitions of macrosomia on which all authorities agree. Thus, there are several definitions in general clinical use. A common scheme includes use of empirical birthweights. In another, macrosomia is viewed as those weights that exceed certain percentiles for populations.

Birthweight Distribution

Commonly, macrosomia is defined based on mathematical distributions of birthweight. Those infants exceeding the 90th percentile for a given gestational week are usually used as the threshold for macrosomia. For example, the 90th percentile at 39 weeks is 4000 g. If, however, birthweights 2 standard deviations above the mean are used, then thresholds lie at the 97th and 99th percentile. Thus, substantially larger infants are considered macrosomic compared with those at the 90th percentile. Specifically, the birthweight threshold at 39 weeks would be approximately 4500 g for the 97th percentile rather than 4000 g for the 90th percentile.

Empirical Birthweight

Newborn weight exceeding 4000 g—8 lb 13 oz—is a frequently used threshold to define macrosomia. Others use 4250 g or even 4500 g—10 lb. As shown in Table 38-2, birthweights of 4500 g or more are uncommon. During a 10-year period at Parkland Hospital, during which there were more than 171,000 singleton births, only 1.5 percent of newborns weighed 4500 g or more. We are of the view that the upper limit of fetal growth, above which growth can be deemed abnormal, is likely two standard deviations above the mean, representing perhaps 3 percent of births. At 40 weeks such a threshold would correspond to approximately 4500 g. This definition of excessive growth is clearly more restrictive than using the upper 10 percent to define macrosomia. The American College of Obstetricians and Gynecologists (2000a) concluded that the term

TABLE 38-2. Birthweight Distribution of 171,755 Liveborn Infants at Parkland Hospital between 1998 and 2008

	Births		Maternal Diabetes
Birthweight (g)	Number	Percent	Percent
500–3999	154,906	90.2	5
4000–4249	9897	5.8	6
4250–4499	4349	2.5	7
4500–4649	1693	1.0	9
4750–4999	606	0.4	12
5000–5249	202	0.1	12
5250–5499	71	.0	25
5500–5749	22	.0	23
5750–5999	7	.0	0
6000–6249	1	.0	0
6250–6499	0	.0	—
6500 or more	1	.0	0
Total	171,755		5.4

macrosomia was an appropriate designation for fetuses who weigh 4500 g or more at birth.

Risk Factors

A number of factors associated with fetal macrosomia are listed in Table 38-3. Some of these are interrelated, and in many cases they are additive. For example, advancing age is usually related to multiparity and diabetes. Obesity is obviously related to diabetes. And among women who are simultaneously diabetic, obese, and postterm, the incidence of fetal macrosomia ranges from 5 to 15 percent (Arias, 1987; Catalano 2007; Chervenak, 1992). Maternal diabetes is an important risk factor for development of fetal macrosomia (see Chap. 52, p. 1109). As shown in Table 38-2, the incidence of maternal diabetes increases as birthweight > 4000 g increases. It should be emphasized, however, that maternal diabetes is associated with only a small percentage of such large infants.

Racial and ethnic factors

Diagnosis

Because there are no current methods to estimate excessive fetal size accurately, the diagnosis of macrosomia cannot be definitively made until delivery. Inaccuracy in clinical estimates of fetal weight by physical examination is often attributable, at least in part, to maternal obesity. Numerous attempts have been made to improve the accuracy of sonographic fetal weight estimations. A number of formulas have been proposed to estimate fetal weight using measurements of the head, femur, and abdomen. The estimates provided by these computations, although reasonably accurate for predicting the weight of small, preterm fetuses, are less valid in predicting the weight of large fetuses. For example, as shown in Figure 38-9, an infant predicted to weigh 4000 g can actually weigh considerably more or less than predicted. Rouse and associates (1996) reviewed 13 studies completed between 1985 and 1995 to assess the accuracy of sonographic prediction of macrosomic fetuses. They found only fair sensitivity—60 percent—in the accurate diagnosis of macrosomia but higher specificity—90 percent—in excluding excessive fetal size.

We can only conclude that the estimation of fetal weight from sonographic measurements is not reliable. Certainly, its routine use to identify macrosomia cannot be recommended. Indeed, the findings of several studies are indicative that clinical estimates of fetal weight are as reliable as, or even superior to, those made from sonographic measurements (O'Reilly-Green and Divon, 2000; Sherman and colleagues, 1998).

Controversies

"Prophylactic" Labor Induction

Some clinicians have proposed labor induction when fetal macrosomia is diagnosed in nondiabetic women. This approach

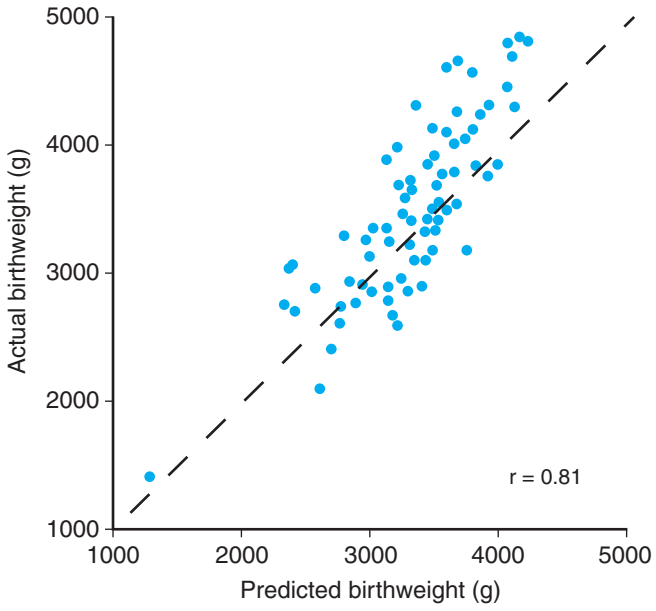

FIGURE 38-9. Relationship between actual birthweight and that predicted from sonographic measurement of abdominal circumference within 7 days of delivery. (From Johnstone and colleagues, 1996, with permission.)

is suggested to obviate further fetal growth and thereby reduce potential delivery complications. Such prophylactic induction should theoretically reduce the risk of shoulder dystocia and cesarean delivery. Gonen and colleagues (1997) randomized 273 nondiabetic women with sonographic fetal weight estimates of 4000 to 4500 g to either induction or expectant management. Labor induction did not decrease the rate of cesarean delivery or shoulder dystocia. Similar results were reported by Leaphart and associates (1997), who also found that induction unnecessarily increased the rate of cesarean delivery. In their systematic review of 11 studies of expectant management versus labor induction for suspected macrosomia, Sanchez-Ramos and colleagues (2002) found that labor induction results in increased cesarean delivery rates without improved perinatal outcomes. We agree with the American College of Obstetricians and Gynecologists (2000a) that current evidence does not support a policy for early induction for suspected macrosomia.

Elective Cesarean Delivery

Rouse and colleagues (1996, 1999) analyzed the potential effects of a policy of elective cesarean delivery for sonographically diagnosed fetal macrosomia compared with standard obstetrical management. They concluded that for women who are not diabetic, a policy of elective cesarean delivery was medically and economically unsound. Conversely, in *diabetic* women with macrosomic fetuses, such a policy of elective cesarean delivery was tenable. Conway and Langer (1998) described a protocol of routine cesarean delivery for sonographic estimates of 4250 g or greater in diabetic women. This management significantly reduced the rate of shoulder dystocia from 2.4 to 1.1 percent.

Prevention of Shoulder Dystocia

A major concern in the delivery of macrosomic infants is shoulder dystocia and attendant risks of permanent brachial plexus palsy. Such dystocia occurs when the maternal pelvis is of sufficient size to permit delivery of the fetal head but not large enough to allow delivery of the larger-diameter fetal shoulders. In this circumstance, the anterior shoulder becomes impacted against the maternal symphysis pubis (see Chap. 20, p. 481). Even with expert obstetrical assistance at delivery, stretching and injury of the brachial plexus may be inevitable (see Chap. 29, p. 636). According to the American College of Obstetricians and Gynecologists (1997), fewer than 10 percent of all shoulder dystocia cases result in a persistent brachial plexus injury.

Planned cesarean delivery on the basis of suspected macrosomia to prevent brachial plexopathy is an unreasonable strategy in the *general population* (Chauhan and colleagues, 2005). Ecker and co-workers (1997) analyzed 80 cases of brachial plexus injury in 77,616 consecutive infants born at Brigham and Women's Hospital. They concluded that an excessive number of otherwise unnecessary cesarean deliveries would be needed to prevent a single brachial plexus injury in infants born to women without diabetes. Conversely, planned cesarean delivery may be a reasonable strategy for diabetic women with an estimated fetal weight exceeding 4250 to 4500 g.

Fueled largely by infertility therapy, over the past 25 years, both the rate and the number of twin and higher-order multifetal births have increased in the United States at an unprecedented pace. Between 1980 and 2005, the twinning rate rose from 18.9 to 32.1 per 1000 live births (Martin and colleagues, 2009). Over the same time period, the number of live births from twin deliveries rose nearly 50 percent, and the number of higher-order multifetal births increased more than 400 percent (Fig. 39-1). However, as discussed later, changing infertility therapy has led to slight decreases in rates of higher-order multifetal births.

This extraordinary increase in multifetal births is a public health concern. The higher rate of preterm delivery of these neonates compromises their survival chances and increases their risk of lifelong disability. More than a fourth of very-low-birthweight (<1500 g) neonates born in the United States are the product of a multifetal gestation, as is one in every seven infants who die (Martin and colleagues, 2006; Mathews and MacDorman, 2006). Data comparing singleton and twin outcomes at Parkland Hospital are found in Table 39-1. Comparing twins with triplets or quadruplets, Luke and Brown (2008) found lower risks with twins for preterm prematurely ruptured membranes, preterm delivery, and perinatal mortality.

Multifetal gestations are at higher risk of fetal malformations, and also twin-twin transfusion syndrome may develop. Maternal complications are also increased. Walker and colleagues (2004) studied more than 44,000 multifetal gestations and found that, compared with singletons, risks for preeclampsia, postpartum hemorrhage, and maternal death were increased twofold or more. Wen and co-workers (2004) reported that these maternal risks correlated with fetal number. Francois and associates (2005) reported that compared with women who delivered singletons, those who delivered twins were three times as likely to undergo emergent peripartum hysterectomy, and those who delivered triplets or quadruplets were 24 times as likely. Maternal risks of multifetal gestation are not exclusively acute or physical. Choi and associates (2009) reported that at 9 months postpartum, mothers of multifetal births were almost 50 percent more likely to have moderate to severe depressive symptoms than mothers of singletons.

ETIOLOGY OF MULTIFETAL GESTATIONS

Twin fetuses usually result from fertilization of two separate ova–*dizygotic* or *fraternal twins*. Less often, twins arise from a single fertilized ovum that subsequently divides–*monozygotic* or *identical twins*. Either or both processes may be involved in the formation of higher numbers. Quadruplets, for example, may arise from as few as one to as many as four ova.

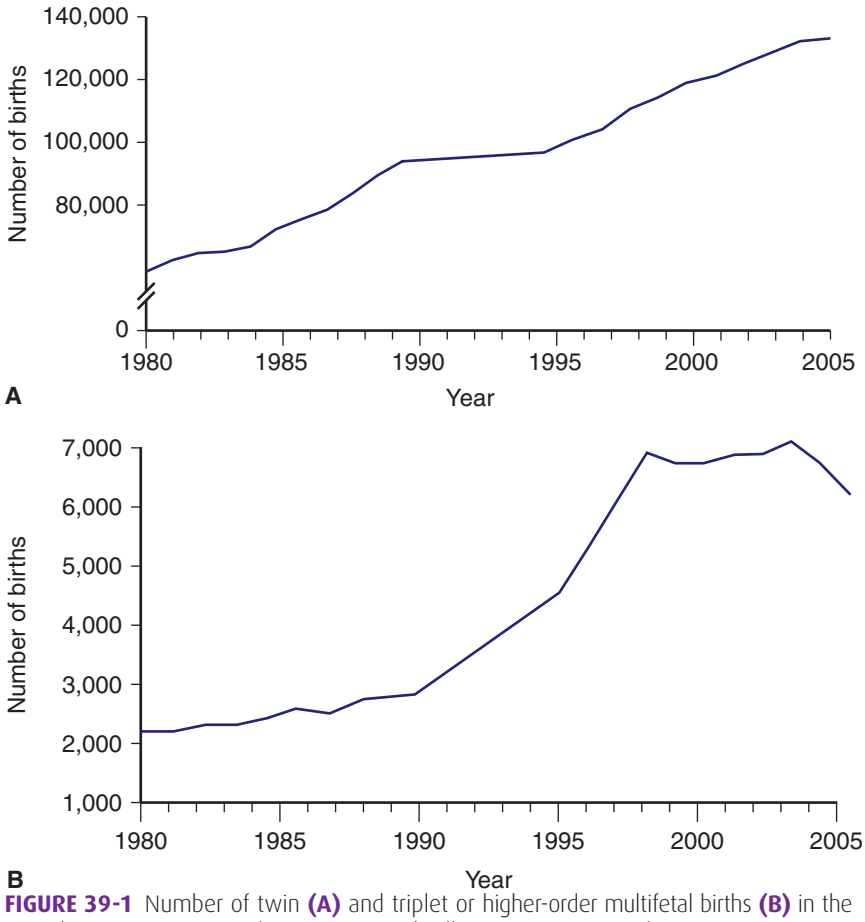

FIGURE 39-1 Number of twin **(A)** and triplet or higher-order multifetal births **(B)** in the United States, 1980-2005. (From Martin and colleagues, 1999, 2007.)

Fraternal versus Identical Twins

Dizygotic twins are not in a strict sense true twins because they result from the maturation and fertilization of two ova during a single ovulatory cycle. Also, monozygotic or identical twins are usually not identical. As discussed subsequently, the division of one fertilized zygote into two does not necessarily result in equal sharing of protoplasmic materials. Monozygotic twins may actually be discordant for genetic mutations as the result of a postzygotic mutation, or may have the same genetic disease but with marked variability in expression. In female fetuses, skewed lyonization can produce differential expression of X-linked traits or diseases. Furthermore, the process of monozygotic twinning is in a sense a teratogenic event, and monozygotic twins have an increased incidence of often discordant malformations (Glinianaia and co-workers, 2008). For example, Machin (1996) found that monozygotic twins may be discordant for malformations that involve asymmetrical organs such as the heart. For these reasons, dizygotic or fraternal twins of the same sex may appear more nearly identical at birth than monozygotic twins, and growth of monozygotic twin fetuses may be discordant, at times dramatically so. Accordingly, determination of zygosity frequently requires sophisticated genetic testing.

Genesis of Monozygotic Twins

The developmental mechanisms underlying monozygotic twinning are poorly understood. Minor trauma to the blastocyst during assisted reproductive technology (ART) may lead to the increased incidence of monozygotic twinning observed in pregnancies conceived in this manner (Wenstrom and co-workers, 1993).

The outcome of the monozygotic twinning process depends on when division occurs. If zygotes divide within the first 72 hours after fertilization, two embryos, two amnions, and two chorions develop, and a diamnionic, dichorionic twin pregnancy evolves (Fig. 39-2). Two distinct placentas or a single, fused placenta may develop. If division occurs between the fourth and eighth day, a diamnionic, monochorionic twin pregnancy results. By approximately 8 days after fertilization, the chorion and the amnion have already differentiated, and division results in two embryos within a common amnionic sac, that is, a monoamnionic, monochorionic twin pregnancy. Conjoined twins result if twinning is initiated later.

It has long been accepted that monochorionicity incontrovertibly indicated monozygosity. Rarely, however, monochorionic twins may in fact be dizygotic (Souter and colleagues,

TABLE 39-1. Selected Outcomes in Singleton and Twin Pregnancies Delivered at Parkland Hospital from 2002 through 2006

Outcome	Singletons	Twins
Pregnancies	78,879	850
Births[a]	78,879	1700
Stillbirths	406 (5.1)	24 (14.1)
Neonatal deaths	253 (3.2)	38 (22.4)

Very-low-birthweight (<1500 g)	895 (1.0)	196 (11.6)

[a]Birth data are represented as number (per 1000).

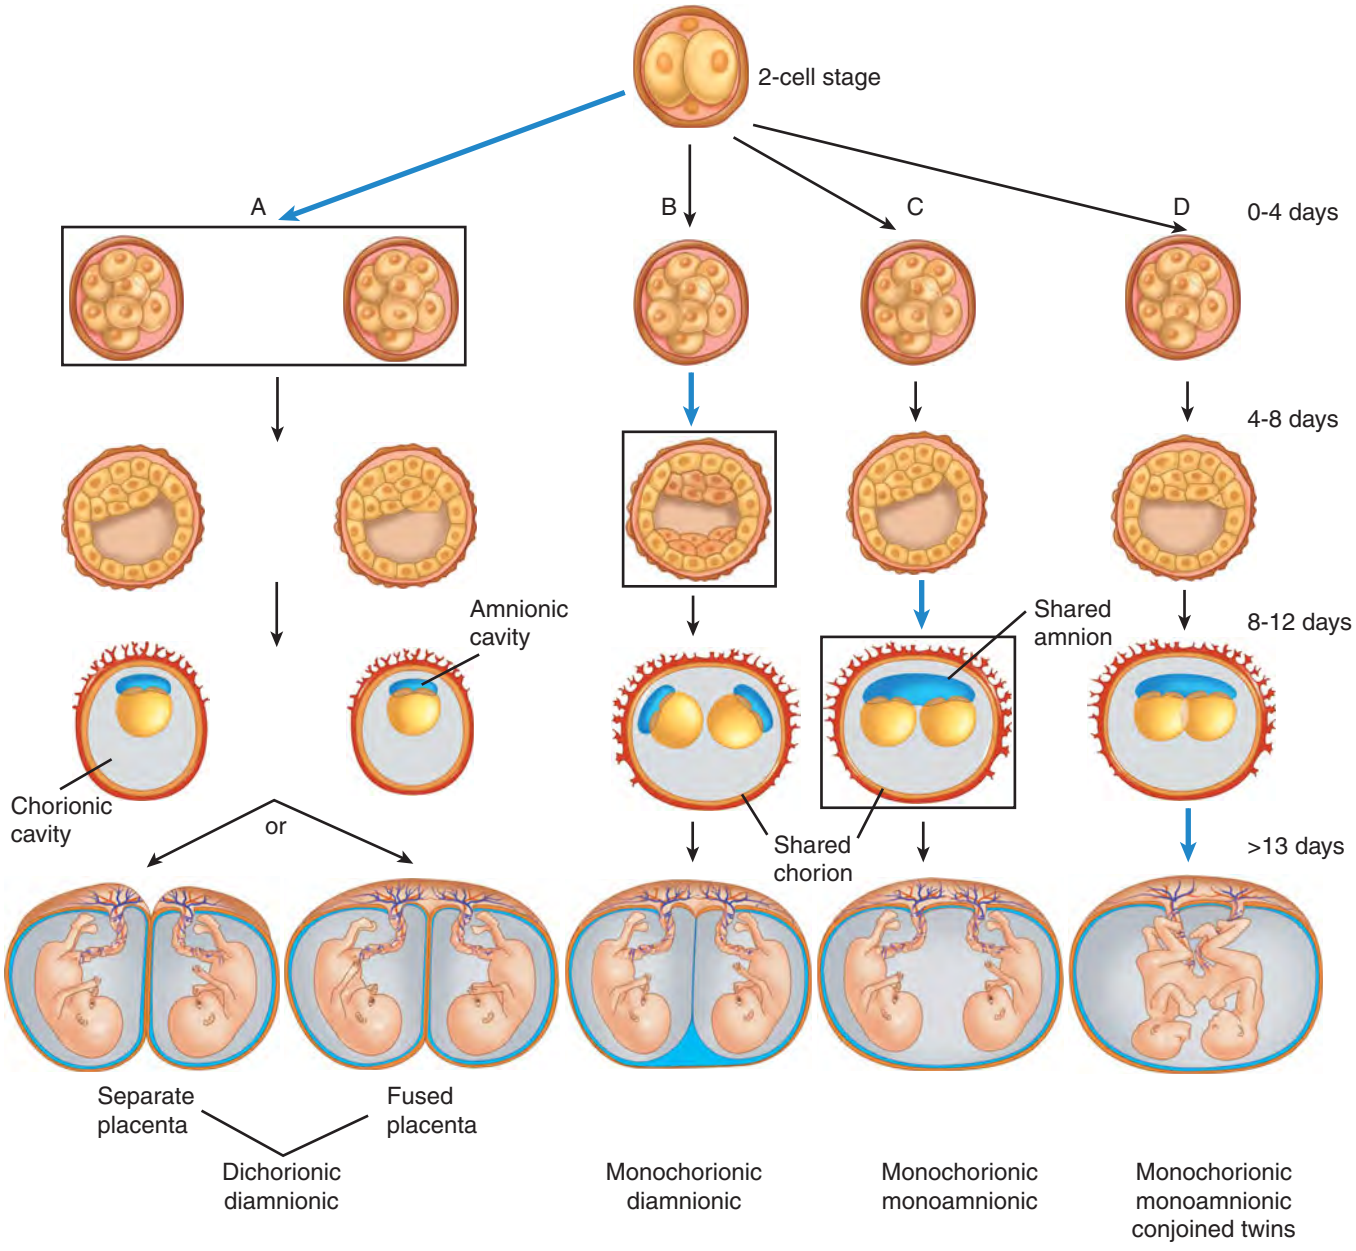

FIGURE 39-2 Mechanism of monozygotic twinning. Black boxing and blue arrows in columns A, B, and C indicates timing of division. **A.** At 0 to 4 days postfertilization, an early conceptus may divide into two. Division at this early stage creates two chorions and two amnions (dichorionic, diamnionic). Placentas may be separate or fused. **B.** Division between 4 to 8 days leads to formation of a blastocyst with two separate embryoblasts (inner cell masses). Each embryoblast will form its own amnion within a shared chorion (monochorionic, diamnionic). **C.** Between 8 and 12 days, the amnion and amnionic cavity form above the germinal disc. Embryonic division leads to two embryos with a shared amnion and shared chorion (monochorionic, monoamnionic). **D.** Differing theories explain conjoined twin development. One describes an incomplete splitting of one embryo into two. The other describes fusion of a portion of one embryo from a monozygotic pair onto the other.

2003). Mechanisms for this are speculative, and zygotic manipulations that accompany ART have been implicated (Redline, 2003).

Superfetation and Superfecundation

In *superfetation*, an interval as long as or longer than a menstrual cycle intervenes between fertilizations. Superfetation requires ovulation and fertilization during the course of an established pregnancy, which is theoretically possible until the uterine cavity is obliterated by fusion of the decidua capsularis to the decidua parietalis. Although known to occur in mares, superfetation is as yet unproven in humans. Most authorities believe that the alleged cases of human superfetation result from markedly unequal growth and development of twin fetuses with the same gestational age.

Superfecundation refers to fertilization of two ova within the same menstrual cycle but not at the same coitus, nor necessarily by sperm from the same male. An instance of superfecundation,

FIGURE 39-3 An example of dizygotic twin boys as the consequence of superfecundation. (Used with permission from Dr. David W. Harris.)

documented by Harris (1982), is demonstrated in **Figure 39-3**. The mother was sexually assaulted on the 10th day of her menstrual cycle and had intercourse 1 week later with her husband. She was delivered of a black neonate whose blood type was A and a white neonate whose blood type was O. The blood type of the mother and her husband was O.

Frequency of Twins

The frequency of monozygotic twin births is relatively constant worldwide—approximately one set per 250 births, and is largely independent of race, heredity, age, and parity. There is now evidence that the incidence of zygotic splitting is also increased following ART (Aston and colleagues, 2008). In contrast, the incidence of dizygotic twinning is influenced remarkably by race, heredity, maternal age, parity, and, especially, fertility treatment.

The "Vanishing Twin"

The incidence of twins in the first trimester is much greater than the incidence of twins at birth. Studies in which fetuses were evaluated with sonography in the first trimester have shown that one twin is lost or "vanishes" before the second trimester in up to 20 to 60 percent of spontaneous twin conceptions (Dickey, 2002; Kol, 1993; Landy, 1986; Parisi, 1983, and all their co-workers).

Monochorionic twins have a significantly greater risk of abortion than dichorionic twins (Sperling and colleagues, 2006). In some cases, the entire pregnancy aborts. In many cases, however, only one fetus dies, and the remaining fetus delivers as a singleton. Undoubtedly, some threatened abortions have resulted in death and resorption of one embryo from an unrecognized twin gestation, whereas the other embryo continued its growth and development (Jauniaux and co-workers, 1988).

Dickey and colleagues (2002) described spontaneous reduction in 709 women with a multifetal pregnancy. Prior to 12 weeks, one or more embryos died in 36 percent of twin pregnancies, 53 percent of triplet pregnancies, and 65 percent of quadruplet pregnancies. Interestingly, pregnancy duration and birthweight were inversely related to the initial gestational sac number regardless of the final number of fetuses at delivery. This effect was most pronounced in twins who started as quadruplets. Chasen and colleagues (2006) reported that spontaneous reduction of an in-vitro fertilization (IVF) twin pregnancy to a singleton pregnancy was associated with perinatal outcomes intermediate between IVF singleton pregnancies and IVF twin pregnancies that did not undergo spontaneous reduction.

A vanishing twin may cause an elevated maternal serum alpha-fetoprotein level, an elevated amnionic fluid alpha-fetoprotein level, and a positive amnionic fluid acetylcholinesterase assay result (Winsor and associates, 1987). Therefore, the diagnosis of vanishing twin should be excluded to avoid confusion during maternal serum screening for Down syndrome or neural-tube defects (see Chap. 13, p. 292). Similarly, a vanishing twin can cause a discrepancy between the karyotype established by chorionic villus sampling and the karyotype of a surviving twin when tissue from a vanished twin is inadvertently sampled. For these reasons, amniocentesis for karyotype may be preferable if a vanishing twin is suspected (Reddy and associates, 1991).

Factors That Influence Twinning

Race

The frequency of multifetal births varies significantly among different races and ethnic groups (**Table 39-2**). In one rural community in Nigeria, Knox and Morley (1960) found that twinning occurred once in every 20 births! These marked differences in twinning frequency may be the consequence of racial variations in levels of follicle-stimulating hormone (FSH) (Nylander, 1973).

Heredity

As a determinant of twinning, the family history of the mother is much more important than that of the father. In a study of 4000 genealogical records, White and Wyshak (1964) found that women who themselves were a dizygotic twin gave birth to twins at a rate of 1 set per 58 births. Women who were not a twin, but whose husbands were a dizygotic twin, gave birth to twins at a rate of 1 set per 116 pregnancies. Genetic studies are beginning to identify genes that increase the rate of dizygotic twinning. That said, the contribution of these variants to the overall incidence of twinning is likely small (Hoekstra and associates, 2008).

Maternal Age and Parity

The rate of natural twinning peaks at age 37 years, when maximal FSH stimulation increases the rate of multiple follicles developing (Beemsterboer and co-workers, 2006). The fall in incidence thereafter probably reflects physiological follicle depletion.

Increasing parity has also been shown to increase the incidence of twinning independently in all populations studied. In Sweden, Pettersson and associates (1976) determined that the frequency of multiple fetuses in first pregnancies was 1.3 percent, compared

with 2.7 percent in the fourth pregnancy. In Nigeria, Azubuike (1982) showed that the frequency of twinning increased from 1 in 50–2 percent–among nulliparous women to 1 in 15–6.6 percent–for women pregnant six or more times!

Nutritional Factors

In animals, litter size increases in proportion to nutritional sufficiency. Evidence from a variety of sources indicates that this occurs in humans as well. Nylander (1971) showed a definite increasing gradient in the twinning rate related to greater nutritional status as reflected by maternal size. Taller, heavier women had a twinning rate 25- to 30-percent greater than short, nutritionally deprived women. MacGillivray (1986) also found that dizygotic twinning is more common in large and tall women than in small women. Evidence acquired during and after World War II showed that twinning correlated more with nutrition than body size. Widespread undernourishment in Europe during those years was associated with a marked fall in the dizygotic twinning rate (Bulmer, 1959). Haggarty and associates (2006) reported that higher folate intake and plasma folate concentrations were associated with an increased rate of twinning in women undergoing IVF.

Pituitary Gonadotropin

The common factor linking race, age, weight, and fertility to multifetal gestation may be FSH levels (Benirschke and Kim, 1973). This theory is supported by the fact that increased fecundity and a higher rate of dizygotic twinning have been reported in women who conceive within 1 month after stopping oral contraceptives, but not during subsequent months (Rothman, 1977). This may be due to the sudden release of pituitary gonadotropin in amounts greater than usual during the first spontaneous cycle after stopping hormonal contraception.

Infertility Therapy

Ovulation induction with FSH plus chorionic gonadotropin or clomiphene citrate remarkably enhances the likelihood of multiple ovulations. The incidence of multifetal gestation following conventional gonadotropin therapy is 16 to 40 percent, of which 75 percent are twins (Schenker and co-workers, 1981). Tuppin and colleagues (1993) reported that in France, the incidence of twin and triplet deliveries and the sale of human menopausal gonadotropin (hMG) rose in parallel between 1972 and 1989. By 1989, half of triplet pregnancies resulted from ovulation induction. Superovulation therapy, which increases the chance of pregnancy by recruiting multiple follicles, results in multifetal gestation rates of 25 to 30 percent (Bailey-Pridham and associates, 1990).

Risk factors for multiple fetuses after ovarian stimulation with hMG include increased estradiol levels on the day of chorionic gonadotropin injection and sperm characteristics such as increased concentration and motility (Dickey and associates, 1992; Pasqualotto and colleagues, 1999). With recognition of these factors, plus the ability to monitor follicular growth and size sonographically, physicians may cancel cycles likely to lead to a multifetal gestation. This approach has reduced the incidence of multifetal births.

Assisted Reproductive Technology (ART)

These techniques are designed to increase the probability of pregnancy. But they also increase the probability of multifetal gestation. In general with IVF, the greater the number of embryos that are transferred, the greater the risk of twins and multiple fetuses. In 2005, 1 percent of infants born in the United States were conceived through ART, and these infants accounted for 17 percent of multiple births (Wright and colleagues, 2008).

Reducing Multifetal Gestation

The American Society for Reproductive Medicine (1999) initiated a concerted effort to reduce the incidence of higher-order multifetal gestation. By this time, some practitioners of ART had already begun to modify their practices to reduce the rate of multifetal gestations. In their review of IVF practices in the United States from 1995 to 2001, Jain and colleagues (2004) found that the number of embryos transferred per cycle decreased steadily *after* 1997, as did the percentage of pregnancies with three or more fetuses (see Fig. 39-1B). Paradoxically, there was a consistent increase in the percentage of live births per cycle. Improved ART techniques explain this paradox. For

TABLE 39-3. Overview of the Incidence of Twin Pregnancy Zygosity and Corresponding Twin-Specific Complications

	Rates of Twin-Specific Complication in Percent				
Type of Twinning	Twins	Fetal-Growth Restriction	Preterm Delivery[a]	Placental Vascular Anastomosis	Perinatal Mortality
Dizygous	80	25	40	0	10–12
Monozygous	20	40	50		15–18
Diamnionic/dichorionic	6–7	30	40	0	18–20

example, culturing embryos for 5 days to the blastocyst stage as opposed to culturing for 3 days results in improved live birth rates (Papanikolaou and associates, 2006).

Sex Ratios with Multiple Fetuses

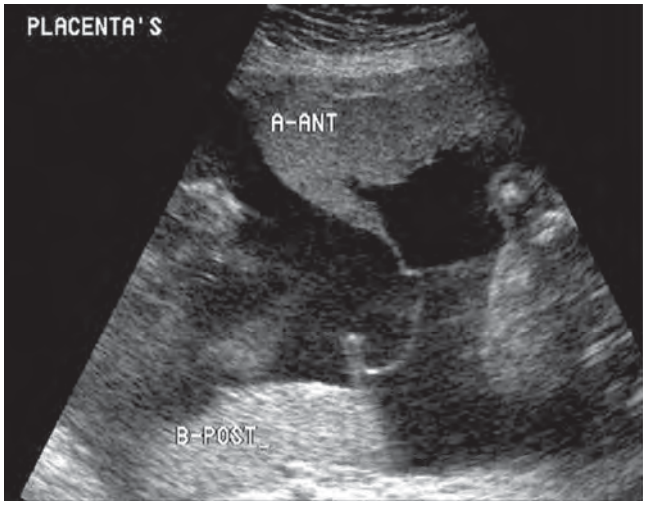
In humans, as the number of fetuses per pregnancy increases, the percentage of male conceptuses decreases. Strandskov and co-workers (1946) found the percentage of males in 31 million singleton births in the United States was 51.6 percent. For twins, it was 50.9 percent; for triplets, 49.5 percent; and for quadruplets, 46.5 percent. Females predominate even more in twins from late twinning events. For example, 70 percent of monochorionic–monoamnionic twins and 75 percent of conjoined twins are female (Machin, 1996). Two explanations have been offered. First, beginning in utero and extending throughout the life cycle, mortality rates are lower in females. Nutritional and space limitations associated with multiple fetuses in utero may exaggerate this biological tendency. Second, female zygotes have a greater tendency to divide.

Determination of Chorionicity

This determination can aid obstetrical risk assessment and guide management of multifetal gestation. The rate of twin-specific complications varies in relation to zygosity and chorionicity, with the latter being the more important determinant (Table 39-3). There are increased rates of perinatal mortality and neurological injury in monochorionic diamnionic twins compared with dichorionic pairs (Hack and co-workers, 2008; Lee and colleagues, 2008). In a study of 146 sets of twins in which zygosity and chorionicity were carefully assessed, monozygotic dichorionic twins had perinatal outcomes equivalent to those of dizygotic twins (Carroll and colleagues, 2005).

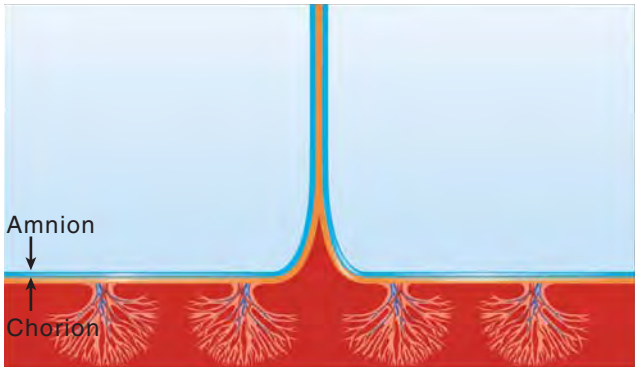
Sonographic Evaluation

Chorionicity can sometimes be determined sonographically in the first trimester. The presence of two separate placentas and a thick–generally 2 mm or greater–dividing membrane supports a presumed diagnosis of dichorionicity (Fig. 39-4). Fetuses of opposite gender are almost always dizygotic, thus dichorionic (Mahony and co-workers, 1985).



In pregnancies in which a single placental mass is identified, it may be difficult to distinguish one large placenta from two placentas lying side by side. Examining the point of origin of the dividing membrane on the placental surface may clarify this situation. If as shown in Figure 39-4, a triangular projection of placental tissue is seen to extend beyond the chorionic surface between the layers of the dividing membrane, then there are two fused placentas–the *twin-peak sign.*

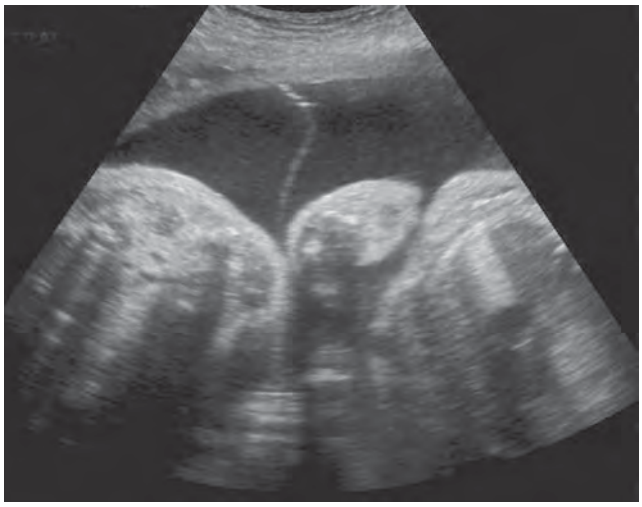
In contrast, monochorionic pregnancies have a dividing membrane that is so thin it may not be seen until the second trimester. The membrane is generally less than 2 mm thick, and magnification reveals only two layers (Scardo and associates, 1995). This right-angle relationship between the membranes and placenta with no apparent extension of placenta between the dividing membrane is called the *T sign* (Fig. 39-5). Sonographic evaluation of the dividing membrane is easiest and most accurate in the first half of pregnancy when fetuses are smaller (Stagiannis and colleagues, 1995).



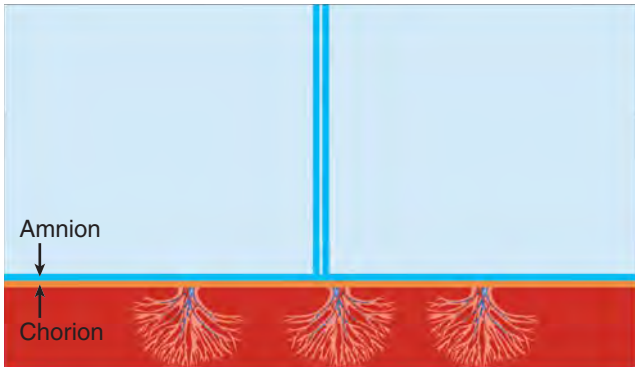
Lee and colleagues (2006) used the combination of placental location, presence or absence of the twin-peak sign, and fetal gender to determine chorionicity in 410 consecutive twins at midgestation. Compared with the pathological diagnosis determined by examining the placenta after delivery, the sonographic determination had 96-percent accuracy. They also reported improved sensitivity and specificity of sonography to determine chorionicity if performed during the first trimester compared with second-trimester imaging.

Placental Examination

A carefully performed visual examination of the placenta and membranes following delivery serves to establish zygosity and chorionicity promptly in approximately two thirds of cases. The following system for examination is recommended: As the first neonate is delivered, one clamp is placed on a portion of its



A



B

FIGURE 39-4 A. Sonographic image of the "twin-peak" sign, also termed the "lambda sign," in a 24-week gestation. At the top of this sonogram, tissue from the anterior placenta is seen extending downward between the amnion layers. This sign confirms dichorionic twinning. **B.** Schematic diagram of the "twin-peak" sign. A triangular portion of placenta is seen insinuating between the amniochorion layers.

A

B

FIGURE 39-5 A. Sonographic image of the "T" sign in a monochorionic diamnionic gestation at 30 weeks. **B.** Schematic diagram of the "T" sign. Twins are separated only by a membrane created by the juxtaposed amnion of each twin. A "T" is formed at the point at which amnions meet the placenta.

cord. Cord blood is not collected until after delivery of the other twin, unless it has been clearly shown prior to delivery that there are two placentas. As the second neonate is delivered, two clamps are placed on that cord. Three clamps are used to mark the cord of a third neonate, and so on as necessary. Until the delivery of the last fetus, each cord segment must remain clamped to prevent fetal hypovolemia and anemia caused by blood leaving the placenta via anastomoses and then through an unclamped cord.

The placenta should be carefully delivered to preserve the attachment of the amnion and chorion, because identification of the relationship of the membranes to each other is critical. With one common amnionic sac, or with juxtaposed amnions not separated by chorion arising between the fetuses, the fetuses are monozygotic. If adjacent amnions are separated by chorion, then the fetuses could be either dizygotic or monozygotic, but dizygosity is more common (see Figs. 39-2 and 39-6). If the neonates are of the same sex, blood typing of cord blood samples may be helpful. Different blood types confirm dizygosity, although demonstrating the same blood type in each fetus does not confirm monozygosity. For definitive diagnosis, more complicated techniques such as DNA fingerprinting can be used, but these tests are generally not performed at birth unless there is a pressing medical indication (St. Clair and associates, 1998).

Infant Sex and Zygosity

Twins of opposite sex are almost always dizygotic. Rarely, monozygotic twins may be discordant for phenotypic sex. This occurs if one twin is phenotypically female due to Turner syndrome (45,X) and her sibling is 46,XY.

DIAGNOSIS OF MULTIPLE FETUSES

History and Clinical Examination

A maternal personal or family history of twins, advanced maternal age, high parity, and large maternal size are weakly associated with multifetal gestation. Recent administration of either clomiphene citrate or gonadotropins or pregnancy accomplished by ART are much stronger associates.

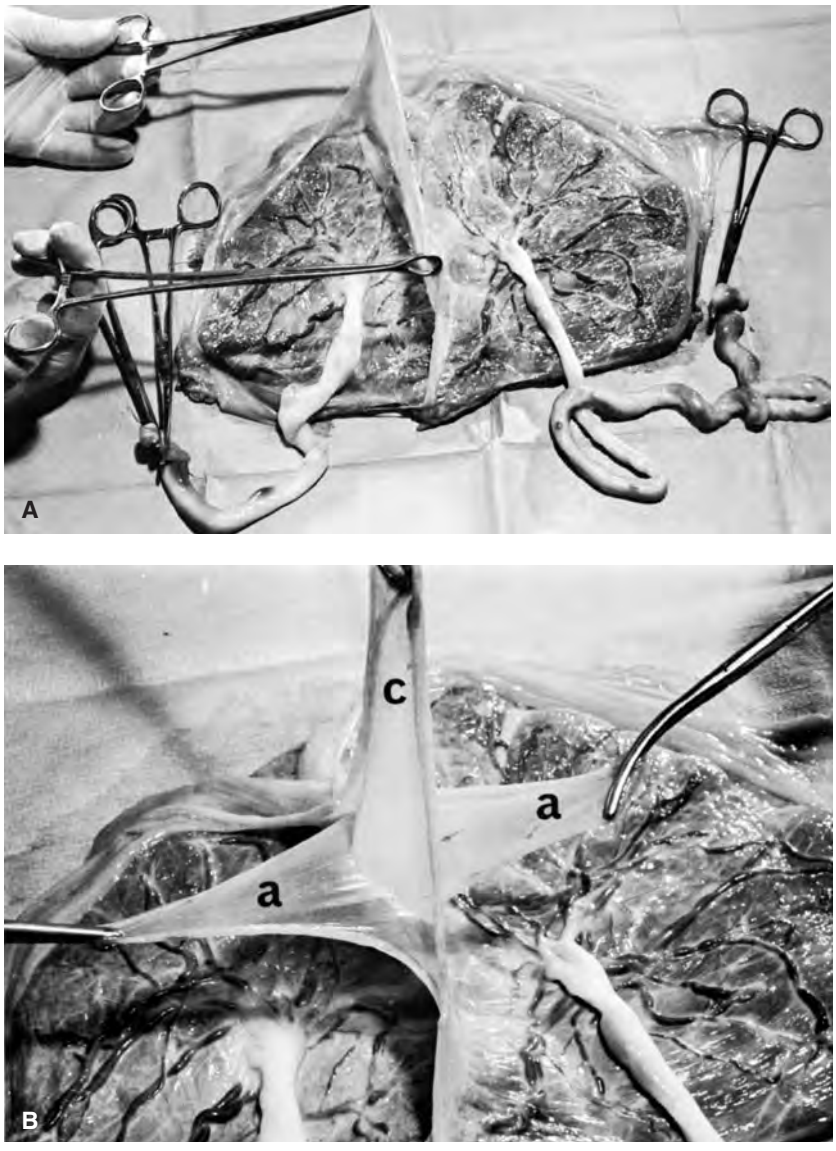


FIGURE 39-6 A. The membrane partition that separated twin fetuses is elevated. **B.** The membrane partition consists of chorion (**c**) between two amnions (**a**).

Clinical examination with accurate measurement of fundal height, as described in Chapter 8 (p. 199), is essential. With multiple fetuses, uterine size is typically larger during the second trimester than expected. Rouse and co-workers (1993) reported fundal heights in 336 well-dated twin pregnancies. Between 20 and 30 weeks, fundal heights were on average approximately 5 cm greater than expected for singletons of the same fetal age.

In women with a uterus that appears large for gestational age, the following possibilities are considered:

1. Multiple fetuses
2. Elevation of the uterus by a distended bladder
3. Inaccurate menstrual history
4. Hydramnios
5. Hydatidiform mole
6. Uterine leiomyomas
7. A closely attached adnexal mass
8. Fetal macrosomia (late in pregnancy)

In general, it is difficult to diagnose twins by palpation of fetal parts before the third trimester. Even late in pregnancy, it may be difficult to identify twins by abdominal palpation, especially if one twin overlies the other, if the woman is obese, or if there is hydramnios. If uterine palpation leads to the diagnosis of twins, it is most often because two fetal heads have been detected, often in different uterine quadrants.

Late in the first trimester, fetal heart action may be detected with Doppler ultrasonic equipment. Thereafter, it becomes possible to identify two fetal heartbeats if their rates are clearly distinct from each other and from that of the mother. Careful examination with an aural fetal stethoscope can identify fetal heart sounds in twins as early as 18 to 20 weeks.

Sonography

By careful sonographic examination, separate gestational sacs can be identified early in twin pregnancy (Fig. 39-7). Subsequently, each fetal head should be seen in two perpendicular planes so as not to mistake a cross section of the fetal trunk for a second fetal head. Ideally, two fetal heads or two abdomens should be seen in the same image plane, to avoid scanning the same fetus twice and interpreting it as twins. Sonographic examination should detect practically all sets of twins. Indeed, one argument in favor of sonographic screening is earlier detection of multiple fetuses (see Chap. 16, p. 350). In a large randomized trial, LeFevre and co-workers (1993) demonstrated that routine midgestation sonographic examinations detected 99 percent of multifetal gestations before 26 weeks, whereas if performed just for specific indications, only 62 percent were detected before this time. Higher-order multifetal gestations are more difficult to evaluate. Even in the first trimester, it can be difficult to determine the actual number of fetuses and their position, which is important for nonselective pregnancy reduction and essential for selective termination (see p. 884).

Other Diagnostic Aids

Radiological Examination

An x-ray of the maternal abdomen can be helpful if the number of fetuses in a higher-order multifetal gestation is uncertain. Radiographs, however, are generally not useful and may lead to an incorrect diagnosis if there is hydramnios, obesity, fetal movement during the exposure, or inappropriate exposure time. Additionally, fetal skeletons before 18 weeks' gestation are insufficiently radiopaque and may be poorly seen. Although not typically used to diagnose multifetal pregnancy, magnetic resonance (MR)

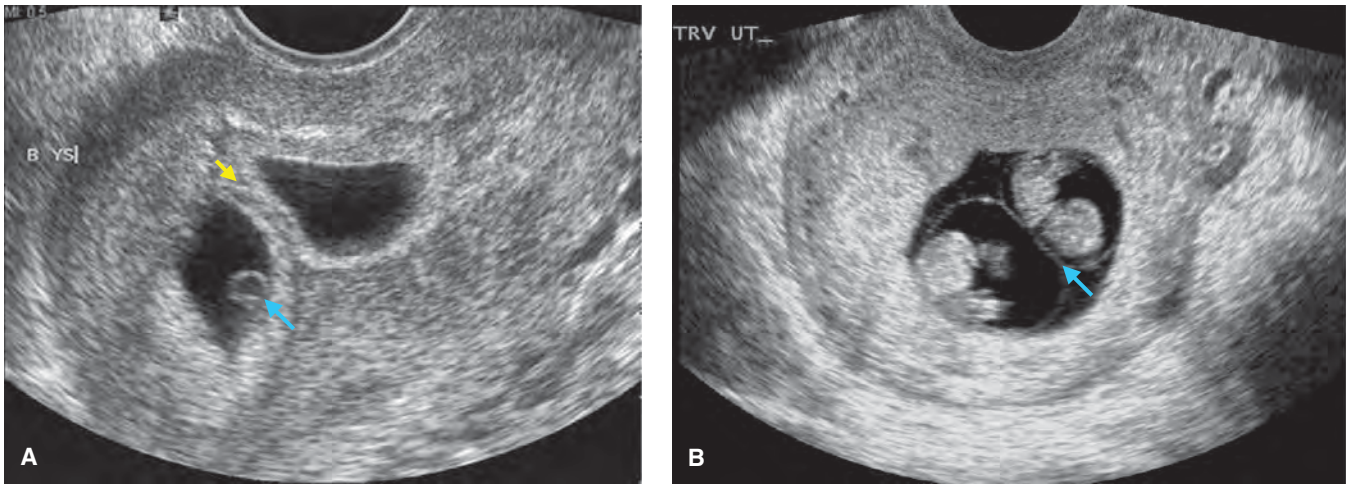

FIGURE 39-7 Sonograms of first-trimester twins. **A.** Dichorionic diamnionic twin pregnancy at 6 weeks' gestation. Note the thick dividing chorion (*yellow arrow*). One of the yolk sacs is indicated (*blue arrow*). **B.** Monochorionic diamnionic twin pregnancy at 8 weeks' gestation. Note the thin amnion encircling each embryo, resulting in a thin dividing membrane (*blue arrow*).

imaging may help delineate complications in monochorionic twins (Hu and associates, 2006).

Biochemical Tests

There is no biochemical test that reliably identifies multiple fetuses. Levels of human chorionic gonadotropin in plasma and in urine, on average, are higher than those found with a singleton pregnancy. These levels, however, are not so high as to allow a definite diagnosis. Twins are frequently diagnosed during evaluation for an elevated maternal serum alpha-fetoprotein level (see Chap. 13, p. 292).

MATERNAL ADAPTATION TO MULTIFETAL PREGNANCY

In general, the degree of maternal physiological change is greater with multiple fetuses than with a single fetus. Beginning in the first trimester, and temporarily associated with higher serum β-hCG levels, women with multifetal gestation often have nausea and vomiting in excess of women with a singleton pregnancy. Normal maternal blood volume expansion is greater (Pritchard, 1965). Whereas the average increase in late pregnancy is 40 to 50 percent with a single fetus, it is 50 to 60 percent with twins–an additional 500 mL. The red cell mass increases as well, but proportionately less in twin pregnancies than in singletons. Both the remarkable increase in maternal blood volume and the increased iron and folate requirements predispose to a greater prevalence of maternal anemia. Average blood loss with vaginal delivery of twins is 1000 mL, or twice that with a single fetus.

Kametas and associates (2003) used two-dimensional and M-mode echocardiography to assess cardiac function in 119 women with a twin pregnancy from 10 to 40 weeks. Cardiac output was increased 20 percent compared with that of women with a singleton pregnancy. This was predominantly due to greater stroke volume, and to a much lesser degree, increased heart rate. At the same time, pulmonary function tests do not differ between women with twins and those with singletons (McAuliffe and colleagues, 2002).

Women carrying twins also have a typical pattern of arterial blood pressure change. Compared with the diastolic blood pressure of mothers carrying singletons, theirs is lower at 20 weeks but increases more by delivery. The increase is at least 15 mm Hg in 95 percent of women carrying twins compared with only 54 percent of women pregnant with singleton pregnancies (Campbell, 1986).

Uterine growth in multifetal gestation is substantively greater than with singleton pregnancy. The uterus and its nonfetal contents may achieve a volume of 10 L or more and weigh in excess of 20 pounds! Especially with monozygotic twins, rapid accumulation of excessive amounts of amnionic fluid may develop. In these circumstances, maternal abdominal viscera and lungs may be appreciably compressed and displaced by the expanding uterus. As a result, the size and weight of the large uterus may preclude more than a sedentary existence for these women.

If hydramnios develops, maternal renal function may become seriously impaired, most likely as the consequence of obstructive uropathy. Quigley and Cruikshank (1977) described two women each carrying twins in whom acute and severe hydramnios led to maternal oliguria and azotemia. Maternal urine output and plasma creatinine levels promptly returned to normal after delivery. In severe hydramnios, therapeutic amniocentesis may be used to provide relief for the mother, to improve obstructive uropathy, and possibly to lower the risk of preterm delivery from preterm labor or prematurely ruptured membranes (see Chap. 21, p. 494). Unfortunately, hydramnios is often characterized by acute onset remote from term and by rapid reaccumulation following amniocentesis.

The various physiological burdens of pregnancy and the likelihood of serious maternal complications are almost invariably greater with multiple fetuses than with a singleton. This should be considered, especially when counseling a woman whose health is compromised and whose multifetal gestation is recognized early. The same is true for a woman who is not pregnant but is considering infertility treatment by ovulation induction or ART.

PREGNANCY OUTCOME

Abortion

Spontaneous abortion is more likely with multiple fetuses. Detailed reviews have identified three times more twins among aborted than among term pregnancies (Livingston and Poland, 1980; Uchida and co-workers, 1983). Monochorionic greatly outnumber dichorionic abortuses with an 18:1 ratio, thus implicating monozygosity as the risk factor.

Malformations

The incidence of congenital malformations is appreciably increased in multifetal gestations compared with singletons. These rates are not increased in twins conceived by ART compared with those spontaneously conceived (McDonald and associates, 2005). Major malformations develop in 2 percent and minor malformations in 4 percent of twins (Cameron and colleagues, 1983; Kohl and Casey, 1975). This increase is almost entirely due to the high incidence of structural defects in monozygotic twins. According to Schinzel and associates (1979), anomalies in monozygotic twins generally fall into one of three categories:

1. Defects resulting from twinning itself, a process that some consider to be a teratogenic event. This category includes conjoined twinning, acardiac anomaly, neural-tube defects, holoprosencephaly, and sirenomelia, which involves fusion of the lower extremities.
2. Defects resulting from vascular interchange between monochorionic twins. Vascular anastomoses can give rise to reverse flow with acardia in one twin (p. 872). Alternatively, if one twin dies and intravascular coagulation develops, emboli to the living twin may traverse these connections. These anastomoses may also transmit dramatic blood pressure fluctuations, causing defects such as microcephaly, hydranencephaly, intestinal atresia, aplasia cutis, or limb amputation.
3. Defects may develop from fetal crowding–examples include talipes equinovarus (clubfoot) or congenital hip dislocation. Dizygotic twins are also subject to these.

Baldwin (1991) comprehensively reviewed anomalies that develop in twins. Persistent hydramnios is associated with anomalies of one or both twins. Hashimoto and colleagues (1986) subjectively identified increased amnionic fluid in a fourth of 75 twin pregnancies. In nine pregnancies, hydramnios was transient, and all of these fetuses were normal. Conversely, there were fetal anomalies in nine of 10 pregnancies in which hydramnios persisted.

Birthweight

Multifetal gestations are more likely to be low birthweight than singleton pregnancies, due to restricted fetal growth and preterm delivery (Buekens and Wilcox, 1993). When more than 500,000 singleton neonates were compared with over 10,000 twin neonates, birthweights in twin infants closely paralleled those of singletons until 28 to 30 weeks. Thereafter, twin birthweights progressively lagged as shown in Figure 39-8. Beginning at 34 to

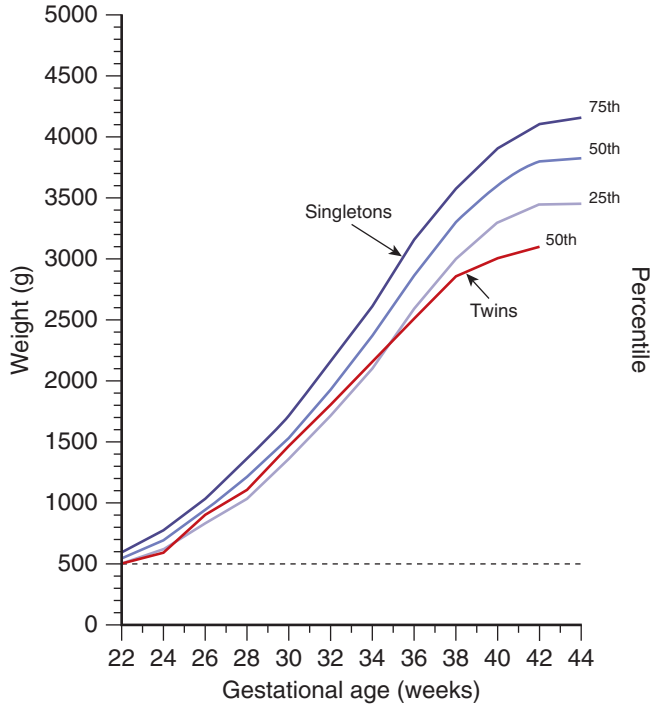

FIGURE 39-8 Birthweight percentiles (25 to 75) for singleton male newborns compared with the 50th birthweight percentile for twin males, Canada, 1986–1988. (Modified from Arbuckle TE, Wilkins R, and Sherman GJ: Birth weight percentiles by gestational age in Canada, *Obstetrics & Gynecology,* 1993, vol. 81, no. 1, pp. 39–48, with permission.)

35 weeks, twin birthweights clearly diverge from those of singletons. At 38 weeks or later, the incidence of overt growth restriction is quadrupled, and almost half of twins are affected.

In general, the more fetuses, the greater the degree of growth restriction. The caveat is that this assessment is based on growth curves established for singletons. Several authorities argue that fetal growth in twins is different from that of singleton pregnancies, and thus abnormal growth should be diagnosed only when fetal size is less than expected for *multifetal gestation.* Accordingly, twin and triplet growth curves have been developed (Ong and associates, 2002; Rodis and colleagues, 1999).

In the third trimester, the larger fetal mass leads to accelerated placental maturation and relative placental insufficiency. In dizygotic pregnancies, marked size discordancy usually results from unequal placentation, with one placental site receiving more perfusion than the other. Size differences may also reflect different genetic fetal-growth potentials. Discordancy can also result from fetal malformations, genetic syndromes, infection, or umbilical cord abnormalities such as velamentous insertion, marginal insertion, or vasa previa (see Chap. 27, p. 582).

The degree of growth restriction in monozygotic twins is likely to be greater than that in dizygotic pairs (Fig. 39-9). With monochorionic embryos, allocation of blastomeres may not be equal, vascular anastomoses within the placenta may cause unequal distribution of nutrients and oxygen, and discordant structural anomalies resulting from the twinning event itself may affect growth. For example, the quintuplets shown in Figure 39-10 represent three dizygotic and two monozygotic fetuses. When delivered at 31 weeks, the three neonates from separate ova

FIGURE 39-9 Marked growth discordance in monochorionic twins. (Courtesy of Dr. Laura Greer).

weighed 1420, 1530, and 1440 g, whereas the two derived from the same ovum weighed 990 and 860 g.

Multiple fetuses may overtax the capacity of the mother, the uterus, or both to provide nutrients. Selective reduction of triplets to twins before 12 weeks results in a growth pattern typical of twins rather than triplets (Lipitz, 1996; Smith-Levitin, 1996; Yaron, 1999, and all their associates). Somewhat related, Casele and co-workers (1996) reported that women with twins were more vulnerable to starvation ketosis after fasting compared with women with singleton pregnancies.

Duration of Gestation

As the number of fetuses increases, the duration of gestation decreases (Fig. 39-11). According to Martin and colleagues (2009), 60 percent of twins and 93 percent of triplets born in the United States in 2006 were delivered preterm.

FIGURE 39-10 Davis quintuplets at 3 weeks following delivery. The first, second, and fourth newborns from the left each arose from separate ova, whereas the third and fifth neonates are from the same ovum.

Preterm Birth

Delivery before term is the major reason for increased neonatal morbidity and mortality rates in twins. Gardner and associates (1995) found that the causes of preterm birth differed between twins and singletons. Spontaneous preterm labor accounted for a larger and preterm ruptured membranes for a smaller proportion of twin preterm birth. Indicated preterm delivery accounted for equal proportions of prematurely delivered twins and singletons.

The rate of preterm birth among multifetal gestations has increased over the past two decades. In an analysis of nearly 350,000 twin births, Kogan and colleagues (2002) showed that during the 16-year period ending in 1997, the rate of term birth among twins declined by 22 percent. Joseph and colleagues (2001) attributed this decline to an increased rate of indicated preterm deliveries. This trend is not necessarily negative, as it was associated with decreased perinatal morbidity and mortality rates among twins that reached 34 weeks. Similarly, twin gestations in women receiving more than the recommended number of prenatal visits showed higher rates of preterm birth but lower neonatal mortality rates (Kogan and colleagues, 2000). Although the causes of preterm delivery in twins and singletons may be different, once delivered, neonatal outcome is generally the same at similar gestational ages (Gardner and co-workers, 1995; Kilpatrick and colleagues, 1996; Ray and Platt, 2009).

The previous statements apply to twins who are essentially concordant. As perhaps expected, outcomes for preterm twins who are markedly discordant may not be comparable with that of singletons because whatever caused the discordance may have long-lasting effects.

Prolonged Pregnancy

More than 40 years ago, Bennett and Dunn (1969) suggested that a twin pregnancy of 40 weeks or more should be considered postterm. Twin stillborn neonates delivered at 40 weeks or beyond had features similar to those of postmature singletons (Chap. 37, p. 834). From an analysis of almost 300,000 twin births from 1995 to 1998, Kahn and colleagues (2003) calculated that at and beyond 39 weeks, the risk of subsequent stillbirth was greater than the risk of neonatal mortality. At Parkland Hospital, twin gestations have empirically been considered to be prolonged at 40 weeks.

Long-Term Infant Development

In a study in Norway, Nilsen and associates (1984) evaluated the physical and intellectual development of male twins at age 18 years. Compared with singletons, twice as many twins were found to be physically unfit for military service. These investigators attributed this to sequelae of preterm delivery, such as visual impairment, rather than to twinning. General intelligence did not appear to differ, a finding confirmed in a Danish cohort of 3411 twins and 7796 singletons born from 1986 to 1988 who were assessed in the ninth grade (Christensen and colleagues, 2006).

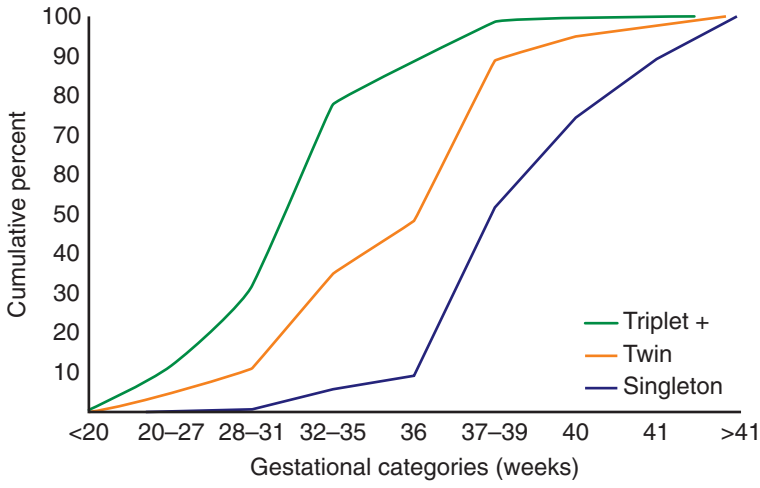

FIGURE 39-11 Cumulative percent of singleton, twin, and triplet or higher-order multifetal births according to gestational age at delivery in the United States during 1990. (Redrawn from Luke B: The changing pattern of multiple births in the United States: Maternal and infant characteristics, 1973 and 1990, *Obstetrics & Gynecology,* 1994, vol. 84, no. 1, pp. 101–106, with permission.)

Birthweight and anthropomorphic discordancy may persist. For example, Babson and Phillips (1973) reported that in monozygotic twins whose birthweights differed on average 35 percent, the smaller twin at birth remained so into adulthood. Height, weight, head circumference, and intelligence often remained greater in the twin who weighed more at birth.

UNIQUE COMPLICATIONS

A number of unique complications develop in multifetal pregnancies. Although these have been best described in twins, they also occur in higher-order multifetal gestation.

Monoamnionic Twins

Approximately 1 percent of monozygotic twins are monoamnionic (Hall, 2003). Their associated high fetal death rate may result from cord entanglement, congenital anomaly, preterm birth, or twin-twin transfusion syndrome, which is described subsequently (Cordero and colleagues, 2006). In a comprehensive review, Allen and colleagues (2001) reported that monoamnionic twins diagnosed antenatally and that are still alive at 20 weeks have an approximately 10-percent risk of subsequent fetal demise. In a report of 98 monoamnionic twin pregnancies from 10 Dutch centers, the perinatal mortality rate was 17 percent (Hack and associates, 2009). Umbilical cord intertwining, a common cause of death, is estimated to complicate at least half of cases (Fig. 39-12). Diamnionic twins can become monoamnionic if the dividing membrane ruptures, and they then have similar associated morbidity and mortality rates (Gilbert and colleagues, 1991).

Management

Once diagnosed, management of monoamnionic twins is somewhat problematic due to the unpredictability of fetal death resulting from cord entanglement and to the lack of an effective means of monitoring for it. Some data suggest that morbid cord entanglement is likely to occur early, and that monoamnionic pregnancies that have successfully reached 30 to 32 weeks are at greatly reduced risk (Carr and coworkers, 1990; Demaria and associates, 2004; Tessen and Zlatnik, 1991). But based on their review, Roqué and colleagues (2003) dispute this.

Although umbilical cords frequently entangle, factors that lead to pathological umbilical vessel constriction during entanglement are unknown. Belfort and colleagues (1993) and Aisenbrey and co-workers (1995) used color-flow Doppler sonography to diagnose umbilical cord entanglement in 10 monoamnionic twin pregnancies. The recognition of cord entanglement in seven of these prompted admission, increased fetal surveillance, or both. Interestingly, only one set of twins with entangled cords required immediate delivery. In fact, the remaining six pregnancies continued for an average of 6 weeks after the diagnosis, and one of these continued for 12 weeks!

Evidence to guide management is observational, retrospective, and subject to biased reporting. At the University of Alabama at Birmingham, management is based in large part on the report of Heyborne and co-workers (2005). There were no stillbirths in 43 twin pregnancies in women admitted at 26 to 27 weeks for daily fetal surveillance. Conversely, there were 13 stillbirths in twin pregnancies in 44 women who were managed as outpatients and admitted only for an obstetrical indication. Because of this report, women with monoamnionic twins are managed with 1 hour of daily fetal heart rate monitoring, either as outpatients or as inpatients, beginning at 26 to 28 weeks. With initial testing, a course of betamethasone is given to promote pulmonary maturation (see Chap. 36, p. 821). If fetal testing remains reassuring, cesarean delivery is performed at 34 weeks after a second course of betamethasone.

FIGURE 39-12 Monozygotic twins in a single amnionic sac. The smaller fetus apparently died first, and the second subsequently succumbed when umbilical cords entwined.

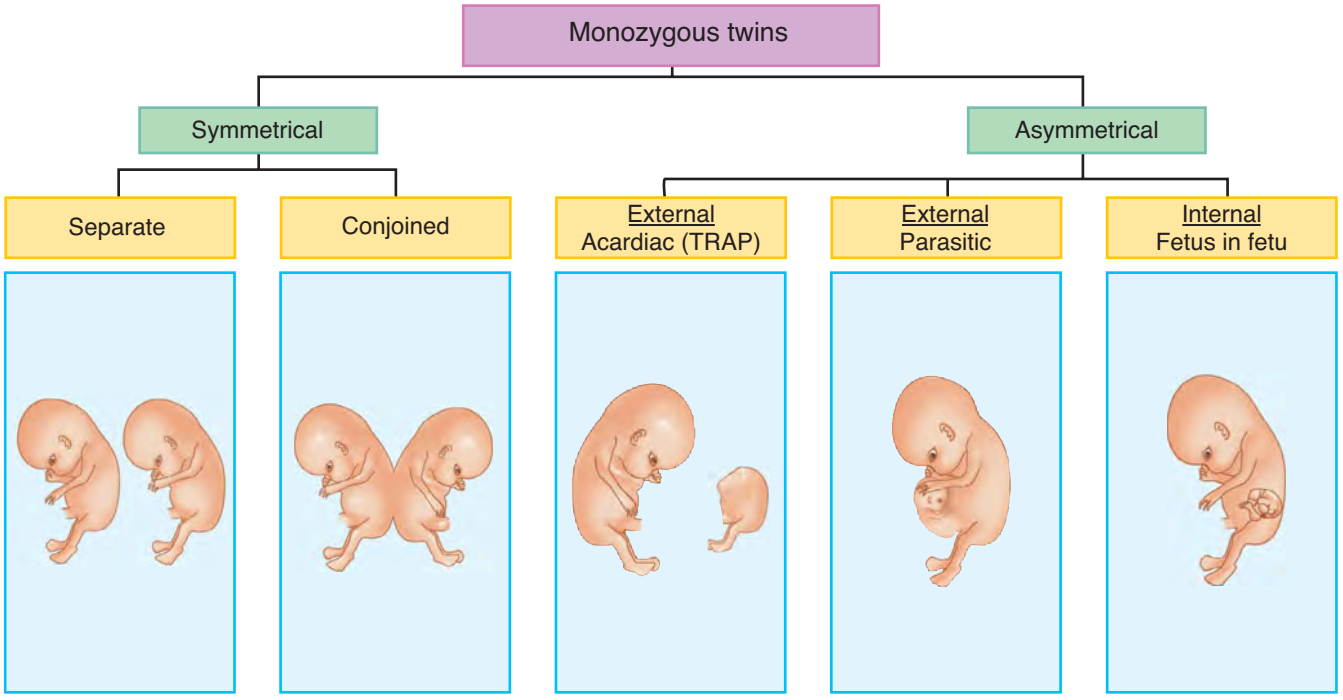

FIGURE 39-13 Possible outcomes of monozygotic twinning.

Abnormal Twinning

Conjoined twins may result from aberrations in the twinning process, traditionally ascribed to incomplete splitting of an embryo into two separate twins (Kaufman, 2004). An alternative hypothesis describes early secondary fusion of two originally separated embryos (Spencer, 2000a, b). As shown in **Figure 39-13**, aberrant twinning encompasses a spectrum of abnormalities that includes not only conjoined twins but also *external parasitic twins* and *fetus in fetu.*

Conjoined Twins

In the United States, united or conjoined twins (see Fig. 39–2) are commonly referred to as *Siamese twins*–after Chang and Eng Bunker of Siam (Thailand), who were displayed worldwide by P.T. Barnum. Joining of the twins may begin at either pole and may produce characteristic forms (**Fig. 39-14**). Of these, *parapagus* is the most common (Spencer, 2001). The frequency of conjoined twins is not well established. At Kandang Kerbau Hospital in Singapore, Tan and co-workers (1971) identified seven cases of conjoined twins among more than 400,000 deliveries–an incidence of 1 in 60,000.

As reviewed by McHugh and associates (2006), conjoined twins can frequently be identified using sonography at midpregnancy, time enough for parents to decide whether to continue the pregnancy. A targeted examination, including a careful evaluation of the point of connection and the organs involved, is necessary before counseling can be provided (**Fig. 39-15**). In

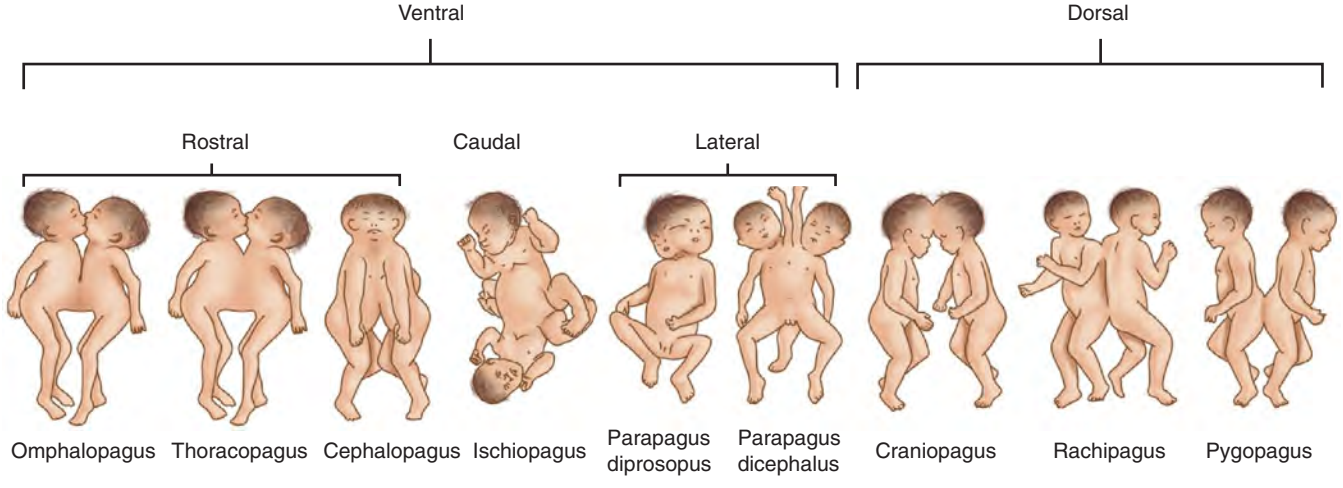

FIGURE 39-14 Types of conjoined twins. (Redrawn from Spencer, 2000a.)

FIGURE 39-15 Sonogram of a conjoined twin pregnancy at 13 weeks' gestation. Twins with two heads but only one torso are termed parapagus dicephalus.

later pregnancy, when there is diminished amnionic fluid and increased fetal crowding, MR imaging may provide necessary anatomical information.

Surgical separation of nearly completely joined twins may be successful if essential organs are not shared (Spitz and Kiely, 2003). Consultation with a pediatric surgeon often assists parental decision making. Conjoined twins may have discordant structural anomalies that further complicate decisions about whether to continue the pregnancy. For example, one of the conjoined twins shown in **Figure 39-16** was anencephalic.

Viable conjoined twins should be delivered by cesarean. For the purpose of pregnancy termination, however, vaginal delivery is possible because the union is most often pliable. Still, dystocia is common, and if the fetuses are mature, vaginal delivery may be traumatic to the uterus or cervix.

FIGURE 39-16 Conjoined twins in which one was anencephalic. (Courtesy of Dr. Craig Syrop, University of Iowa.)

External Parasitic Twins

This is a grossly defective fetus or merely fetal parts, attached externally to a relatively normal twin. A parasitic twin usually consists of externally attached supernumerary limbs, often with some viscera. Classically, however, a functional heart or brain is absent. Attachment mirrors those sites described earlier for conjoined twins (see Fig. 39-13). Parasites are believed to result from demise of the defective twin, with its surviving tissues attached to and vascularized by its normal twin (Spencer, 2001).

Fetus-in-Fetu

Early in development, one embryo may be enfolded inside its twin. Normal development of this rare parasitic twin usually arrests at the first trimester. As a result, normal spatial arrangement of and presence of many organs is lost. Classically, vertebral or axial bones are found in these fetiform masses, whereas heart and brain are lacking. These masses are typically supported by their host by a few large parasitic vessels (Spencer, 2000a).

Vascular Anastomoses between Fetuses

With rare exceptions, vascular anastomoses between twins are present only in monochorionic twin placentas (Baldwin, 1991; Hall, 2003). And although nearly all of these have anastomoses, there are marked variations in the number, size, and direction of these seemingly haphazard connections (**Fig. 39-17**). Artery-to-artery anastomoses are most common and are found on the chorionic surface of the placenta in up to 75 percent of monochorionic twin placentas. Vein-to-vein and artery-to-vein communications are each found in approximately half. One vessel may have several connections, sometimes to both arteries and veins. In contrast to these superficial vascular connections on the surface of the chorion, deep artery-to-vein communications extend through the capillary bed of the villous tissue. These deep arteriovenous anastomoses create a common villous compartment or third circulation that has been identified in approximately half of monochorionic twin placentas (**Fig. 39-18**).

Most of these vascular communications are hemodynamically balanced and of little fetal consequence. In others, however, hemodynamically significant shunts develop between fetuses. Two such significant patterns include *acardiac twinning* and *twin-twin transfusion syndrome*. The incidence of the latter syndrome is unclear, but approximately one fourth of monochorionic twins have some of its clinical features (Sperling and co-workers, 2007).

Acardiac Twin

Twin reversed-arterial-perfusion (TRAP) sequence is a rare—1 in 35,000 births, but serious complication of monochorionic multifetal gestation. In the TRAP sequence, there is usually a normally formed donor twin who has features of heart failure as well as a recipient twin who lacks a heart (acardius) and other structures. It has been hypothesized that the

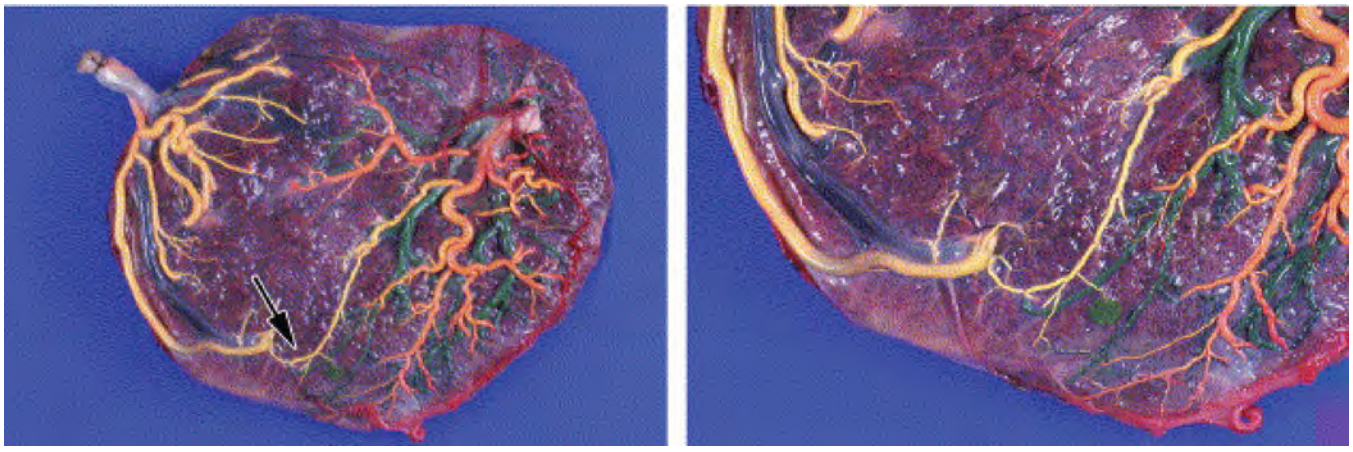

FIGURE 39-17 Placenta from pregnancy complicated by twin-twin transfusion syndrome. The following color code was applied for injection. Left twin: yellow = artery, blue = vein; right twin: red = artery, green = vein. **A.** Part of the arterial network of the right twin is filled with yellow dye, due to the presence of a small artery-to-artery anastomosis (*arrow*). **B.** Close-up of the lower portion of the placenta displays the yellow dye-filled anastomosis (Reprinted from Placenta, Vol. 26, ME De Paepe, P DeKoninck, and RM Friedman, Vascular distribution patterns in monochorionic twin placentas, pp. 471–475, Copyright 2005, with permission from Elsevier.)

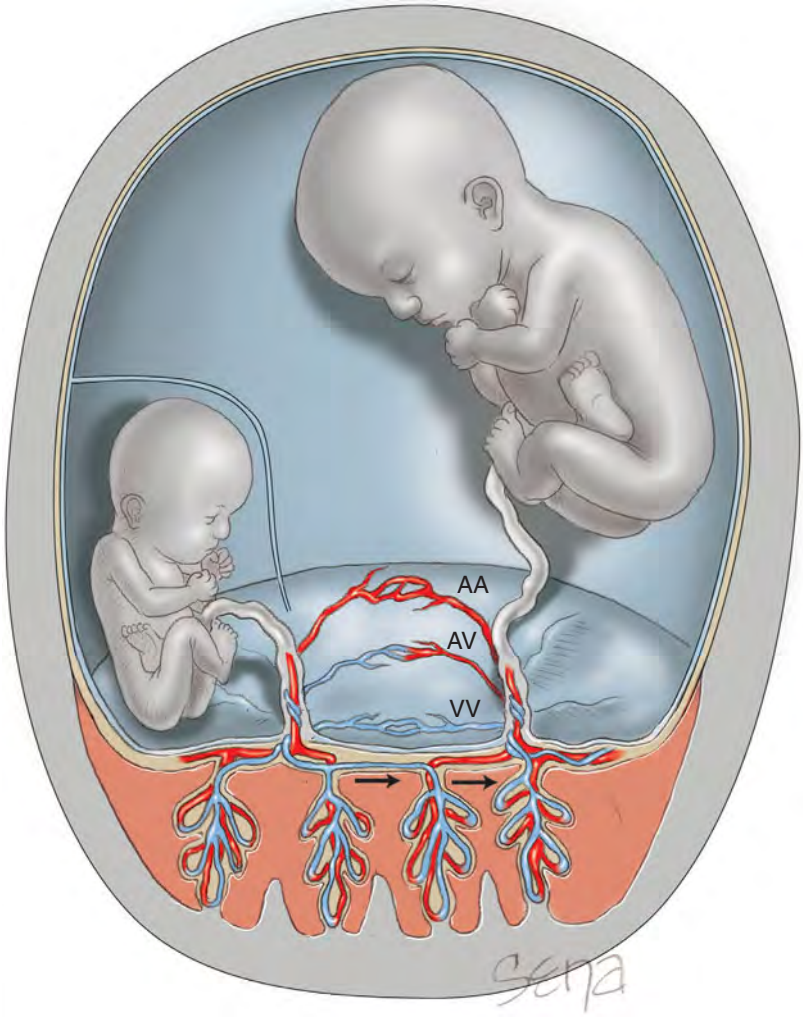

FIGURE 39-18 Anastomoses between twins may be artery-to-venous (AV), artery-to-artery (AA), or vein-to-vein (VV). Schematic representation of an AV anastomosis in twin-twin transfusion syndrome that forms a "common villous district" or "third circulation" deep within the villous tissue. Blood from a donor twin may be transferred to a recipient twin through this shared circulation. This transfer leads to a growth-restricted discordant donor twin with markedly reduced amnionic fluid, causing it to be "stuck."

TRAP sequence is caused by a large artery-to-artery placental shunt, often also accompanied by a vein-to-vein shunt (**Fig. 39-19**). Within the single, shared placenta, arterial perfusion pressure of the donor twin exceeds that in the recipient twin, who thus receives reverse blood flow of deoxygenated arterial blood from its co-twin (Jones, 1997). This "used" arterial blood reaches the recipient twin through its umbilical arteries and preferentially goes to its iliac vessels. Thus, only the lower body is perfused, and disrupted growth and development of the upper body results. Failure of head growth is called *acardius acephalus*; a partially developed head with identifiable limbs is called *acardius myelacephalus*; and failure of any recognizable structure to form is *acardius amorphous* shown in **Figure 39-20** (Faye-Petersen and colleagues, 2006). Because of this vascular connection, the normal donor twin must not only support its own circulation but also pump its blood through the underdeveloped acardiac recipient. This may lead to cardiomegaly and high-output heart failure in the normal twin (Fox and Sebire, 2007).

Without treatment, the death rates of a donor or "pump" twin range from 50 to 75 percent (Moore and colleagues, 1990). Quintero and colleagues (1994, 2006) have reviewed methods of in utero treatment of acardiac twinning in which the goal is interruption of aberrant vascular communication between the twins. Of these methods, Livingston (2007) and Lee (2007), with their colleagues, found an approximately 90-percent survival rate with radiofrequency ablation, which cauterizes umbilical vessels in the malformed recipient twin so as to terminate blood flow from the donor.

Conversely, survival has been reported for nine of 10 donor twins managed expectantly (Sullivan

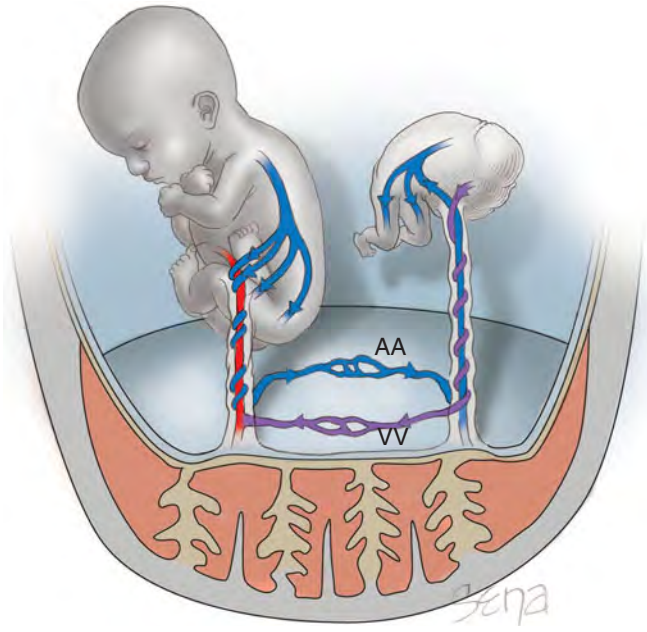

FIGURE 39-19 In the TRAP sequence, there is usually a normally formed donor twin, who has features of heart failure, and a recipient twin, who lacks a heart. It has been hypothesized that the TRAP sequence is caused by a large artery-to-artery placental shunt, often also accompanied by a vein-to-vein shunt. Within the single, shared placenta, perfusion pressure of the donor twin overpowers that in the recipient twin, who thus receives reverse blood flow from its twin sibling. The "used" arterial blood that reaches the recipient twin preferentially goes to its iliac vessels and thus perfuses only the lower body. This disrupts growth and development of the upper body.

FIGURE 39-20 Photograph of an acardiac twin weighing 475 grams. The underdeveloped head is indicated by the black arrow, and its details are shown in the inset. A yellow clamp is seen on this twin's umbilical cord. Its viable donor co-twin was delivered vaginally at 36 weeks and weighed 2325 grams. (Courtesy of Dr. Michael D. Hnat.)

and associates, 2003). These authors advocate that expectant management with close fetal surveillance as a management option.

Twin-Twin Transfusion Syndrome (TTTS)

In this syndrome, blood is transfused from a donor twin to its recipient sibling such that the donor becomes anemic and its growth may be restricted. In contrast, the recipient becomes polycythemic and may develop circulatory overload manifest as hydrops. The donor twin is pale, and its recipient sibling is plethoric (**Fig. 39-21**). Similarly, one portion of the placenta often appears pale compared with the remainder.

In the recipient twin, the neonatal period may be complicated by circulatory overload with heart failure, if severe hypervolemia and hyperviscosity are not identified promptly and treated. Occlusive thrombosis is also much more likely to develop in this setting. During the neonatal period, polycythemia in the recipient twin may lead to severe hyperbilirubinemia and kernicterus (see Chap. 29, p. 625).

Pathophysiology. Any of the different types of vascular anastomoses discussed before may be found with monochorionic placentas. Classically, chronic TTTS results from unidirectional flow through arteriovenous anastomoses. Deoxygenated blood from a donor placental artery is pumped into a cotyledon shared by the recipient (see Fig. 39-18). Once oxygen exchange is completed in the chorionic villus, the oxygenated blood leaves the cotyledon via a placental vein of the recipient twin. Unless compensated, this unidirectional flow leads to an imbalance in blood volumes (Lopriore and Oepkes, 2008; Machin and co-workers, 2000).

Clinically important twin-twin transfusion syndrome frequently is chronic and results from significant vascular volume differences between the twins. The syndrome typically presents in midpregnancy when the donor fetus becomes oliguric from decreased renal perfusion (Mari and co-workers, 1993). This fetus develops oligohydramnios, and the recipient fetus develops severe hydramnios, presumably due to increased urine production. Virtual absence of amnionic fluid in the donor sac prevents fetal motion, giving rise to the descriptive term *stuck twin* or *hydramnios-oligohydramnios–"poly-oli"–syndrome.* This amnionic fluid imbalance is associated with growth restriction, contractures, and pulmonary hypoplasia in one twin, and premature rupture of the membranes and heart failure in the other.

Fetal Brain Damage. Cerebral palsy, microcephaly, porencephaly, and multicystic encephalomalacia are serious complications associated with placental vascular anastomoses in multifetal gestation. Neurological damage is most likely caused by ischemic necrosis leading to cavitary brain lesions (**Fig. 39-22**). In the donor twin, ischemia results from hypotension, anemia, or both. In the recipient, ischemia develops from blood pressure instability and episodes of severe hypotension (Larroche and associates, 1990). Quarello and colleagues (2007) reviewed data from 315 liveborn fetuses from

FIGURE 39-21 Twin-twin transfusion syndrome at 23 weeks. Pale donor twin (690 g) is shown on the left. The plethoric recipient twin (730 g) on the right also had hydramnios. The donor twin had oligohydramnios. (This figure was published in *American Journal of Obstetrics & Gynecology,* Vol. 169, PR Mahone, DM Sherer, JS Abramowicz, and JR Woods, Twin-twin transfusion syndrome: Rapid development of severe hydrops of the donor following selective feticide of the hydropic recipient, pp. 166–168, Copyright Elsevier 1993.)

pregnancies with twin-twin transfusion syndrome. They found that cerebral abnormalities developed in 8 percent.

If one twin of an affected pregnancy dies, cerebral pathology in the survivor most likely results from acute hypotension (Benirschke, 1993). A less likely cause is emboli of thromboplastic material originating from the dead fetus. Fusi and co-workers (1990, 1991) observed that with the death of one twin, acute twin-twin anastomotic transfusion from the high-pressure vessels of the living twin to the low-resistance vessels of the dead twin leads rapidly to hypovolemia and ischemic antenatal brain damage in the survivor. Pharoah and Adi (2000) surveyed 348 survivors whose twin sibling had died in utero. The prevalence of cerebral palsy was 83 per 1000 live births–a 40-fold increased risk over baseline.

The acute nature of the twin-twin transfusion and subsequent hypotension following the death of one twin makes successful intervention for the survivor nearly impossible. Even with delivery immediately after the co-twin demise is recognized, the hypotension that occurs at the moment of death has likely already caused irreversible damage (Langer and associates, 1997; Wada and co-workers, 1998).

Diagnosis. There have been dramatic changes in the criteria used to diagnose and classify varying severities of TTTS. Classically, weight discordancy and hemoglobin differences in monochorionic twins were calculated, however, it was soon appreciated that in many cases, these were later clinical findings. Harkness and Crombleholme (2005) propose the following sonographic findings as being suggestive of this diagnosis: (1) monochorionicity, (2) same-sex gender, (3) hydramnios defined if the largest vertical pocket is $>$ 8 cm in one twin and oligohydramnios defined if the largest vertical pocket is $<$ 2 cm in the other twin, (3) umbilical cord size discrepancy, (4) cardiac dysfunction in the recipient twin with hydramnios, (5) abnormal umbilical vessel or ductus venosus Doppler velocimetry, and (6) significant growth discordance.

Once identified, TTTS is typically staged by the Quintero staging system (Quintero and colleagues, 1999). These are defined as follows:

- Stage I–discordant amnionic fluid volumes as described above, but urine still visible sonographically within the donor twin's bladder
- Stage II–criteria of stage I, but urine is not visible within the donor's bladder
- Stage III–criteria of stage II and abnormal Doppler studies of the umbilical artery, ductus venosus, or umbilical vein
- Stage IV–ascites or frank hydrops in either twin; and
- Stage V–demise of either fetus.

In addition to these criteria, there is now evidence that cardiac function of the recipient twin correlates with fetal outcome (Crombleholme and associates, 2007). Thus, many also assess cardiovascular function of TTTS twins with echocardiography (Rychik and co-workers, 2007). One scoring system–the *cardiovascular profile score or CVPS*–evaluates presence or absence of hydrops, abnormal venous and arterial Doppler findings, cardiomegaly, atrioventricular valve regurgitation, and cardiac dysfunction (Shah and colleagues, 2008). Cardiac function is measured by the Doppler *myocardial performance index or MPI*, which is an index of global ventricular function and calculated for each ventricle (Michelfelder and associates, 2007).

Prior to treatment at Parkland Memorial Hospital, our protocol includes anatomical and neurological fetal assessment using echocardiography, MPI calculation, Doppler velocimetry, and MR imaging; genetic counseling and amniocentesis; and placental mapping.

Therapy and Outcome. The prognosis for multifetal gestations complicated by TTTS is extremely guarded. Unfortunately, the most serious form of TTTS, with acute hydramnios in one sac and a stuck twin with anhydramnios in the other sac, usually presents between 18 and 26 weeks. The survival rate for those diagnosed before 28 weeks varies widely, from 7 to 75 percent (Berghella and Kaufmann, 2001).

Several therapies are currently used for TTTS, including amnioreduction, laser ablation of vascular anastomoses, selective feticide, and septostomy (intentional creation of a communication in the dividing amnionic membrane). Recently, comparative data from randomized trials for some of these techniques have become available.

In a randomized trial of 142 women with severe TTTS diagnosed before 26 weeks, Senat and colleagues (2004) reported increased survival of at least one twin to age 6 months with laser ablation of vascular anastomoses compared with serial amnioreduction–76 versus 51 percent, respectively. Moreover, analyses

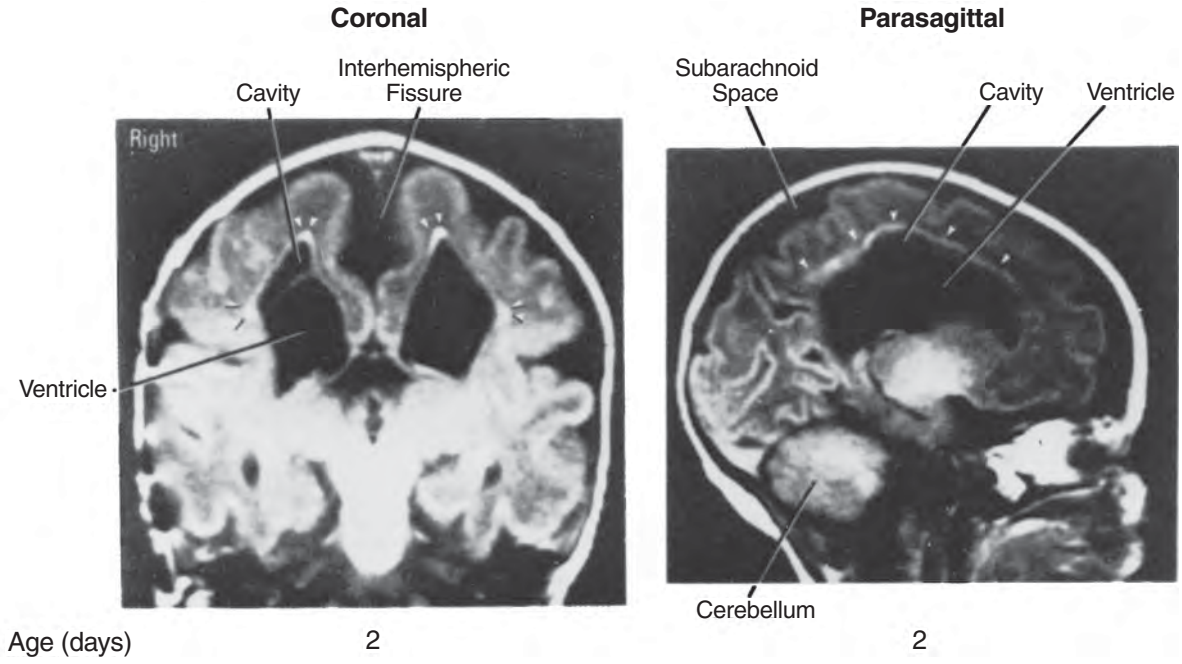

FIGURE 39-22 Cranial magnetic resonance imaging study of a diamnionic–monochorionic twin performed on day 2 of life. The subarachnoid space and lateral ventricles are markedly enlarged. There are large cavitary lesions in the white matter adjacent to the ventricles. The bright signals (*arrowheads*) in the periphery of the cavitary lesions most probably correspond to gliosis. (This figure was published in *American Journal of Obstetrics & Gynecology,* Vol. 162, R Bejar, G Vigliocco, H Gramajo, et al., Antenatal origin of neurological damage in newborn infants. II. Multiple gestations, pp. 1230–1236, Copyright Elsevier 1990.)

of randomized studies by Roberts and colleagues (2008) and Rossi and D'Addario (2008) showed better neonatal outcomes with laser therapy compared with selective amnioreduction. In contrast, Crombleholme and colleagues (2007), in a randomized trial of 42 women, found equivalent rates of 30-day survival of one or both twins treated with either amnioreduction or selective fetoscopic laser ablation–75 versus 65 percent, respectively.

At this time, laser ablation of anastomoses is preferred for severe TTTS, although optimal therapy for Stage I and Stage II disease is controversial. Even after laser therapy, however, close ongoing surveillance is necessary. Robyr and associates (2006) reported that a fourth of 101 pregnancies treated with laser required additional invasive therapy because of recurrent TTTS–14, or middle cerebral artery Doppler evidence of anemia or polycythemia–13.

Moise and colleagues (2005) compared amnioreduction and septostomy in a multicentered randomized trial of 73 women. Repeated procedures were performed for symptoms or if the greatest vertical pocket of amnionic fluid met the original inclusion criteria of $>$ 8 to 12 cm, depending on gestational age. Perinatal outcomes were the same in each group, with at least one survivor in 80 percent of pregnancies. The average number of additional procedures was two in each group.

Selective reduction has generally been considered if severe amnionic fluid and growth disturbances develop before 20 weeks. In such cases, both fetuses typically will die without intervention. Selection of which twin is to be terminated is based on evidence of damage to either fetus and comparison of their prognoses. Any substance injected into one twin may affect the other twin because of shared circulations. Therefore, feticidal techniques may include injection of an occlusive substance into the selected twin's umbilical vein or radiofrequency ablation, fetoscopic ligation, laser coagulation, monopolar coagulation, or bipolar cautery of one umbilical cord (Challis, 1999; Donner, 1997; Weiner, 1987; Wittmann, 1986, and all their colleagues). Even after these procedures, however, the risks to the remaining fetus are still appreciable (Rossi and D'Addario, 2009).

DISCORDANT TWINS

Size inequality of twin fetuses, which can be a sign of pathological growth restriction in one fetus, is calculated using the larger twin as the index. Generally, as the weight difference within a twin pair increases, perinatal mortality rates increase proportionately. As discussed further in Chapter 38 (p. 846), restricted growth of one twin fetus usually develops late in the second and early third trimester and is often asymmetrical (Leveno and coworkers, 1979). Earlier discordancy is usually symmetrical and indicates higher risk for fetal demise. Generally, the earlier discordancy in pregnancy develops, the more serious the sequelae. In an extreme example, Weissman and colleagues (1994) identified weight discordancy between 6 and 11 weeks in five twin gestations, and all of the smaller twins had major malformations.

Pathology

The cause of birthweight inequality in twin fetuses is often unclear, but we assume that the etiology differs in monochorionic compared with dichorionic twins. Discordancy in monochorionic twins is usually attributed to placental vascular anastomoses that cause hemodynamic imbalance between the twins. Reduced pressure and perfusion of the donor twin likely cause diminished placental and fetal growth (Benirschke, 1993).

Occasionally, monochorionic twins are discordant in size because they are discordant for structural anomalies.

Discordancy in dichorionic twins is likely due to a variety of factors. Importantly, dizygotic fetuses may have different genetic growth potential, especially if they are of opposite genders. Alternatively, because the placentas are separate and require more implantation space, there is a greater chance that one of the placentas would have a suboptimal implantation site. Mordel and colleagues (1993) observed that the incidence of discordancy is twice as great in triplets as it is in twins. This finding lends additional credence to the view that in utero crowding plays a role in fetal-growth restriction. Placental pathology may also play a role. Eberle and co-workers (1993) evaluated placental abnormalities in 147 twin gestations. They quantified placental lesions that are usually associated with singleton growth restriction. Placentas from the smaller fetus in discordant dichorionic twin pairs demonstrated these typical lesions, whereas these lesions were not found in discordant monochorionic twin pairs.

Diagnosis

Size discordancy between twins can be determined in several ways. One common method of determining discordancy uses all fetal measurements to compute the estimated weight of each twin and then to compare the weight of the smaller twin with that of the larger twin. Thus, percent discordancy = weight of larger twin minus weight of smaller twin, divided by weight of larger twin. Alternatively, considering that growth restriction is the primary concern and that abdominal circumference reflects fetal nutrition, some authors diagnose discordancy when abdominal circumferences differ by more than 20 mm (Brown and associates, 1987; Hill and colleagues, 1994).

Several different weight disparities between twins have been used to define discordancy. Accumulated data suggest that weight discordancy greater than 25 to 30 percent most accurately predicts an adverse perinatal outcome. Hollier and co-workers (1999) retrospectively evaluated 1370 twin pairs delivered at Parkland Hospital and stratified twin weight discordancy in 5-percent increments within a range of 15 to 40 percent. They found that the incidence of respiratory distress, intraventricular hemorrhage, seizures, periventricular leukomalacia, sepsis, and necrotizing enterocolitis increased directly with the degree of weight discordancy. These conditions increased substantially if discordancy was greater than 25 percent. The relative risk of fetal death increased significantly to 5.6 if there was more than 30-percent discordancy. It increased to 18.9 if there was greater than 40-percent discordancy.

Management

Sonographic monitoring of growth within a twin pair and calculating discordancy has become a mainstay in management. Other sonographic findings, such as oligohydramnios, may be helpful in gauging fetal risk. Depending on the degree of discordancy and the gestational age, fetal surveillance may be indicated, especially if one or both fetuses exhibit growth restriction. Delivery is usually not performed for size discordancy alone, except occasionally at advanced gestational ages.

TWIN DEMISE

Death of One Fetus

On occasion, one fetus dies remote from term, but pregnancy continues with one living fetus. Rydhström (1994) reviewed fetal death in 15,066 twin pairs weighing 500 g or more. One or both twins died in 1.1 percent of opposite-sex twins and 2.6 percent of same-sex twins. Weight discordancy also increased the risk of death. In opposite-sex twins, however, the risk of death remained constant at 1.2 percent until weight discordancy exceeded 40 to 50 percent or 1000 g. In same-sex twins, discordancy of only 20 percent or 250 g increased the risk. After the death of one twin, the risk of subsequent death in the surviving twin was sixfold greater in same-sex twins. Although chorionicity was not known in all cases, the authors estimated that the death rate for same-sex dizygotic twins was the same as for opposite-sex twins–0.8 percent, and that monochorionic twins had the greatest risk of death–3 percent.

At delivery, a dead fetus may be identifiable but may be compressed appreciably–*fetus compressus*. In others, it may be flattened remarkably through loss of fluid and most of the soft tissue–*fetus papyraceous* (Fig. 39-23).

The prognosis for the surviving twin depends on the gestational age at the time of the demise, the chorionicity, and the length of time between the demise and delivery of the surviving twin. Early demise such as a "vanishing twin" does not appear to increase the risk of death in the surviving fetus after the first trimester. Afterwards, however, the neurological prognosis for a surviving co-twin depends almost exclusively on chorionicity. In their comprehensive review, Ong and colleagues (2006) found an 18-percent rate of neurological abnormality with

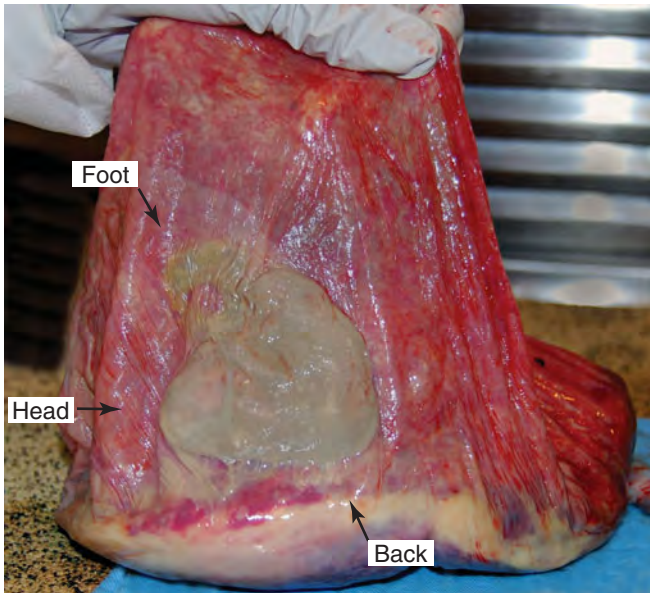

FIGURE 39-23 This fetus papyraceous is a tan ovoid mass compressed against the fetal membranes. Anatomical parts can be identified as marked. Demise of this twin had been noted during sonographic examination performed at 17 weeks' gestation. Its viable co-twin delivered at 40 weeks' gestation. (Courtesy of Dr. Michael V. Zaretsky.)

monochorionic placentation compared with only 1 percent with dichorionic placentation.

Later in gestation, the death of one of multiple fetuses could theoretically trigger coagulation defects in the mother. Only a few cases of maternal coagulopathy after a single fetal death in a twin pregnancy have been reported, probably because the surviving twin is usually delivered within a few weeks of the demise (see Chap. 35, p. 788). That said, we have observed transient, spontaneously corrected consumptive coagulopathy in multifetal gestations in which one fetus died and was retained in utero along with its surviving twin. The plasma fibrinogen concentration initially decreased but then increased spontaneously, and the level of serum fibrinogen-fibrin degradation products increased initially but then returned to normal levels. At delivery, the portions of the placenta that supplied the living fetus appeared normal. In contrast, the part that had once provided for the dead fetus was the site of massive fibrin deposition.

Management decisions should be based on the cause of death and the risk to the surviving fetus. Most cases of a single fetal death in twin pregnancy involve monochorionic placentation. Evidence indicates that morbidity in the monochorionic twin survivor is almost always due to vascular anastomoses, which first cause the demise of one twin followed by sudden hypotension in the other.

Occasionally, death of one but not all fetuses results from a maternal complication such as diabetic ketoacidosis or severe preeclampsia with abruption. Pregnancy management is based on the diagnosis and the status of both mother and surviving fetus. If the death of one dichorionic twin is due to a discordant congenital anomaly, its death should not affect its surviving twin. Santema and co-workers (1995b) assessed the cause and outcome of 29 consecutive twin pregnancies in which one of the fetuses died after 20 weeks. The causes of fetal death were not clear in all cases. The most common associations were monochorionic placentation and severe preeclampsia. These investigators concluded that in most cases, the benefit derived from continuation of a multifetal pregnancy exceeded the risks of preterm delivery after diagnosis of fetal death. They recommended conservative management of the living fetus.

Impending Death of One Fetus

Abnormal antepartum test results of fetal health in one twin fetus, but not the other, pose a particular dilemma. Delivery may be the best option for the compromised fetus yet may result in death from immaturity of the second. If fetal lung maturity is confirmed, salvage of both the healthy fetus and its jeopardized sibling is possible. Unfortunately, ideal management if twins are immature is problematic but should be based on the chances of intact survival for both fetuses. Often the compromised fetus is severely growth restricted or anomalous. Thus, performing amniocentesis for fetal karyotyping in women of advanced maternal age carrying twin pregnancies is advantageous, even for those who would continue their pregnancies regardless of the diagnosis. Aneuploidy identification in one fetus allows rational decisions about interventions.

Death of Both Twin Fetuses

Rydhström (1996) reported that, excluding abortions, both fetuses died in 0.5 percent of twin pregnancies. Causes implicated in these deaths were monochorionic placentation and discordant fetal growth.

COMPLETE HYDATIDIFORM MOLE AND COEXISTING FETUS

This entity is different from a partial molar pregnancy because there are two separate conceptuses. A normal placenta supplies nutrition to one twin, and the co-pregnancy is a complete molar gestation. Optimal management is uncertain, but preterm delivery is frequently required because of bleeding or severe preeclampsia. Bristow and colleagues (1996) reviewed 26 cases and found that 73 percent required evacuation before fetal viability. The remainder continued without serious complications until fetal viability was reached. Sebire and colleagues (2002) reported a live-birth rate of almost 40 percent in 53 such pregnancies. Any pregnancy consisting of a complete mole carries significant risk for subsequent gestational trophoblastic neoplasia, but Niemann and colleagues (2007) did not find rates of persistent trophoblastic disease following a twin gestation complicated by a complete mole to be higher than those following a singleton complete mole (see Chap. 11, p. 258).

ANTEPARTUM MANAGEMENT OF TWIN PREGNANCY

To reduce perinatal mortality and morbidity rates in pregnancies complicated by twins, it is imperative that:

1. Delivery of markedly preterm neonates be prevented
2. Fetal-growth restriction be identified and afflicted fetuses be delivered before they become moribund
3. Fetal trauma during labor and delivery be avoided, and
4. Expert neonatal care be available.

Diet

The requirements for calories, protein, minerals, vitamins, and essential fatty acids are further increased in women with multiple fetuses. The Recommended Dietary Allowances made by the Food and Nutrition Board of the National Research Council for uncomplicated pregnancy should not only be met but in most instances exceeded (see Chap. 8, p. 200). Caloric consumption should be increased by another 300 kcal/day. Brown and Carlson (2000) have recommended that weight gain be based in part on prepregnancy weight but that women with triplet pregnancies should gain at least 50 pounds. Supplementation with 60 to 100 mg/day of iron and with 1 mg/day of folic acid is preferred.

Hypertension

Hypertensive disorders due to pregnancy are more likely to develop with multiple fetuses. The exact incidence attributable to twin gestation is difficult to determine, because twin pregnancies

are more likely to deliver preterm before preeclampsia can develop, and because women with twin pregnancies are often older and multiparous. For example, the incidence of pregnancy-related hypertension in women with twins is 20 percent at Parkland Hospital. Santema and co-workers (1995a) performed a case-control study in which 187 twin and 187 singleton pregnancies were matched for maternal age, parity, and gestational age at delivery. The incidence of hypertension was significantly higher in women carrying twin pregnancies–15 versus 6 percent. Mastrobattista and colleagues (1997) compared 53 triplet with 53 twin pregnancies and observed that the rate of severe preeclampsia was significantly higher in women with triplets–23 versus 6 percent.

These data suggest that fetal number and placental mass are involved in the pathogenesis of preeclampsia. With multifetal gestation, hypertension not only develops more often but also tends to develop earlier and to be more severe.

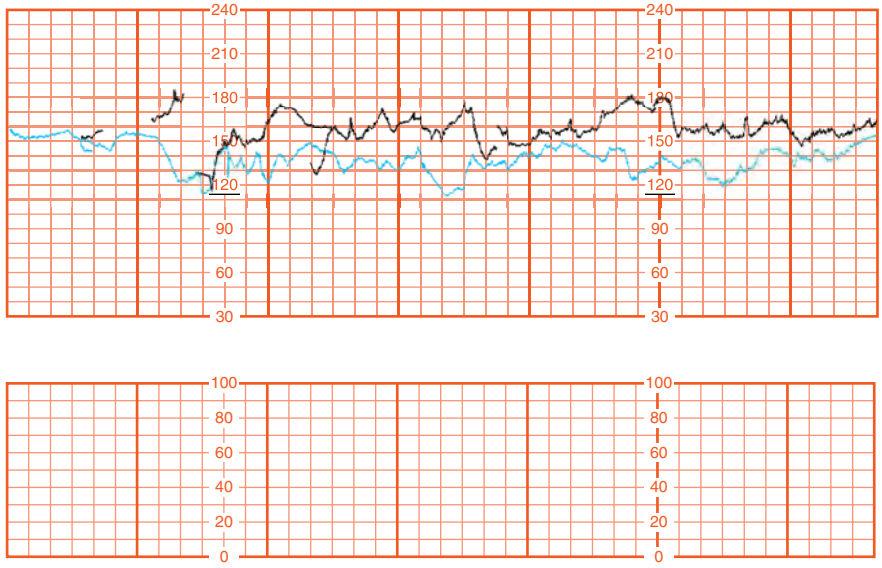

FIGURE 39-24 Simultaneous antepartum fetal heart rate recordings from twin fetuses showing that accelerations are not necessarily synchronous.

Antepartum Surveillance

Serial sonographic examinations are usually performed throughout the third trimester to monitor fetal growth. Assessment of amnionic fluid volume is also important. Associated oligohydramnios may indicate uteroplacental pathology and should prompt further evaluation of fetal well-being. That said, quantifying amnionic fluid volume in multifetal gestation is sometimes difficult. Some measure the deepest vertical pocket in each sac or assess the fluid subjectively. If sacs are side by side, as opposed to one on top of the other, measurement of the amnionic fluid index (AFI) may be helpful. Using data from 405 uncomplicated twin pregnancies, Porter and associates (1996) described a protocol for measuring the AFI in twin gestations and provided normal values. As in singletons, the deepest vertical pocket in each quadrant was measured, regardless of the dividing membrane location. An AFI of < 8 cm–below the 5th percentile or > 24 cm–above the 95th percentile–was considered abnormal at gestational ages of 28 to 40 weeks. If the overall AFI is abnormal, a determination should be made as to which sac is involved and how quantitatively severe the abnormality is. Subjective assessment may be required but is not always accurate. Magann and co-workers (1995) reported that oligohydramnios, defined as less than 500 mL, is poorly identified by any sonographic method in twin gestations.

Tests of Fetal Well-Being

As described throughout Chapter 15, there are several methods of assessing fetal health in singleton pregnancies. The nonstress test or biophysical profile is commonly used in management of twin or higher-order multifetal gestations. Because of the complexity of complications associated with multifetal gestations, and the potential technical difficulties in differentiating fetuses during antepartum testing, the usefulness of these methods appears limited. For example, Elliott and Finberg (1995) used the biophysical profile as the primary method for monitoring higher-order multifetal gestations. They reported that four of 24 monitored pregnancies had a poor outcome despite reassuring biophysical profile scores. In a randomized trial of 526 twin pregnancies, the addition of umbilical artery Doppler velocimetry to management compared with fetal testing based on fetal-growth parameters alone resulted in no improvement in perinatal outcome (Giles and associates, 2003).

Whatever method is used, care must be taken to evaluate each fetus separately. Gallagher and colleagues (1992) analyzed fetal heart rate accelerations, fetal movement, and other behavioral states in 15 twin pairs. If one twin of a pair was awake or asleep, so was its sibling, however, accelerations and movements were usually not coincidental (Fig. 39-24).

Doppler Velocimetry

As discussed in Chapters 15 and 16, Doppler evaluation of vascular resistance may provide a measure of fetal well-being. Increased resistance with diminished diastolic flow velocity often accompanies restricted fetal growth. Doppler values in twins and triplets are the same as in singletons and can thus be used in a similar manner (Akiyama and co-workers, 1999). As in singletons, however, the clinical utility of this technology is controversial.

Gerson and co-workers (1987) used duplex Doppler ultrasound to measure umbilical venous blood flow and arterial systolic–diastolic velocity ratios to predict concordant and discordant growth in twins. Normal studies correctly predicted concordancy in 44 of 45 concordant twin pairs. Abnormal values, especially those from the umbilical artery, correctly predicted discordancy in nine of 11 sets of discordant twins. Conversely, DiVou and co-workers (1989) reported that velocimetry alone was not consistently useful in identifying twin discordancy. Ezra and colleagues (1999) found that in triplets and

quadruplets, as in singletons, absent end-diastolic blood flow in the umbilical artery was associated with low birthweight and increased perinatal mortality rates.

Prevention of Preterm Delivery

Preterm labor is common in multifetal pregnancies and may complicate up to 50 percent of twin, 75 percent of triplet, and 90 percent of quadruplet pregnancies (Elliott, 2007). Several techniques have been applied in attempts to prolong these multifetal gestations. These include bed rest–especially through hospitalization, prophylactic administration of beta-mimetic drugs or progestins, and prophylactic cervical cerclage.

Bed Rest

Most evidence suggests that routine hospitalization is not beneficial in prolonging multifetal pregnancy. In one study, Crowther and co-workers (1990) randomly chose hospitalization or routine care for 139 Zimbabwean women with twin pregnancies. They found that hospitalized bed rest did not prolong pregnancy or improve neonatal survival, although it did improve fetal growth. At Parkland Hospital, elective hospitalization at 26 weeks was compared with outpatient management, and no advantages were found (Andrews and colleagues, 1991). Importantly, however, almost half of the women required admission for specific indications such as hypertension or threatened preterm delivery.

Limited physical activity, early work leave, more frequent health care visits and sonographic examinations, and structured maternal education on preterm delivery risks have been advocated to reduce preterm births in women with multiple fetuses. Unfortunately, there is little evidence that these measures substantially change outcome. For example, Pons and co-workers (1998) found virtually no difference in outcomes of 70 triplet pregnancies managed intensively from 1987 to 1993 and compared with 21 triplet pregnancies managed routinely between 1975 and 1986. The only major difference between these two periods was that neonates born in the later period group had significantly less hyaline membrane disease–13 versus 31 percent–which these investigators attributed to the use of corticosteroids.

Tocolytic Therapy

As for singleton pregnancies, there is no valid evidence that tocolytic therapy improves neonatal outcomes in multifetal gestation (Gyetvai and co-workers, 1999). Importantly, tocolytic therapy in these women entails a higher risk than in singletons. This is in part because twin-induced maternal increased blood volume and cardiovascular demands increase susceptibility to hydration-associated pulmonary edema. Gabriel and colleagues (1994) compared outcomes of 26 twin and six triplet pregnancies with those of 51 singletons–all treated with a beta-mimetic for preterm labor without ruptured membranes. Women with a multifetal gestation had significantly more cardiovascular complications–43 versus 4 percent–including three with pulmonary edema.

Progesterone Therapy

Weekly injections of 17-α hydroxyprogesterone caproate fail to reduce birth rates in women carrying twins or triplets (Caritis and associates, 2009; Rouse and colleagues, 2007).

Corticosteroids for Lung Maturation

Although corticosteroids are less studied in multifetal gestations than in singletons, there is no biological reason that these drugs would not benefit multiple fetuses (Roberts and Dalziel, 2006). Therefore, guidelines for the use of corticosteroids are not different from those for singleton gestation (American College of Obstetricians and Gynecologists, 2004).

Cervical Cerclage

Prophylactic cerclage has not been shown to improve perinatal outcome in women with multifetal pregnancies. Studies have included women who were not specially selected as well as those who were selected because of a shortened cervix as assessed by transvaginal sonography (Dor, 1982; Elimian, 1999; Newman, 2002; Rebarber, 2005, and all their colleagues). In fact, cerclage my actually worsen outcomes in the latter group (Berghella and colleagues, 2005).

PRETERM LABOR PREDICTION

Goldenberg and colleagues (1996) prospectively screened 147 twin pregnancies for more than 50 potential risk factors for preterm birth and found that only cervical length and fetal fibronectin levels predicted preterm birth (see Chap. 36, p. 814). At 24 weeks, a cervical length of 25 mm or less was the best predictor of birth before 32 weeks. At 28 weeks, an elevated fetal fibronectin level was the best predictor. Similarly, To and co-workers (2006) sonographically measured the cervical length in 1163 twin pregnancies at 22 to 24 weeks. Rates of preterm delivery before 32 weeks were 66 percent in those with cervical lengths of 10 mm; 24 percent for lengths of 20 mm; 12 percent for 25 mm; and only 1 percent for 40 mm. Conversely, McMahon and colleagues (2002) found that women with multifetal gestation at 24 weeks who had a closed internal os on digital cervical examination, a normal cervical length by sonographic examination, and a negative fetal fibronectin test result were at *low* risk to deliver before 32 weeks. Interestingly, a closed internal os by digital examination was as predictive as the combination of normal measured cervical length and negative fetal fibronectin test results.

Pulmonary Maturation

As measured by determination of the lecithin-sphingomyelin ratio, pulmonary maturation is usually synchronous in twins (Leveno and associates, 1984). Moreover, although this ratio usually does not exceed 2.0 until 36 weeks in singleton pregnancies, it often does so by approximately 32 weeks in multifetal pregnancies. In some cases, however, pulmonary function may be markedly different, with the smallest, most stressed fetus being more mature.

Preterm Premature Membrane Rupture

Twin gestations with preterm ruptured membranes are managed expectantly much like singleton pregnancies (see Chap. 36, p. 817). Mercer and colleagues (1993) compared outcomes of twin and singleton pregnancies, both with ruptured membranes at 19 to 36 weeks. They found that labor ensued earlier in twins.

Specifically, the median time from rupture to delivery was 1.1 days in twins compared with 1.7 days in singletons. More than 90 percent in both groups delivered within 7 days of membrane rupture.

Delayed Delivery of Second Twin

Infrequently, after preterm birth of the presenting fetus, it may be advantageous for undelivered fetus(es) to remain in utero. Trivedi and Gillett (1998) reviewed the English literature and found 45 case reports of asynchronous birth in multifetal gestation. Although likely biased, those pregnancies with a surviving retained twin or triplet continued for an average of 49 days. Management with tocolytics, prophylactic antimicrobials, and cerclage appeared to make no difference. Oyelese and associates (2005), in their retrospective cohort study of 258 twins with delayed delivery of the second fetus, found no improvement in rates of second-twin mortality if the first delivered between 24 to 28 weeks. Reduced rates were seen if the first twin delivered between 22 to 23 weeks, and the second delivery was delayed for 1 to 3 weeks. Livingston and colleagues (2004) described 14 pregnancies in which an active attempt was made to delay delivery of 19 fetuses after delivery of the first neonate. Only one fetus survived without major sequelae, and one mother developed sepsis syndrome with shock. Arabin and van Eyck (2009) reported better outcomes in the minority of 93 twin and 34 triplet pregnancies that qualified for delayed delivery in their center over a 17-year period.

If asynchronous birth is attempted, there must be careful evaluation for infection, abruption, and congenital anomalies. The mother must be thoroughly counseled, particularly about the potential for serious, even life-threatening infection. The range of gestational age in which the benefits outweigh the risks for delayed delivery is likely narrow. Avoidance of delivery from 23 to 26 weeks would seem most beneficial. In our experience, good candidates for delayed delivery are rare.

LABOR AND DELIVERY

Labor

Many complications of labor and delivery are encountered more often with multiple fetuses than with singletons. These include preterm labor, uterine contractile dysfunction, abnormal presentation, umbilical cord prolapse, premature separation of the placenta, and immediate postpartum hemorrhage. For these reasons, certain precautions and special arrangements are prudent. Recommendations for intrapartum management include:

1. An appropriately trained obstetrical attendant should remain with the mother throughout labor. Continuous external electronic monitoring is employed. If membranes are ruptured and the cervix dilated, then simultaneous evaluation of both the presenting fetus by internal electronic monitoring and the remaining sibling(s) by external monitors is typically used
2. Blood transfusion products are readily available
3. An intravenous infusion system capable of delivering fluid rapidly is established. In the absence of hemorrhage, lactated Ringer or an aqueous dextrose solution is infused at a rate of 60 to 125 mL/hr
4. An obstetrician skilled in intrauterine identification of fetal parts and in intrauterine manipulation of a fetus should be present
5. A sonography machine is made readily available to help evaluate position and status of the remaining fetus(es) after delivery of the first
6. Experienced anesthesia personnel are immediately available in the event that intrauterine manipulation or cesarean delivery is necessary
7. For each fetus, two attendants, one of whom is skilled in resuscitation and care of newborns, are appropriately informed of the case and remain immediately available
8. The delivery area should provide adequate space for all team members to work effectively. Moreover, the site must be appropriately equipped to provide maternal and neonatal resuscitation.

Presentation and Position

With twins, all possible combinations of fetal positions may be encountered. The most common presentations at admission for delivery are cephalic-cephalic, cephalic-breech, and cephalic-transverse (Fig. 39-25). Importantly, these presentations, especially those other than cephalic–cephalic, are unstable before and during labor and delivery. Compound, face, brow, and footling breech presentations are relatively common, especially if fetuses are small, amnionic fluid is excessive, or maternal parity is high. Cord prolapse is also common in these circumstances. The presentation can often be ascertained by sonography. If any confusion about the relationship of the twins to each other or to the maternal pelvis persists, a single anteroposterior radiograph of the abdomen may be helpful.

Induction or Stimulation of Labor

Although labor is generally shorter with twins, it can be desultory (Schiff and associates, 1998). If women meet all criteria for

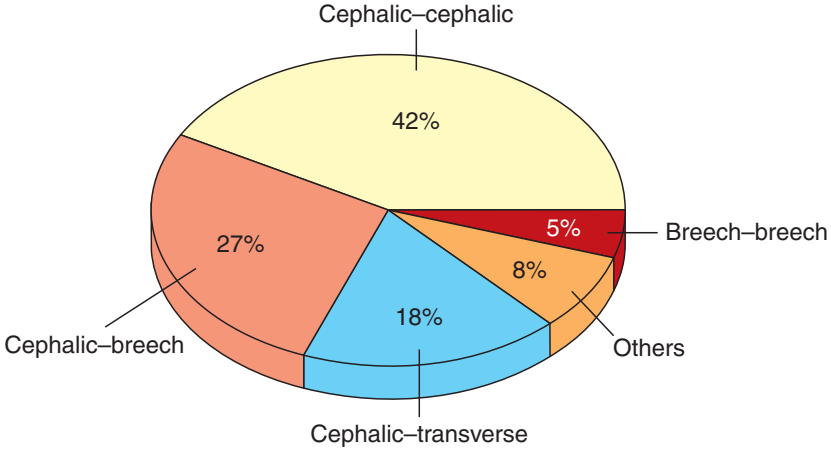

FIGURE 39-25 Presentations of twin fetuses on admission for delivery. (Data from Divon and colleagues, 1993.)

the administration of oxytocin, it may be used as described in Chapter 22 (see p. 505).

Analgesia and Anesthesia

During labor and delivery of multiple fetuses, decisions regarding analgesia and anesthesia may be complicated by problems imposed by preterm labor, preeclampsia, desultory labor, need for intrauterine manipulation, and postpartum uterine atony and hemorrhage.

Epidural analgesia is recommended by many because it provides excellent pain relief and can be rapidly extended cephalad if internal podalic version or cesarean delivery is required (Koffel, 1999). Special care must be taken in hypertensive women or in those who have hemorrhaged because epidural analgesia may cause hypotension with inadequate perfusion of vital organs, especially the placenta (see Chap. 19, p. 455). Therefore, placement and maintenance of continuous epidural analgesia should be performed by anesthesia personnel knowledgeable in obstetrics. It should be preceded by adequate hydration and administered slowly. Because women pregnant with multiple fetuses are especially vulnerable to supine hypotension during labor and delivery, they should be placed in full lateral position during and after induction of epidural analgesia. Left uterine displacement is maintained for cesarean delivery.

If general anesthesia is used, the increased maternal oxygen demand associated with multifetal gestation increases the risk of hypoxemia, thus making adequate preoxygenation essential. Pudendal blockade if administered with nitrous oxide plus oxygen can provide pain relief for spontaneous delivery. If intrauterine manipulation is necessary, as with internal podalic version, uterine relaxation can be accomplished rapidly with the inhalation anesthetic isoflurane. Such agents provide effective relaxation for intrauterine manipulation, but they also cause an increase in blood loss during the third stage of labor. Some clinicians use intravenous or sublingual nitroglycerin to achieve uterine relaxation yet avoid the aspiration and hypoxia risks associated with general anesthetics (Vinatier and associates, 1996).

Vaginal Delivery

Cephalic-Cephalic Presentation

During labor, the presenting twin typically dilates the cervix. If a first twin is cephalic, delivery can usually be accomplished spontaneously or with forceps. Hogle and colleagues (2003) performed an extensive literature review and concluded that planned cesarean delivery does not improve neonatal outcome when both twins are cephalic. Muleba and associates (2005) identified increased rates of respiratory distress in the second twin of preterm pairs regardless of the mode of delivery or corticosteroid use.

Cephalic-Noncephalic Presentation

The optimal delivery route for cephalic–noncephalic twins is controversial. Several reports attest to the safety of vaginal delivery of second noncephalic twins who weigh more than 1500 g (Blickstein, 1987; Chervanak, 1985; Gocke, 1989, and all their associates). Thus, when the estimated fetal weight is greater than 1500 g, vaginal delivery of a nonvertex second twin is reasonable. If the estimated fetal weight is less than 1500 g, the issue is less clear, although comparable or even improved fetal outcomes have been reported with vaginal delivery (Caukwell and Murphy, 2002; Davidson and co-workers, 1992; Rydhström, 1990). Mauldin and colleagues (1998) retrospectively reviewed the delivery courses of 84 cephalic–noncephalic twins. They found that vaginal delivery of the presenting twin followed by breech extraction of the second twin resulted in significantly shorter maternal and neonatal hospital stays, in part because vaginally extracted breech twins had less respiratory disease and fewer infections.

Breech Presentation

As in singletons, if a first fetus presents as a breech, major problems may develop if:

1. The fetus is unusually large, and the aftercoming head is larger than the birth canal
2. The fetus is sufficiently small. The extremities and trunk may deliver through an inadequately effaced and dilated cervix, but the head may become trapped above the cervix
3. The umbilical cord prolapses.

If these problems are anticipated or identified, cesarean delivery is often preferred except in those instances in which the fetuses are so immature that they will not survive. Even without these problems, if the first twin is breech, many obstetricians perform cesarean delivery. However, Blickstein and colleagues (2000) reported the collective experience from 1990 to 1997 of 13 European centers that attempted vaginal delivery in 374 of 613 twin pairs when the presenting twin was breech. In their report, vaginal delivery did not increase the mortality rate of breech-presenting first twins who weighed at least 1500 g. Fetuses with breech presentation may be delivered as described in Chapter 24.

The phenomenon of locked twins is rare. According to Cohen and co-workers (1965), it occurred only once in 817 twin gestations. For twins to lock, the first fetus must present breech and the second, cephalic. With descent of the breech through the birth canal, the chin of the first fetus locks between the neck and chin of the second. Cesarean delivery is recommended when the potential for locking is identified.

Vaginal Delivery of the Second Twin

Following delivery of the first twin, the presenting part of the second twin, its size, and its relationship to the birth canal should be quickly and carefully ascertained by combined abdominal, vaginal, and at times, intrauterine examination. Sonography may be a valuable aid. If the fetal head or the breech is fixed in the birth canal, moderate fundal pressure is applied and membranes are ruptured. Immediately afterward, digital examination of the cervix is repeated to exclude prolapse of the cord. Labor is allowed to resume. If contractions do not resume within approximately 10 minutes, dilute oxytocin may be used to stimulate contractions.

In the past, the safest interval between delivery of the first and second twins was commonly cited as less than 30 minutes. Subsequently, as shown by Rayburn and colleagues (1984), as

well as others, if continuous fetal monitoring is used, a good outcome is achieved even if this interval is longer. Leung and colleagues (2002) demonstrated a direct correlation between worsening umbilical cord blood gas values and increasing time between delivery of first and second twins. Thus, vigilant monitoring for nonreassuring fetal heart rate or bleeding is required. Hemorrhage may indicate placental abruption.

If the occiput or breech presents immediately over the pelvic inlet, but is not fixed in the birth canal, the presenting part can often be guided into the pelvis by one hand in the vagina, while a second hand on the uterine fundus exerts moderate pressure caudally. Alternatively, with abdominal manipulation, an assistant can guide the presenting part into the pelvis. Sonography can add guidance and allow heart rate monitoring. Intrapartum external version of a noncephalic second twin has also been described (Chervanak and co-workers, 1983).

A presenting shoulder may be gently converted into a cephalic presentation. If the occiput or breech is not over the pelvic inlet and cannot be so positioned by gentle pressure, or if appreciable uterine bleeding develops, delivery of the second twin can be problematic.

To obtain a favorable outcome, it is essential to have an obstetrician skilled in intrauterine fetal manipulation and anesthesia personnel skilled in providing anesthesia to effectively relax the uterus for vaginal delivery of a noncephalic second twin. To take maximum advantage of the dilated cervix before the uterus contracts and the cervix retracts, delay must be avoided. Prompt cesarean delivery of the second fetus is preferred if no one present is skilled in the performance of internal podalic version or if anesthesia that will provide effective uterine relaxation is not immediately available.

Internal Podalic Version

With this maneuver, a fetus is turned to a breech presentation using the hand placed into the uterus (**Fig. 39-26**). The obstetrician grasps the fetal feet to then effect delivery by breech extraction. Chauhan and colleagues (1995) compared outcomes of 23 second twins delivered by podalic version and breech extraction with those of 21 who underwent external cephalic version. Breech extraction was considered superior to external version, because less fetal distress developed. The technique of breech extraction is described in Chapter 24 (p. 536).

Vaginal Birth after Cesarean

There are studies that support an attempt at vaginal birth after cesarean for selected women with twins. With this situation, there is approximately the same risk for uterine rupture as an attempt at vaginal birth with a singleton gestation (Cahill, 2005; Ford, 2006; Varner, 2005, and all their co-workers).

Cesarean Delivery

Twin fetuses create unusual intraoperative problems. Hypotension commonly develops in women carrying twins when they are placed supine. Therefore, these women should be positioned in a left lateral tilt to deflect uterine weight off the aorta (see Chap. 5, p. 119). The uterine incision should be large enough to allow atraumatic delivery of both fetuses. In some cases, a vertical incision in the lower uterine segment may be advantageous. For example, if a fetus is transverse with its back down, and the arms are inadvertently delivered first, it is much easier and safer to extend a vertical uterine incision upward than to extend a transverse incision. If a second twin is breech and delivery of the head is obstructed, Piper forceps can be used just as for a vaginal delivery (see Fig. 24-16, p. 539).

At times, attempts to deliver a second twin vaginally after delivery of a first twin are not only unwise but also impossible. In these cases, prompt cesarean delivery is required. Cesarean delivery of the second twin may be necessary, for example, when the second fetus is much larger than the first and is breech or transverse. Even more perplexing, cesarean delivery may be required if the cervix promptly contracts and thickens after delivery of the first twin and does not dilate subsequently or if a nonreassuring fetal heart rate pattern develops.

TRIPLET OR HIGHER-ORDER GESTATION

Fetal heart rate monitoring during labor is challenging. A scalp electrode can be attached to the presenting fetus, but it is difficult to ensure that the other two triplets are each being monitored separately. With vaginal delivery, the first neonate is usually born spontaneously or with little manipulation. Subsequent fetuses, however, are delivered according to the presenting part. This often requires complicated obstetrical maneuvers such as total breech extraction with or without internal podalic version or even cesarean delivery. Associated with malposition of fetuses is an increased incidence of cord prolapse. Moreover, reduced

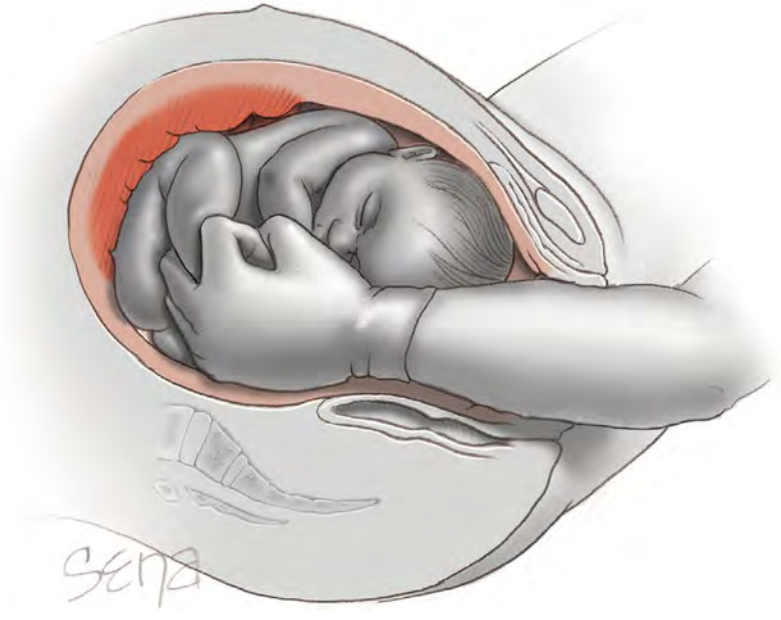

FIGURE 39-26 Internal podalic version. Upward pressure on the head by an abdominal hand is applied as downward traction is exerted on the feet.

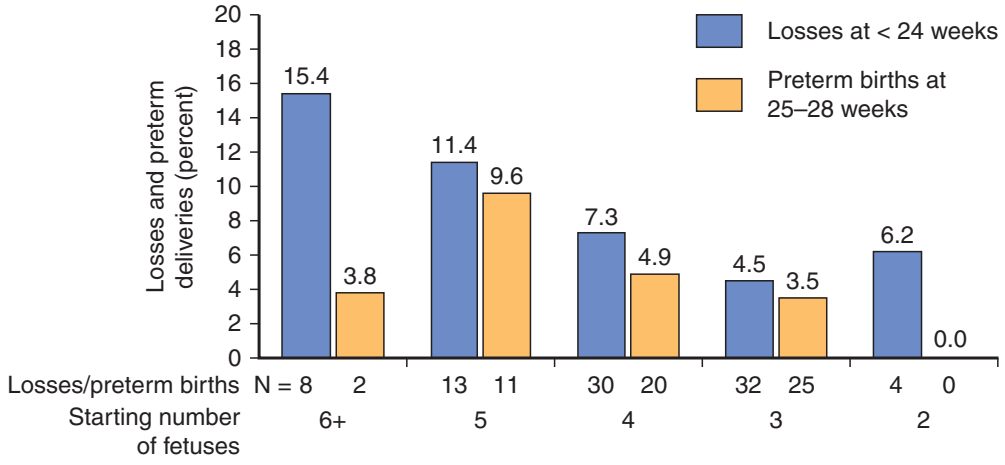

FIGURE 39-27 Histogram showing the rate of pregnancy losses at less than 24 weeks and preterm birth at 25 to 28 weeks as a function of the initial number of multiple fetuses in more than 1000 women who underwent selective reduction of pregnancy from 1995 to 1998. (Modified from *American Journal of Obstetrics & Gynecology*, Vol. 184, No. 2, MI Evans, RL Berkowitz, RJ Wapner, et al., Improvement in outcomes of multifetal pregnancy reduction with increased experience, pp. 97–103, Copyright 2001, with permission from Elsevier.)

placental perfusion and hemorrhage from separating placentas are more likely during delivery.

For all these reasons, many clinicians believe that pregnancies complicated by three or more fetuses are best delivered by cesarean. Vaginal delivery is reserved for those circumstances in which survival is not expected because fetuses are markedly immature or maternal complications make cesarean delivery hazardous to the mother. Other clinicians believe that vaginal delivery is safe under certain circumstances. For example, Alamia and colleagues (1998) evaluated a protocol for vaginal delivery of triplet pregnancies in which the presenting fetus was cephalic. A total of 23 sets of triplets were analyzed, and a third of these were delivered vaginally. Neonatal outcomes were the same in the vaginal and cesarean delivery groups, with no morbidity and 100-percent fetal survival. Grobman and colleagues (1998) and Alran and co-workers (2004) reported vaginal delivery completion rates of 88 and 84 percent, respectively, in women carrying triplets who underwent a trial of labor. Neonatal outcomes did not differ from those of a matched group of triplet pregnancies delivered by elective cesarean. As in any obstetrical procedure, the safety of vaginal triplet delivery depends on the skill and experience of the operator.

SELECTIVE REDUCTION OR TERMINATION

In some cases of higher-order multifetal gestation, reduction in the number of fetuses to two or three improves survival of the remaining fetuses. Selective reduction implies early pregnancy intervention, whereas selective termination is performed later.

Selective Reduction

Reduction of a selected fetus or fetuses in a multichorionic multifetal gestation may be chosen as a therapeutic intervention to enhance survival of the other fetuses. Pregnancy reduction can be performed transcervically, transvaginally, or transabdominally, but the transabdominal route is usually easiest. Transabdominal fetal reductions are typically performed between 10 and 13 weeks. This gestational age is chosen because most spontaneous abortions have already occurred, the remaining fetuses are large enough to be evaluated sonographically, the amount of devitalized fetal tissue remaining after the procedure is small, and the risk of aborting the entire pregnancy as a result of the procedure is low. The smallest fetuses and any anomalous fetuses are chosen for reduction. Potassium chloride is then injected into the heart or thorax of each selected fetus under sonographic guidance, taking care not to enter or traverse the sacs of fetuses selected for retention. In most cases, pregnancies are reduced to twins to increase the chances of delivering at least one viable fetus.

Evans and associates (2005) reported continued improvement in fetal outcomes with this procedure. They analyzed more than 1000 pregnancies managed in 11 centers from 1995 to 1998 (Fig. 39-27). The pregnancy loss rate varied from a low of 4.5 percent for triplets who were reduced to twins, and increased with each addition to the starting number of fetuses, peaking at 15 percent for six or more fetuses (Evans and colleagues, 2001). Operator skill and experience are believed responsible for the low and declining rates of pregnancy loss.

Selective Termination

With the identification of multiple fetuses discordant for structural or genetic abnormalities, three options are available: abortion of all fetuses, selective termination of the abnormal fetus, or continuation of the pregnancy. Because anomalies are typically not discovered until the second trimester, selective termination is performed later in gestation than selective reduction and entails greater risk. This procedure is therefore usually not performed unless the anomaly is severe but not lethal, meaning that the anomalous fetus would survive and require lifetime care, or the estimated risk of continuing the pregnancy is greater than the risk of the procedure.

Thus, a triplet pregnancy in which one fetus has Down syndrome might be a candidate for selective termination, whereas a twin pregnancy in which one has trisomy 18 might not. In

some cases, termination is considered because the abnormal fetus may jeopardize the normal one. For example, pathological hydramnios in a twin with esophageal atresia could lead to preterm birth of its sibling. Audibert and colleagues (2003) reported the selective termination of a severely growth-restricted twin fetus at 32 weeks, with marked improvement in the severity of maternal preeclampsia and subsequent delivery of a healthy sibling twin at 38 weeks. Prerequisites to selective termination include a precise diagnosis for the anomalous fetus and absolute certainty of fetal location. Thus, if genetic amniocentesis is performed on a multifetal gestation, a map of the uterus with locations of all the fetuses clearly labeled should be made at the time of the diagnostic procedure. Unless a special procedure such as umbilical cord interruption is used, selective termination should be performed only in multichorionic multifetal gestations to avoid damaging the surviving fetus(es) (Lewi and associates, 2006).

Evans and co-workers (1999) have provided the most comprehensive results to date on second-trimester selective termination for fetal abnormalities. A total of 402 cases were analyzed from eight centers worldwide. Included were 345 twin, 39 triplet, and 18 quadruplet pregnancies. Selective termination using potassium chloride resulted in delivery of a viable neonate or neonates in more than 90 percent of cases, with a mean age at delivery of 35.7 weeks. Loss of the entire pregnancy was 7.1 percent of pregnancies reduced to singletons and 13 percent of those reduced to twins. The gestational age at the time of the procedure did not appear to affect pregnancy loss. Several losses occurred because the pregnancy was actually monochorionic and potassium chloride also killed the normal fetus through placental vascular anastomoses.

Ethics

The ethical issues associated with these techniques are almost limitless. The interested reader is referred to the excellent reviews by Evans and co-workers (1996, 2004) and Simpson and Carson (1996).

Informed Consent

Prior to selective termination or reduction, a discussion should include the morbidity and mortality rates expected if the pregnancy is continued; the morbidity and mortality rates expected with surviving twins or triplets; and the risks of the procedure itself.

With couples seeking infertility treatment, the issue of selective reduction should ideally be discussed *prior* to conception. Grobman and associates (2001) reported that these couples were generally unaware of the risks associated with multifetal gestation, and they were less desirous of having a multifetal gestation once apprised of the risks.

Specific risks that are common to selective termination or reduction include:

1. Abortion of the remaining fetuses
2. Abortion of the wrong (normal) fetus(es)
3. Retention of genetic or structurally abnormal fetuses after a reduction in number
4. Damage without death to a fetus
5. Preterm labor
6. Discordant or growth-restricted fetuses
7. Maternal infection, hemorrhage, or possible disseminated intravascular coagulopathy because of retained products of conception.

The procedure should be performed by an operator skilled and experienced in sonographically guided procedures. Because selective reduction increases the maternal serum alpha-fetoprotein level, a couple should be informed that this screening test will not be useful after the procedure (Lynch and Berkowitz, 1993). Instead, a second-trimester targeted sonographic evaluation or possibly amniocentesis may be offered.

Psychological Reaction

Women and their spouses who elect to undergo selective termination or reduction find this decision highly stressful. Schreiner-Engel and associates (1995) retrospectively studied the emotional reactions of 100 women following selective reduction. Although 70 percent of the women mourned for their dead fetus(es), most grieved only for 1 month. Persistent depressive symptoms were mild, although moderately severe sadness and guilt continued for many for them. Fortunately, most were reconciled to the termination of some fetuses to preserve the lives of a remaining few. Indeed, 93 percent of the women would have made the same decision again.

CHAPTER 40

Reproductive Tract Abnormalities

DEVELOPMENTAL REPRODUCTIVE TRACT ABNORMALITIES 890
ACQUIRED REPRODUCTIVE TRACT ABNORMALITIES 898
ENDOMETRIOSIS AND ADENOMYOSIS 904

In some cases, pregnancy is complicated by preexisting abnormalities of the reproductive tract. Most of these are developmental anomalies formed during embryogenesis, but they may be acquired during adulthood and sometimes during pregnancy.

DEVELOPMENTAL REPRODUCTIVE TRACT ABNORMALITIES

Due to abnormal embryogenesis, a number of sporadic genitourinary defects may occur. Serious defects are hazardous for the fetus and mother. Even minor maternal defects may result in an increased incidence of miscarriage, preterm labor, and abnormal fetal presentation.

Embryogenesis of the Reproductive Tract

To understand the etiology of developmental abnormalities of the vagina, cervix, and uterus, it is important to first understand their embryogenesis. This is discussed in further detail in Chapter 4 (p. 98) and summarized in **Figure 40-1**. The proper temporal sequence of gene expression and appropriate spatial relationships of developing tissues are crucial to normal development.

Development of the reproductive organs from intermediate mesodermal elements begins between the third and fifth gestational weeks. Differentiation of the urinary system begins as the mesonephric ducts emerge and connect with the cloaca. Between the fourth and fifth weeks, two ureteric buds develop from the mesonephric (Wolffian) ducts and begin to grow cephalad toward the mesonephros. As each bud lengthens, it induces differentiation of the metanephros, which will become the kidney. The genital system begins development when the müllerian (paramesonephric) ducts form bilaterally between the developing gonad and the mesonephros. The müllerian ducts extend downward and laterally to the mesonephric ducts. They finally turn medially to meet and fuse together in the midline. The fused müllerian duct descends to the urogenital sinus to join the müllerian tubercle behind the cloaca. The close association between the müllerian and mesonephric ducts has clinical relevance. Damage to either duct system is often associated with anomalies that involve the uterine horn, kidney, and ureter.

The uterus is formed by the union of the two müllerian ducts at about the 10th week. Fusion begins in the middle and then extends caudally and cephalad. The characteristic uterine shape is then formed, with cellular proliferation at the upper portion and a simultaneous dissolution of cells at the lower pole, thus establishing the first uterine cavity. This cavity is formed at the lower pole, whereas a thick wedge of tissue lies above it, which is the septum. As the septum is slowly resorbed, it creates the uterine cavity, which is usually completed by the 20th week. Failure of fusion of the two müllerian ducts leads to separate uterine horns, whereas failure of cavitation between them results in some degree of persistent uterine septum. Uncommonly, there is cervical and vaginal duplication associated with a septate uterus. This supports Müller's alternative hypothesis that fusion and absorption begin at the isthmus and progress in both cranial and caudad directions simultaneously.

The uterovaginal canal is the distal end of the fused müllerian ducts. The vagina forms between the urogenital sinus and the müllerian tubercle by a dissolution of the cell cord between the two structures. It is believed that this dissolution starts at the hymen and moves upward toward the cervix. Failure of this process is associated with persistence of the cell cord. *Vaginal*

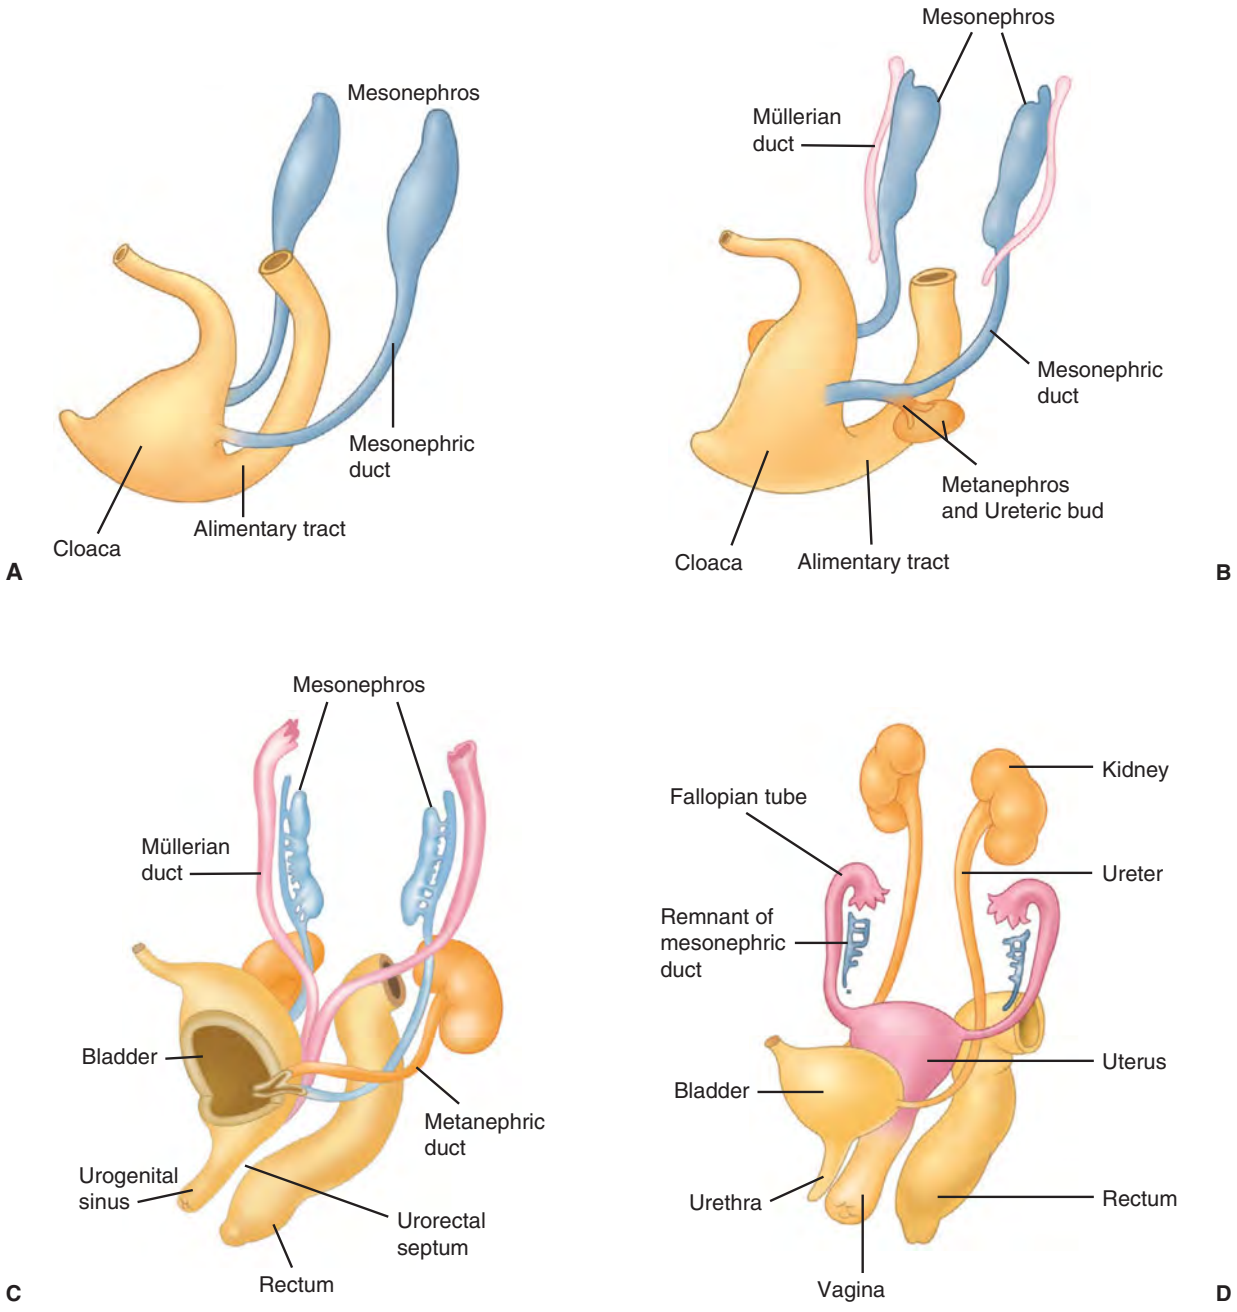

FIGURE 40-1 Development of the female reproductive systems from the genital ducts and urogenital sinus. Vestigial structures are also shown. **A.** Reproductive system at 6 weeks before differentiation. **B.** In the female, the müllerian (paramesonephric) ducts grow downward and extend to enter the urogenital sinus, after which they become fused. **C.** Uterine cavitation occurs at site of fused müllerian ducts and the uterus continues downward growth. **D.** Cavitation is complete and the lower segment and cervix, along with the upper vagina, are formed. (Reprinted from Schorge J, Schaffer J, Halvorson L, et al: *Williams Gynecology*, p. 403. Copyright © 2008 The McGraw-Hill Companies, Inc.)

agenesis is the result of either failed caudal migration of the fused müllerian duct or incomplete cell cord resorption. The latter may result in complete vaginal obstruction, or, if less severe, partial persistence and a *vaginal septum*.

The cephalad portion of the urogenital sinus forms the bladder. The caudal portion of the mesonephric ducts penetrates the trigone area. Later, metanephric ducts penetrate nearby and will become the ureters. The close association of the mesonephric–Wolffian and paramesonephric-müllerian ducts explains why there are commonly simultaneous abnormalities involving these structures. *Bladder exstrophy* is likely caused by abnormalities from failure of ingrowth of supporting mesoderm. For a more detailed discussion, see Bradshaw (2008) in *Williams Gynecology*.

Genesis and Classification of Müllerian Abnormalities

Because fusion of the two müllerian ducts forms the upper two thirds of the vagina as well as the cervix and uterus, the principal groups of deformities arising from three types of embryological defects can be classified as follows:

TABLE 40-1. American Fertility Society Classification of Müllerian Anomalies

I.	**Segmental müllerian hypoplasia or agenesis**
	a. Vaginal
	b. Cervical
	c. Uterine fundus
	d. Tubal
	e. Combined anomalies
II.	**Unicornuate uterus**
	a. Communicating rudimentary horn
	b. Noncommunicating horn
	c. No endometrial cavity
	d. No rudimentary horn
III.	**Uterine didelphys**
IV.	**Bicornuate uterus**
	a. Complete—division to internal os
	b. Partial
V.	**Septate uterus**
	a. Complete—septum to internal os
	b. Partial
VI.	**Arcuate**
VII.	**Diethylstilbestrol related**

Adapted from the American Fertility Society (1988).

1. Defective canalization of the vagina resulting in a transverse septum, or in the most extreme form, vaginal agenesis
2. Unilateral maturation of the müllerian duct with incomplete or absent development of the opposite duct resulting in defects associated with upper urinary tract abnormalities
3. Absent or faulty midline fusion of the müllerian ducts–the most common defect. Complete lack of fusion results in two entirely separate uteri, cervices, and vaginas. Incomplete tissue resorption between the two fused müllerian ducts results in a uterine septum. Fusion anomalies are thought to be polygenic or multifactorial (see Chap. 12, p. 280).

Various classifications of these anomalies have been proposed. As shown in Table 40-1, the American Fertility Society uses one suggested by Buttram and Gibbons (1979), which is based on failure of normal development. It separates a diversity of anomalies into groups with similar clinical characteristics, prognosis for pregnancy, and treatment. It includes a category for abnormalities associated with fetal exposure to diethylstilbestrol (DES). Vaginal anomalies have not been classified because they are not associated with fetal loss. In the current classification, they are most often associated with uterine didelphys and bicornuate anomalies. Class I segmental defects as shown in Figure 40-2 can affect the vagina, cervix, uterus, or tubes.

Vulvar Abnormalities

Complete *vulvar atresia* involves the introitus and lower third of the vagina. In most cases, however, atresia is incomplete and results from adhesions or scars following injury or infection. The defect may present a considerable obstacle to vaginal delivery, and although the resistance usually is overcome, deep perineal tears may result.

Labial fusion in adult women is most commonly due to classical congenital adrenal hyperplasia (see Chap. 4, p. 102). Other causes include fetal exogenous androgen exposure or abdominal wall defects. *Imperforate hymen* is persistence of the fusion between the sinovaginal bulbs at the vestibules. Typically, it is associated with primary amenorrhea and hematocolpos and is not encountered often during pregnancy.

Vaginal Abnormalities

Developmental abnormalities of the normal single vagina include:

1. Vaginal agenesis
2. Vaginal atresia
3. Double vagina
4. Longitudinal vaginal septum
5. Transverse vaginal septum

Obstetrical Significance

With complete müllerian agenesis, pregnancy is impossible because the uterus and vagina are absent. **About one third of women with vaginal atresia have associated urological abnormalities**. *Complete vaginal atresia*, unless corrected operatively, obviously precludes pregnancy by vaginal intercourse (American College of Obstetricians & Gynecologists, 2006). *Incomplete atresia* can be a manifestation of faulty development, as shown in Figure 40-2, or the result of scarring from injury or inflammation as discussed subsequently. In most cases of partial atresia, because of pregnancy-induced tissue softening, obstruction during labor is gradually overcome.

A *complete longitudinal vaginal septum* usually does not cause dystocia because half of the vagina through which the fetus descends dilates satisfactorily. An incomplete septum, however, occasionally interferes with descent. Sometimes the upper vagina is separated from the rest of the canal by a *transverse septum* with a small opening. Some of these are associated with in utero exposure to DES and are discussed on page 897. Such strictures may be mistaken for the upper limit of the vaginal vault. If so, at the time of labor, the septal opening is misidentified as an undilated cervical os. After the external os has dilated completely, the head impinges on the septum and causes it to bulge downward. If the septum does not yield, slight pressure on its opening usually leads to further dilatation, but occasionally cruciate incisions are required to permit delivery (Blanton and Rouse, 2003).

Cervical Abnormalities

There are a number of anatomical and developmental anomalies of the normal single cervix:

1. *Atresia*. The entire cervix may fail to develop. This may be combined with incomplete development of the upper vagina or lower uterus (see Fig. 40-2)

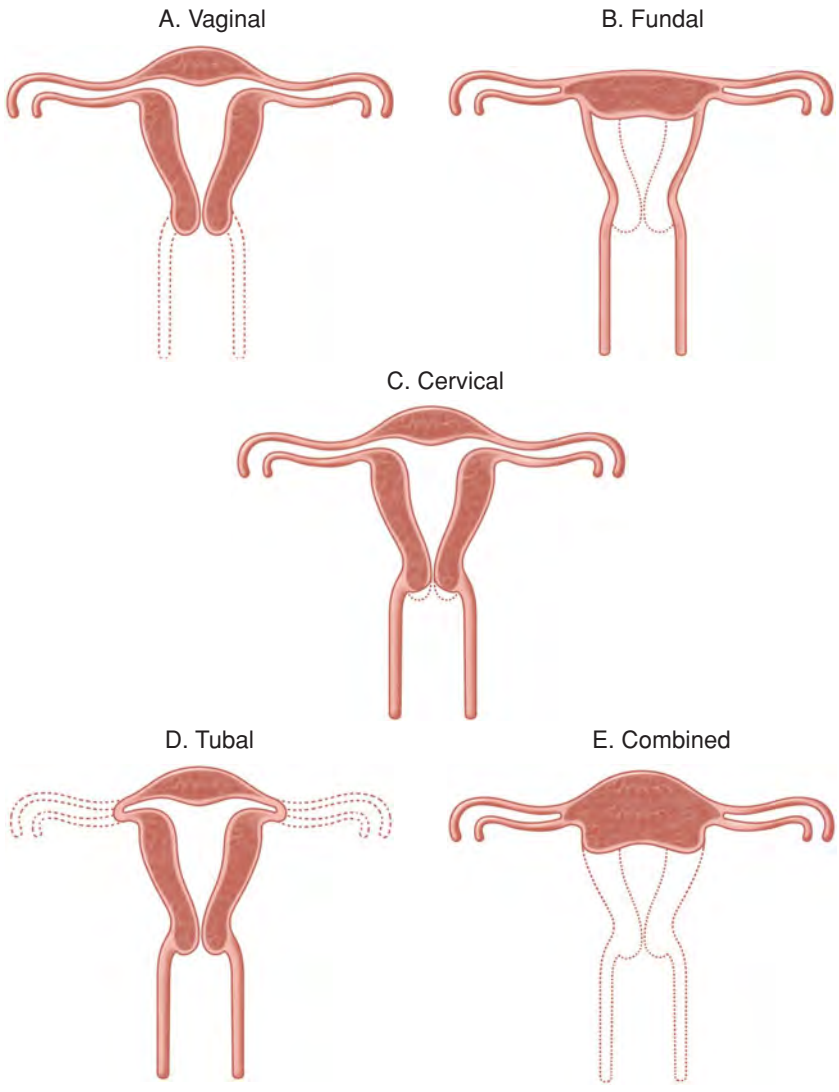

FIGURE 40-2 Class I müllerian anomaly: Segmental müllerian agenesis or hypoplasia (*hatched areas*).

2. *Double cervix.* Both septate and true double cervices are frequently associated with a longitudinal vaginal septum. Many septate cervices are erroneously classified as double
3. *Single hemicervix*
4. *Septate cervix.* This consists of a single muscular ring partitioned by a septum. The septum may be confined to the cervix, or more often, it may be the downward continuation of a uterine septum or the upward extension of a vaginal septum.

Obstetrical Significance

Uncorrected complete cervical atresia is incompatible with natural conception. Deffarges and colleagues (2001) reported six successful pregnancies in four women with cervical atresia after creation of a uterovaginal anastomosis.

Uterine Malformations

Some of the large variety of congenital uterine malformations are listed in Table 40-1, and examples shown in Figure 40-3. Although some are simply innocuous oddities, others may preclude normal procreation. Their incidence in all women is about 0.5 percent. Nahum (1998) reviewed 22 studies with more than 573,000 women who were screened for these malformations. Overall, the incidence was 1 in 200–it was about 1 in 600 for fertile women and 1 in 30 for those who were infertile. The distribution of uterine anomalies was as follows: bicornuate, 39 percent; septate, 24 percent; didelphic, 11 percent; arcuate, 7 percent; and hypo- or aplastic, 4 percent. Müllerian anomalies associated with recurrent pregnancy loss are discussed in Chapter 9 (p. 218).

Diagnosis

Some uterine anomalies are discovered by routine pelvic examination. Frequently, they are discovered at cesarean delivery. Others are first discovered at laparoscopy, for example, at the time of tubal sterilization. Several radiological modalities can aid diagnosis. However, each has diagnostic limitations, and thus they may be used in combination to completely define anatomy (Olpin and Heilbrun, 2009). Sonographic screening for uterine anomalies, while specific, is not sensitive (Nicolini and associates, 1987). Sonohysterography can be used to differentiate septate and bicornuate uteri (Alborzi and associates, 2002). In some cases, hysteroscopy and hysterosalpingography (HSG) are of value in ascertaining the configuration of the uterine cavity. In yet other cases, magnetic resonance (MR) imaging may be necessary to delineate müllerian duct anomalies and their extent. Although MR imaging is more expensive, it has a reported accuracy of up to 100 percent in evaluation of müllerian duct anomalies (Fedele and co-workers, 1989; Pellerito and colleagues, 1992).

Urological Defects

Asymmetrical reproductive tract abnormalities are frequently associated with urinary tract anomalies. When unilateral uterine atresia is present or when one side of a double vagina terminates blindly, an ipsilateral urological anomaly is common (Fedele and associates, 1987; Heinonen, 1983, 1984).

Auditory Defects

Up to a third of women with müllerian defects will have auditory defects (Letterie and Vauss, 1991). Typically these are sensorineural hearing deficits in the high-frequency range.

Uterine Anomalies in Wilms Tumor Survivors

This rare malignancy appears to be associated with an increased incidence of congenital urinary and reproductive tract anomalies

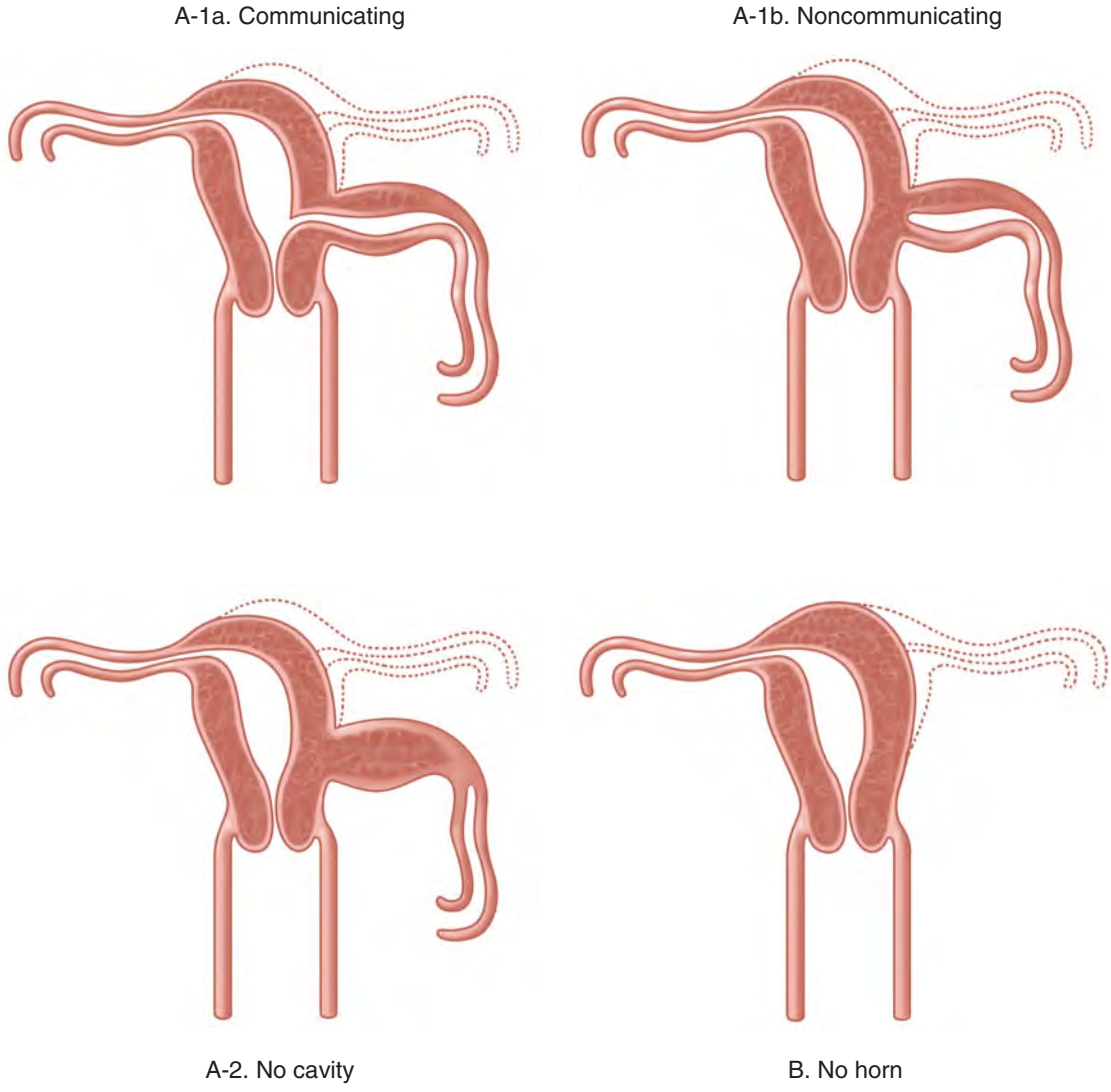

FIGURE 40-3 Class II müllerian anomalies: Unicornuate uterus either with rudimentary horn **(A)** or without rudimentary horn **(B)**. Those with a rudimentary horn are divided into groups with an endometrial cavity (**A-1**) or without an endometrial cavity (**A-2**). Those with an endometrial cavity either have a communication with the opposite uterine horn (**A-1-a**) or do not have a communication with the opposite horn (**A-1-b**). Hatching reflects the expected normal anatomy that is absent in these anomalies.

(Nicholson and colleagues, 1996). This might partially explain the increased rate of infertility reported in female survivors.

Obstetrical Significance

Major difficulties arise from many uterine anomalies. Defects that result from development of only one müllerian duct, or from lack of fusion, often give rise to a hemiuterus that fails to dilate and hypertrophy appropriately (Fig. 40-3). This may result in miscarriage, ectopic pregnancy, rudimentary horn pregnancy, preterm delivery, fetal growth restriction, abnormal fetal lie, uterine dysfunction, or uterine rupture (Ben-Rafael and associates, 1991; Michalas, 1991). In 64 women with a variety of uterine anomalies, Airoldi and associates (2005) found that midtrimester sonographic assessment of cervical length was fairly accurate for predicting preterm birth.

Valli and colleagues (2001) reported a 32-percent recurrent miscarriage rate in 344 women with a septate or unicornuate uterus compared with 6 percent in 922 control women. Miscarriage is even increased in women whose only anomaly is a uterine septum (Buttram and Gibbons, 1979; Raga and associates, 1997). That said, the American College of Obstetricians and Gynecologists (2001) cautions that repair of such defects may not prevent miscarriage. Anomalies may cause late pregnancy complications as well. Ravasia and colleagues (1999) reported that two of 25 women–8 percent–with a müllerian anomaly who underwent a trial of labor after cesarean delivery experienced uterine rupture. Tikkanen and associates (2006) found an eight-fold increased incidence of placental abruption in women with uterine anomalies.

Unicornuate Uterus (Class II). In a series of 1160 uterine anomalies, Zanetti and associates (1978) reported the incidence of unicornuate uterus diagnosed by HSG to be 14 percent. HSG, however, cannot be used to identify a noncommunicating rudimentary horn–by far the more common type.

TABLE 40-2. Pregnancy Outcomes in Women with a Unicornuate Uterus

Outcome	Heinonen 1983	Moutos 1992	Acien 1993	Fedele 1995	Total
Patients	15	20	24	26	85
Pregnancies	35	36[a]	55	57	183
Spontaneous abortions (%)[b]	4 (11)	13 (36)	12 (22)	33 (58)	62 (34)
Ectopic pregnancies (%)[b]	4 (11)	1 (2.8)	1 (1.8)	3 (5.2)[c]	9 (5)
Deliveries (%)[b]	27 (77)	22 (61)	42 (76)	21 (37)	112 (61)
Breech presentations[d]	9 (33)	—	13 (31)	—	
Cesarean deliveries[d]	8 (30)	8 (36)	—	—	
Preterm deliveries[d]	4 (15)	3 (14)	9 (21)	5 (24)	21 (19)
Term deliveries[d]	23 (85)	19 (86)	33 (79)	16 (76)	91 (81)
Fetal survival (%)[b]	25 (71)	21 (58)	39 (71)	20 (35)	105 (57)

[a]Excludes four elective abortions.
[b]Of all pregnancies.
[c]Includes one blind-horn pregnancy.
[d]Excludes abortions and ectopic pregnancies.

Women with a unicornuate uterus have an increased incidence of infertility, endometriosis, and dysmenorrhea (Fedele and associates, 1987, 1995; Heinonen, 1983). Obstetrical outcomes from a number of studies are shown in Table 40-2. Implantation in the normal-sized hemiuterus is associated with increased incidences of spontaneous abortion, preterm delivery, and intrauterine fetal demise (Reichman and coworkers, 2009).

Pregnancies in the rudimentary horn are usually disastrous (Fig. 40-4). Rolen and associates (1966) reported that uterine rupture occurred prior to 20 weeks in most of 70 rudimentary horn pregnancies. Nahum (2002) reviewed the literature from 1900 to 1999 and identified 588 such pregnancies. Half had uterine rupture, and 80 percent of these were before the third trimester. Of the total 588, neonatal survival was only 6 percent. Most of the 23 maternal deaths were before 1950. More liberal use of high-resolution sonography and MR imaging may result in an earlier diagnosis of rudimentary horn pregnancy, allowing surgical or medical therapy before rupture (Edelman, 2003; Vo, 2003; Worley, 2008, and all their colleagues).

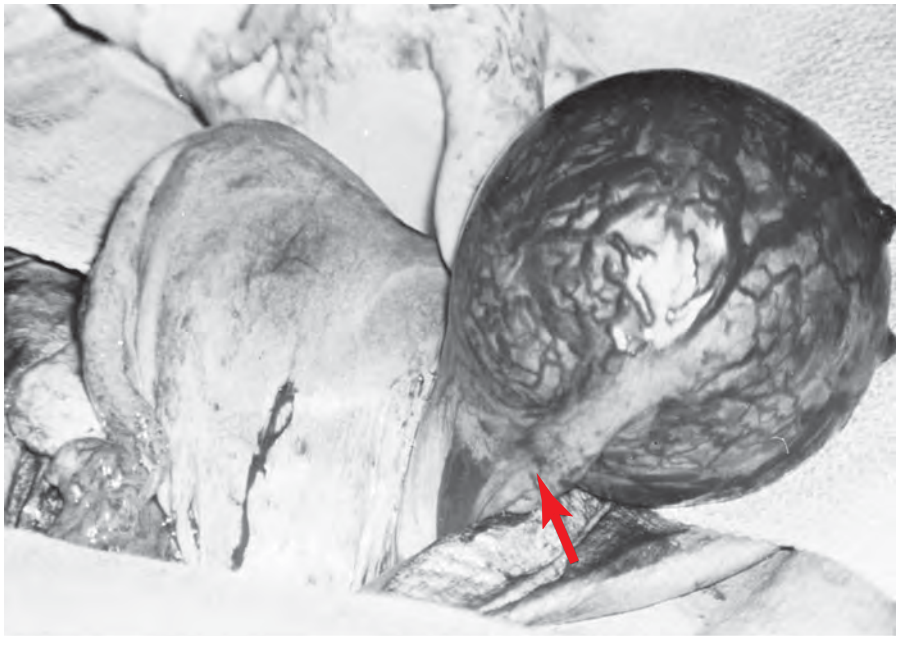

FIGURE 40-4 A 15-week pregnancy in a woman with three prior vaginal breech deliveries. As seen at laparotomy, the pregnancy is in the left noncommunicating rudimentary uterine horn. The attached fallopian tube (*arrow*) was patent.

Uterine Didelphys (Class III). This anomaly is distinguished from bicornuate and septate uteri by the presence of complete nonfusion of the cervix and hemiuterine cavity (Fig. 40-5). Heinonen (1984) reported that all 26 women with a uterine didelphys had a longitudinal vaginal septum as well. Occasionally, one hemivagina is obstructed by an oblique or transverse vaginal septum (Asha, 2008; Coskun, 2008; Hinckley, 2003, and all their associates).

Except for ectopic and rudimentary horn pregnancies, problems associated with uterine didelphys are similar but less frequent than those seen with unicornuate uterus. Heinonen (1984) reported 70 percent successful pregnancy outcomes. There was preterm delivery in 20 percent, fetal-growth restriction in 10 percent, and breech presentation in 43 percent. The cesarean delivery rate was 82 percent. Multifetal gestation is unusual in these women (Oláh, 2002).

An increasing number of cases have been described in which there is a septate uterus–instead of two hemiuteri–along with a duplicated cervix and longitudinal

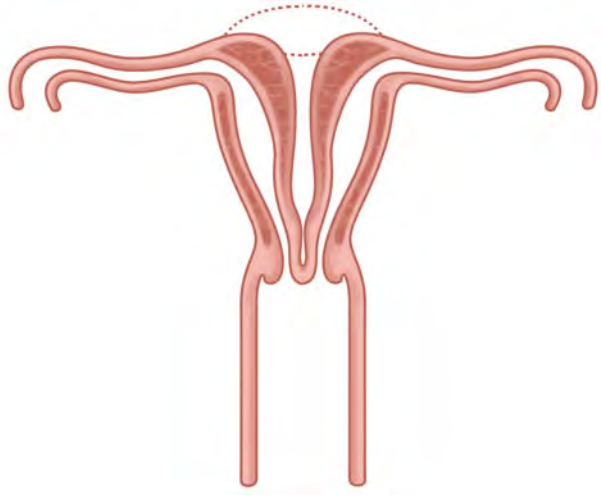

FIGURE 40-5 Class III müllerian anomaly: Uterine didelphys.

vaginal septum (Patton, 2004; Pavone, 2006; Saygili-Yilmaz, 2004, and all their colleagues). And Varras and colleagues (2007) described such duplication with a single, nonseptate uterine cavity. These constellations of features do not fit into the standard classification scheme (Table 40-1).

Bicornuate and Septate Uteri (Classes IV and V). In both of these types of anomalies–shown in **Figures 40-6** and **40-7**, there is a marked increase in miscarriages that is likely due to the abundant muscle tissue in the septum (Dabirashrafi and colleagues, 1995). In addition, abnormal endometrium overlying the uterine septum may lead to abnormal implantation or defective early embryo development and subsequent miscarriage (Candiani and co-workers, 1983; Fedele and colleagues, 1996). Of the two defects, miscarriage with a septate uterus is more common (Proctor and Haney, 2003). Pregnancy losses in the first 20 weeks were reported by Buttram and Gibbons (1979) to be 70 percent for bicornuate and 88 percent for septate uteri. Woelfer and colleagues (2001) reported a first-trimester loss rate for septate uteri of 42 percent. The majority of women with müllerian anomalies

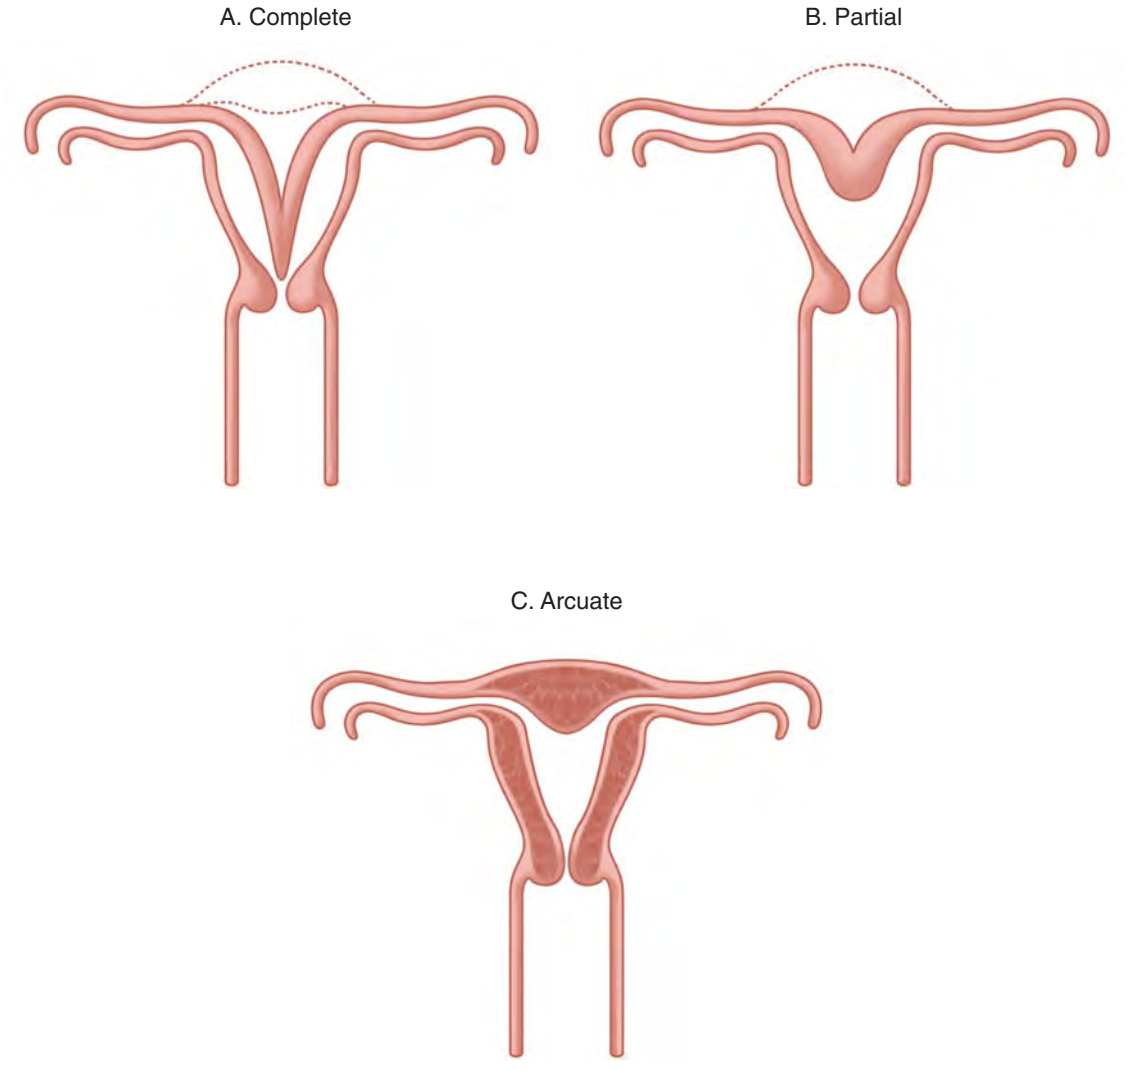

FIGURE 40-6 Class IV müllerian anomaly: Complete bicornuate uterus **(A)** and partial **(B)**. Class VI arcuate uterus **(C)**.

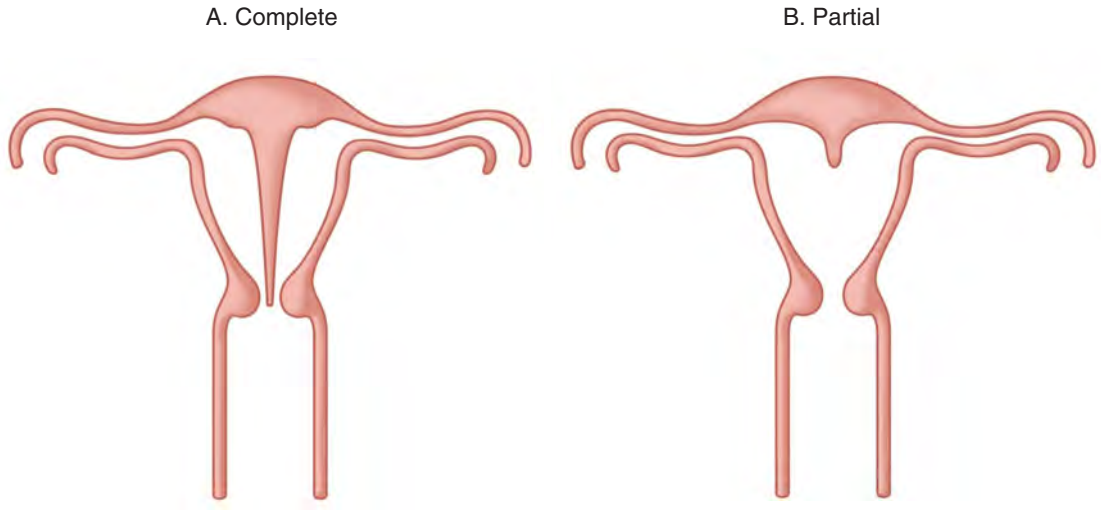

FIGURE 40-7 Class V müllerian anomaly: Septate uterus with complete septum to the cervical os **(A)** or partial septum **(B)**.

have lateral placental implantation with poor perinatal outcomes (Leible and associates, 1998). There also is an increased incidence of preterm delivery, abnormal fetal lie, and cesarean delivery. Heinonen (1999) described three newborns with a limb-reduction defect born to women with a septate uterus.

Arcuate Uterus (Class VI). This malformation is only a mild deviation from the normally developed uterus. Raga and associates (1997) reported no impact on reproductive outcomes. Conversely, Woelfer and colleagues (2001) found excessive second-trimester losses and preterm labor.

Management

Women with nonobstructive defects such as uterine didelphys and unicornuate uterus usually do not need surgical correction (Stenchever, 2001). Although abnormal fetal presentation is common, external cephalic version is less likely to be successful.

Cerclage. A number of investigators have reported that cervical cerclage in women with some of these anomalies and repetitive pregnancy losses may improve outcomes (Golan, 1990b, 1992; Golan and Caspi, 1992; Maneschi, 1988; Seidman, 1991, and all their co-workers). Transabdominal cerclage may offer the best prognosis for women with partial cervical atresia or hypoplasia (Hampton and colleagues, 1990; Mackey and co-workers, 2001). Transvaginal cerclage has been used successfully in DES-exposed women with cervical hypoplasia (Ludmir and co-workers, 1991).

Cerclage should not be done simply because a uterine septum has been resected. It probably should still be used following abdominal metroplasties for uterine didelphys and bicornuate uteri. If active labor supervenes, the cervical ligature is removed to prevent uterine rupture. Cerclage is discussed in detail in Chapter 9 (p. 219).

Metroplasty. Women with septate or bicornuate anomalies and poor reproductive outcomes may benefit from uterine surgery (Lolis and associates, 2005; Papp and co-workers, 2006). Repair of a bicornuate uterus is by transabdominal metroplasty involving septal resection and fundal recombination (Candiani and associates, 1990).

Repair of a septate uterus is usually by hysteroscopic septal resection (Grimbizis and colleagues, 1998; Pabuccu and Gomel, 2004). Some prefer transabdominal surgery (Papp and colleagues, 2006). In a review of pregnancy outcomes following repair of a septate uterus, Stenchever (2001) reported that about half of 351 pregnancies resulted in a liveborn infant. Preterm labor is common (Litta and colleagues, 2004). Despite minimal operative uterine wall invasion, disastrous fundal rupture has been reported (Angell and co-workers, 2002).

Diethylstilbestrol-Induced Reproductive Tract Abnormalities

Through the early 1960s, diethylstilbestrol (DES), a synthetic nonsteroidal estrogen, was prescribed for an estimated 3 million pregnant women in the United States to treat abortion, preeclampsia, diabetes, and preterm labor. Although the drug was remarkably *ineffective* for these indications, Herbst and co-workers (1971) discovered that fetal DES exposure was linked to the later development of rare vaginal clear cell adenocarcinoma. Subsequently, it was found that women exposed as fetuses also had an increased risk of developing cervical intraepithelial neoplasia, small-cell cervical carcinoma, vaginal adenosis, and several non-neoplastic structural abnormalities. Although most, if not all, of women exposed as fetuses have passed childbearing age, a summary of this pharmaceutical debacle follows.

About a fourth of women exposed to DES in utero have identifiable structural variations in the cervix and vagina (Swan, 2000). These are in class VII of the American Fertility Society (1988) and include transverse septa, circumferential ridges involving the vagina and cervix, and cervical collars. Smaller uterine cavities, shortened upper uterine segments, and T-shaped and irregular cavities have also been described, as well as oviduct abnormalities (Barranger and associates, 2002).

In general, DES-exposed women have impaired conception rates possibly associated with cervical hypoplasia and atresia (Palmer and colleagues, 2001; Senekjian and co-workers, 1988). Their incidences of miscarriage, ectopic pregnancy, and preterm delivery are also increased, especially in women with structural abnormalities (Goldberg and Falcone, 1999; Kaufman and associates, 1984, 2000). Exposed women enter menopause slightly earlier than nonexposed controls (Hatch and coworkers, 2006). Spontaneous uterine rupture with pregnancy is more likely and was reported as early as 12 weeks (Porcu and colleagues, 2003). The risk of ectopic pregnancy is increased at least fourfold. Finally, an increased incidence of cervical incompetence is associated with midpregnancy losses and preterm delivery (Ludmir and colleagues, 1987).

Transgenerational Anomalies

Genital tract anomalies have been described in the offspring of women exposed to DES *when they were a fetus.* Felix and colleagues (2007) recently discussed a possible transgenerational association with tracheoesophageal anomalies (see Chap. 14, p. 322).

ACQUIRED REPRODUCTIVE TRACT ABNORMALITIES

Vulvar Abnormalities

A number of acute and chronic vulvar conditions may prove vexing to both the woman and her obstetrician.

Edema

Many women have some degree of vulvar edema during pregnancy. At times, it can be impressive and without an identifiable pathological cause. In women with the nephrotic syndrome and hypoproteinemia, vulvar edema may be problematic as early as midpregnancy (see Fig. 48-6, p. 1044). During labor, the vulva may become edematous, especially in women with severe preeclampsia. Venous thromboses and hematomas occasionally cause edema and significant pain. In postpartum women, edema associated with a paravaginal, vulvar, or perineal hematoma arising from lacerations or an episiotomy may be extensive (see Chap. 35, p. 783).

Inflammatory Lesions

Extensive perineal inflammation and scarring from *hidradenitis suppurativa, lymphogranuloma venereum*, or *Crohn disease* may create difficulty with vaginal delivery, episiotomy, and repair. A mediolateral episiotomy may prevent some of these difficulties. McCarthy-Keith and Coggins (2008) described a woman with a known perineal endometrioma that grew slightly but became more painful during pregnancy.

Bartholin Gland Lesions

Cysts of the Bartholin gland duct are usually sterile and need no treatment during pregnancy. If the cysts are large enough to cause difficulty at delivery, then needle aspiration as a temporary measure is sufficient. If the gland is infected, there is tenderness accompanying vulvar edema. Treatment is given with broad-spectrum antimicrobials, and if there is an abscess, drainage is established. Cultures for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are obtained. For a large abscess with extensive cellulitis, drainage is best performed in the operating room. The cut edges of the abscess cavity are marsupialized and packed with gauze, which is removed the next day. Alternatively, a Word catheter may be used. In some cases, especially in diabetic or immunocompromised women, life-threatening *necrotizing fasciitis* may develop (see Chap. 31, p. 669).

Urethral and Bladder Lesions

Infections may cause periurethral abscesses that usually resolve spontaneously, but some become asymptomatic cysts. Urethral diverticula are associated with recurrent urinary infections. From their review, Patel and Chapple (2006) recommend MR imaging for evaluation. Drainage may be necessary, but in general, excision of cysts or diverticula is not performed during pregnancy.

Bladder lesions are uncommon, but obstructed labor by stones has been reported (Penning and associates, 1997; Rai and Ramesh, 1998). Occasionally, *bladder tumors* may require cesarean delivery (Hendry, 1997).

Condyloma Acuminata

Genital infection with the sexually transmitted human papillomavirus (HPV) results in condyloma acuminata–also called *venereal warts*. Rarely, they are so extensive that they preclude vaginal or vulvar distension and prohibit vaginal delivery (see Chap. 59, p. 1245). The newly approved quadrivalent HPV vaccines are expected to prevent some of these (Garland and colleagues, 2007).

Female Genital Mutilation

Inaccurately called female circumcision, mutilation refers to medically unnecessary vulvar and perineal modification. According to the World Health Organization (2006), forms of female genital mutilation are practiced in countries throughout Africa, the Middle East, and Asia. As many as 130 million women have undergone one of these procedures, and approximately 230,000 live in the United States (Nour and colleagues, 2006). Cultural sensitivity is imperative, because many women may be offended by the suggestion that they have been mutilated (American College of Obstetricians and Gynecologists, 2002).

The World Health Organization (2000) classifies genital mutilations into four types shown in **Table 40-3**. Other commonly used terms include *sunna* for type I, *excision* for type II, and *infibulation* or *pharaonic circumcision* for type III. A type I procedure performed under sterile conditions, which is often not the case, rarely has long-term adverse physical consequences (Toubia, 1994). A type III extreme form of mutilation consists of the removal of the entire clitoris and labia minora, and at least two thirds of the labia majora (**Fig. 40-8**). The procedure is typically performed on girls 7 years of age without anesthesia by midwives or village women. Commonly used instruments are razor blades, kitchen knives, scissors, glass, and even the teeth of the midwife. The two vulvar edges are stitched together by silk or catgut or are held together by thorns. A small open-

TABLE 40-3. World Health Organization Classification of Female Genital Mutilation

Type I	Excision of the prepuce with or without excision of the clitoris
Type II	Excision of the clitoris and partial or total excision of the labia minora
Type III	Excision of part or all of the external genitalia and infibulation
Type IV	Unclassified and includes pricking, piercing, incision, stretching, and introduction of corrosive substances into the vagina

Adapted from the World Health Organization, 1997.

ing–usually made by the insertion of a matchstick–is left for the passage of menstrual blood and urine. The legs of the girl are then bound from hip to ankle for as many as 40 days so that scar tissue will form. Immediate dangers are exsanguination and severe infections. Urinary retention is common.

Long-term sequelae depend on the severity of mutilation. Okonofua and associates (2002) reported that half of women attending clinics in Nigeria had been mutilated. Of these, 70 percent had undergone type I and 25 percent type II procedures. These women had normal sexual function but a threefold risk of vaginal infection or genital ulcers. Complications of type III procedures include sterility, dysmenorrhea, dyspareunia, and propensity to HIV infection (Almroth and co-workers, 2005; Chen and associates, 2004; Nour, 2004, 2006). Neuroma formation after clitoral amputation has also been described (Ferñandez-Aguilar and Noël, 2003). In another case, a urinary calculus formed under an infibulation scar from urine stagnation (Nour, 2006).

FIGURE 40-8 Sequelae of type III infibulation or pharaonic circumcision. This ritual mutilation procedure included clitoridectomy, excision of labia minora, and incision of labia majora. Remnant labia majora have been approximated, leaving a small neointroitus (*arrowhead*) into which scissors are inserted. The arrow points to the clitoris. (Reprinted from Nour NM, Michels KB, and Bryant AE: Defibulation to treat female genital cutting: Effect on symptoms and sexual function, *Obstetrics & Gynecology*, 2006, vol. 108, no. 1, pp. 55–60, with permission.)

In general, women with significant symptoms following type III procedures are candidates for surgical defibulation, also referred to as deinfibulation.

Legislation to Prohibit Mutilations. The American College of Obstetricians and Gynecologists (2002), along with the International Federation of Gynecology and Obstetrics, the American Medical Association, the United Nations International Children's Emergency Fund, and the World Health Organization, has supported legislation to eliminate female genital mutilation. The American Academy of Pediatrics (1998) encourages development of community educational programs for immigrant populations. In the United States it is a federal crime to perform unnecessary genital surgery on a girl younger than 18 years. In some countries where female genital mutilation has been routinely performed, laws are being enacted to prohibit such mutilation (Ciment, 1999; Cook and colleagues, 2002; Eke and Nkanginieme, 1999).

Pregnancy Complications. There are a number of associated adverse maternal and neonatal complications, and the degree of mutilation correlates with their incidence. The World Health Organization (2006) estimated that these procedures *increased* perinatal morbidity rates by 10 to 20 per 1000.

For those women who do not desire deinfibulation until they become pregnant, the procedure can be done at midpregnancy using spinal analgesia (Nour and colleagues, 2006). Another option is to wait until delivery, at which time scarred tissue is incised between the index and middle fingers inserted between the crowning fetal head and the scar. In our experiences, in many cases, intrapartum deinfibulation allows successful vaginal delivery without major complications.

Vaginal Abnormalities

Acquired vaginal abnormalities are uncommon. Even after major trauma, long-term sexual and reproductive function is usually normal (Fallat and colleagues, 1998). Vaginal stenosis may develop as a result of mucositis from graft-versus-host reaction following organ transplantation (Louis-Sylvestre and associates, 2003).

Partial Atresia

Incomplete atresia may result from infection or trauma that leads to extensive scarring. During labor, this is usually overcome by pressure from the presenting part, but occasionally incisions or even cesarean delivery are necessary.

Genital Tract Fistulas

Fistulas found during pregnancy likely existed previously, but in rare cases they develop during pregnancy. McKay and Hanlon (2003) described a *vesicovaginal fistula* following a McDonald cerclage done at 20 weeks. In prolonged obstructed labor, the genital tract may be compressed between the fetal head and the

bony pelvis. Brief pressure is not significant, but prolonged pressure may result in necrosis with subsequent fistula formation. Miklos and colleagues (1995) described a *vesicouterine fistula* that developed following vaginal delivery after prior cesarean delivery. Rarely, the anterior cervical lip is compressed against the symphysis pubis with development of a *vesicocervical fistula.* In an unusual case, after 5 days of obstructed labor at home, a psychotic woman presented with sepsis from necrosis of the bladder and uterus (Korell and co-workers, 2007).

In some cases, these fistulas heal spontaneously, but subsequent repair may be necessary. Murray and associates (2002) report a high rate of successful closures performed in more than 15,000 cases at The Fistula Hospital in Addis Ababa, Ethiopia. Unfortunately, urinary incontinence persisted in 55 percent. Wall (2002) has provided a poignant chronicle of the societal impact of obstetrical fistulas on Nigerian culture.

Cervical Abnormalities

Cicatricial *cervical stenosis* is uncommon, but it may follow cervical trauma such as conization. Cryotherapy occasionally produces stenosis, but the loop electrosurgical excision procedure (LEEP) and laser surgery usually do not (Mathevet and associates, 2003a). Overall, both surgical and laser conization or loop excision for cervical intraepithelial neoplasia increase preterm delivery (Albrechtsen, 2008; Kyrgiou, 2006; Samson, 2005, and all their co-workers). Cervical stenosis almost always yields during labor. A so-called *conglutinated cervix* may undergo almost complete effacement without dilation, with the presenting part separated from the vagina by only a thin layer of cervical tissue. Dilatation usually promptly follows pressure with a fingertip, although manual dilatation or cruciate incisions may be required. Incompetent cervix is discussed in Chapter 36. Finally, extensive *cervical carcinoma* may impair vaginal delivery (see Chap. 57, p. 1201).

Uterine Abnormalities

A number of acquired uterine abnormalities may adversely affect pregnancy as well as fertility.

Anteflexion

Exaggerated degrees of anteflexion frequently observed in early pregnancy are without significance. In later months, particularly when the abdominal wall is very lax, the uterus may fall forward. This may be so exaggerated that the fundus lies below the lower margin of the symphysis. Marked anteflexion usually is associated with *diastasis recti* and a pendulous abdomen. The abnormal uterine position sometimes prevents proper transmission of contractions, however, this is usually overcome by repositioning and application of an abdominal binder.

Retroflexion

The growing normally retroflexed uterus will occasionally remain incarcerated in the hollow of the sacrum. Symptoms include abdominal discomfort, pelvic pressure, and voiding disorders. As pressure from the full bladder increases, small amounts of urine are passed involuntarily, but the bladder never empties entirely–so called *paradoxical incontinence.* Acute urinary retention is common in our experience and was described by Myers and Scotti (1995). Such blockage also can cause severe obstructive nephropathy. The diagnosis is usually made on the basis of symptoms and examination. The cervix will be behind the symphysis pubis and the uterus is appreciated as a mass in the pelvis. If the diagnosis is not clear, sonography or MR imaging may clarify it (Beekhuizen and co-workers, 2003).

Incarceration is managed by repositioning the uterus (Özel, 2005). After bladder catheterization, the uterus can usually be pushed out of the pelvis when the woman is placed in the knee-chest position. Often, this is best accomplished by digital pressure applied through the rectum. Occasionally spinal analgesia or general anesthesia is necessary. Following repositioning, the catheter is left in place until bladder tone returns. Insertion of a soft pessary for a few weeks usually prevents reincarceration. Lettieri and colleagues (1994) described seven cases of uterine incarceration not amenable to these simple procedures. In two women, laparoscopy was used at 13 to 14 weeks to reposition the uterus using the round ligaments for traction. Seubert and associates (1999) used colonoscopy to dislodge an incarcerated uterus in five women. Hamoda and co-workers (2002) simply observed one woman and performed cesarean delivery of a healthy infant at 36 weeks. In a similar case described by Rose and colleagues (2008) in which a large myoma became incarcerated, there was spontaneous reduction at 20 weeks.

Sacculation

Persistent entrapment of the pregnant uterus in the pelvis may result in an anterior uterine sacculation (**Fig. 40-9**). Extensive dilatation of the lower uterine segment takes place to accommodate the fetus (Jackson and associates, 1988; Lettieri and co-workers, 1994). Sonography and MR imaging are typically required to define anatomy (Gottschalk and colleagues, 2008; Lee and associates, 2008). Cesarean delivery is necessary in these cases, and Spearing (1978) stressed the importance of identifying the distorted anatomy. An elongated vagina passing above the level of a fetal head that is deeply placed into the pelvis is suggestive of a sacculation or an abdominal pregnancy. The Foley catheter is frequently palpated above the level of the umbilicus! Spearing (1978) recommended extending the abdominal incision to above the umbilicus and delivery of the entire uterus from the abdomen before an attempt is made to incise it. **This procedure will restore anatomy to the correct relationships and prevent inadvertent incisions into and through the vagina and bladder.** Unfortunately, this may not always be possible to accomplish (Singh and colleagues, 2007).

Friedman and associates (1986) described a rare case of posterior uterine sacculation following aggressive treatment for intrauterine adhesions, or *Asherman syndrome.* Uterine retroversion and a true uterine diverticulum have been mistaken for uterine sacculations (Engel and Rushovich, 1984; Hill and associates, 1993; Rajiah and co-workers, 2009).

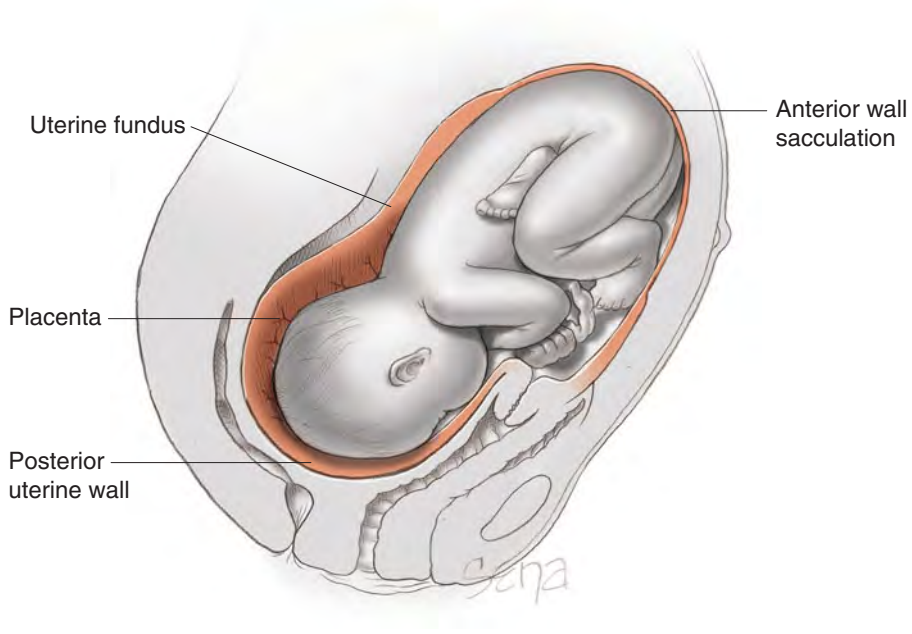

FIGURE 40-9 Anterior sacculation of a pregnant uterus. Note the markedly attenuated anterior uterine wall and atypical location of the true uterine fundus.

Uterine Prolapse

The cervix, and occasionally a portion of the uterine body, may protrude to a variable extent from the vulva during early pregnancy (Fig. 40-10). With further growth, the uterus usually rises above the pelvis and may draw the cervix up with it. If the uterus persists in its prolapsed position, symptoms of incarceration may develop from 10 to 14 weeks. To prevent this, the uterus is replaced early in pregnancy and held in position with a suitable pessary. Successful pregnancy and vaginal deliveries have been reported following sacrospinous uterosacral fixation done before pregnancy (Kovac and Cruikshank, 1993).

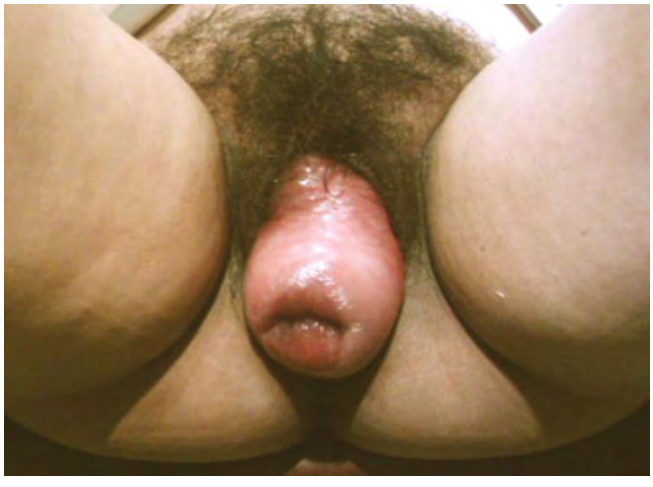

FIGURE 40-10 Uterine procidentia in a parous woman at 27 weeks. The cervix was easily reduced and was held in place by a ring pessary. Spontaneous preterm labor and uncomplicated vaginal delivery followed at 30 weeks. There was no prolapse at the postpartum examination 2 weeks later. (Courtesy of Dr. Charles P. Read.)

Cystocele and Rectocele

Attenuation of fascial support between the vagina and the bladder can lead to prolapse of the bladder into the vagina, that is, a cystocele. Urinary stasis with a cystocele predisposes to infection. Pregnancy may worsen associated *urinary stress incontinence* because urethral closing pressures do not increase sufficiently to compensate for the progressively increased bladder pressure (Iosif and Ulmsten, 1981). Attenuation of rectovaginal fascia results in a rectocele. A large defect may fill with feces that occasionally can be evacuated only manually. During labor, cystocele and rectocele can block fetal descent unless they are emptied and pushed out of the way.

Enterocele

In rare instances, an enterocele of considerable size may complicate pregnancy. If symptomatic, the protrusion should be replaced, and the woman kept in a recumbent position. If the mass interferes with delivery, it should be pushed up or held out of the way.

Uterine Torsion

Rotation of the uterus, most often to the right, is common during pregnancy. Conversely, complete torsion is rare and is usually not sufficient to cause infarction. One exception reported by Cook and Jenkins (2005) was a 270-degree torsion in a 36-week pregnancy. Oláh (2002) described a case in which one horn of a bicornuate uterus became ischemic from torsion. There are other problems. In a case of severe levotorsion necessitating cesarean delivery, the hysterotomy incision was inadvertently made in the posterior uterine wall (Bakos and Axelson, 1987). Thus, as with uterine incarceration, the severely malpositioned uterus should be repositioned anatomically prior to hysterotomy. Torsion can be confused with abdominal pregnancy, and in some but not all cases, sonography or MR imaging may allow correct identification (Sherer and colleagues, 1994; Worley and associates, 2008). The vagina normally appears as an H-shaped structure but with torsion it appears X-shaped–the "X sign."

Uterine Leiomyomas

Also known as *myomas* and somewhat erroneously called *fibroids*, uterine leiomyomas are common benign smooth muscle tumors. Their incidence during pregnancy is probably about 2 percent and depends on population characteristics and the frequency of routine sonography. For example, Sheiner and

co-workers (2004) cited an incidence of 0.65 percent in nearly 106,000 pregnancies. But with midtrimester sonographic screening in nearly 15,000 women, Qidwai and associates (2006) identified 2.7 percent to have at least one myoma. In a recent study of 4271 women, Laughlin and co-workers (2009) reported a first-trimester myoma prevalence of 11 percent. The prevalence was highest in black women—18 percent—and lowest in whites—8 percent.

Symptoms from leiomyomas depend principally on their location. They may be located immediately beneath the endometrial or decidual lining of the uterine cavity–*submucous*, immediately beneath the uterine serosa–s*ubserous,* or they may be confined within the myometrium–*intramural*. As an intramural myoma grows, it may develop a significant subserous or submucosal component, or both. Submucous and subserous myomas may be pedunculated and can undergo torsion with necrosis. At times, a subserous myoma becomes *parasitic* and derives its blood supply through the highly vascularized omentum. In one case, a large myoma was incarcerated until it spontaneously reduced at 20 weeks (Rose and colleagues, 2008).

Myomas during pregnancy occasionally undergo *red* or *carneous degeneration*, which is in actuality hemorrhagic infarction. Findings include focal pain, tenderness on palpation, and sometimes low-grade fever and leukocytosis. On occasion, the parietal peritoneum overlying the infarcted myoma becomes inflamed and a peritoneal friction rub develops. Myoma degeneration may be difficult to differentiate from appendicitis, placental abruption, ureteral stone, or pyelonephritis, and imaging techniques aid in discrimination. Treatment of symptomatic myomas consists of analgesia and observation. Most often, signs and symptoms abate within a few days, but inflammation may stimulate labor. Surgery is rarely necessary during pregnancy. An unusual exception was described by MacDonald and colleagues (2004) of small bowel obstruction due to degeneration of a pedunculated myoma. The rare form of *cotyledonoid leiomyoma* may involve bowel with fibrous adhesions (Mathew and co-workers, 2007).

Subfertility

In spite of the relatively high prevalence of myomas in young women, it is not clear whether they diminish fertility, other than by possibly causing early miscarriage (Stewart, 2001). In a review of 11 studies, Pritts (2001) concluded that only submucous myomas had a significant negative impact on fertility. He also reported that hysteroscopic myomectomy improved infertility and early miscarriage rates in women with submucous tumors. For a more detailed review, see Chapter 9 in *Williams Gynecology* (Hoffman, 2008).

Uterine Artery Embolization

Data on pregnancy outcomes following arterial embolization of uterine myomas are inconsistent despite a number of studies. Pron and colleagues (2005) described two cases of placenta previa and one of placenta accreta among 18 pregnancies following embolization. Walker and McDowell (2006) reported 56 completed pregnancies in a group of 1200 women who had undergone myoma embolization. Thirty-three women—60 percent— had successful outcomes including six preterm deliveries. However, the cesarean delivery rate was almost 75 percent, and nearly 20 percent of women had postpartum hemorrhage. In their most recent review, Goldberg and Pereira (2006) compared pregnancy outcomes following laparoscopic myomectomy versus embolization techniques. They found that miscarriage, abnormal placentation, preterm delivery, and postpartum hemorrhage were uniformly increased in women undergoing embolization procedures. The American College of Obstetricians and Gynecologists (2004) considers embolization for leiomyoma investigational or relatively contraindicated in women wishing to retain fertility. Interestingly, Rebarber and associates (2009) reported use of embolization at 20 weeks' gestation to treat a large arteriovenous malformation followed by delivery of a healthy infant at 35 weeks.

Effects of Pregnancy on Myomas

The stimulatory effects of pregnancy on the growth of uterine myomas is sometimes quite impressive. These tumors respond differently in individual women, and thus, accurate prediction of their growth is not possible. For example, in the study summarized in Table 40-4, only half of myomas changed significantly in size during pregnancy. During the first trimester, myomas of all sizes either remained unchanged or increased in size–a possible early response to increased estrogen. During the second trimester, smaller myomas–2 to 6 cm–usually remained unchanged or increased in size, whereas those larger than 6 cm became smaller–probably from initiation of estrogen receptor downregulation. Regardless of initial myoma size, during the third trimester, myomas usually remained unchanged or decreased,

TABLE 40-4. Sonographically Measured Changes in Myomas During Pregnancy—Percentage of Myomas with Change

	Small Myomas (2–6 cm) (n = 111)			Large Myomas (6–12 cm) (n = 51)		
Trimester	No Change	Increase	Decrease	No Change	Increase	Decrease
First	60	40	0	20	80	0
Second	55	30	15	40	15	50
Third	60	5	35	30	10	60

Modified from Lev-Toaff and co-workers (1987), with permission. Percentages are rounded to nearest 5 percent.

TABLE 40-5. Pregnancy Complications by Location of Myomas to Placenta

		Myoma No. (%)	
Investigators	**Complication**	**No Contact with Placenta**	**Contact with Placenta**
Winer-Muram et al (1984)	Bleeding and pain	5/54 (9)	8/35 (23)
	Major complications		
	Abortion	1/54 (2)	9/35 (26)
	Preterm labor	0	5/35 (14)
	Postpartum hemorrhage	0	4/35 (11)
Rice et al (1989)	Major complications		
	Preterm labor	19/79 (24)	1/14 (7)
	Abruption	2/79 (3)	8/14 (57)
	Total	48/133 (36)	35/49 (71)

reflecting estrogen receptor downregulation. Other studies have also reported increased growth of myomas in early pregnancy, but not later. The study by Neiger and co-workers (2006), who followed 72 women with 137 myomas longitudinally across pregnancy, does not reflect the findings of most others. They found no increase in mean myoma volume as pregnancy progressed.

Effects of Myomas on Pregnancy

These common tumors are associated with a number of obstetrical complications including preterm labor, placental abruption, fetal malpresentation, obstructed labor, cesarean delivery, and postpartum hemorrhage (Davis, 1990; Klatsky, 2008; Qidwai, 2006; Sheiner, 2004, and all their colleagues). In a review of pregnancy outcomes in 2065 women with leiomyoma, Coronado and co-workers (2000) reported that placental abruption and breech presentation were increased fourfold, first-trimester bleeding and dysfunctional labor twofold, and cesarean delivery sixfold. Salvador and associates (2002) reported an eightfold increased second-trimester abortion risk in women with myomas but found that genetic amniocentesis did not increase this risk.

The two factors most important in determining morbidity in pregnancy are myoma size and location (**Fig. 40-11**). As shown in **Table 40-5**, proximity of myomas to the placental implantation site is important. Specifically, abortion, placental abruption, preterm labor, and postpartum hemorrhage all are increased if the placenta is adjacent to or implanted over a myoma. Tumors in the cervix or lower uterine segment are particularly troublesome because they may obstruct labor (**Fig. 40-12**). In addition, cervical myomas displace the ureters laterally, and hysterectomy can be technically difficult. Large myomas may also distort anatomy, and a woman with complete vena caval obstruction by a large myoma at 17 weeks was described by Greene and colleagues (2002).

Despite these complications, Qidwai and colleagues (2006) reported a 70 percent vaginal delivery rate in women with uterine myomas that measured at least 10 cm. These data argue against empirical cesarean delivery when myomas are present. At our hospitals, unless myomas clearly obstruct the birth canal, or there is another indication for cesarean delivery, we allow a trial of labor.

Imaging Studies

Sonography is indispensable to correctly identify myomas (see Fig. 40-11). Myomas can be confused with ovarian masses–both benign and malignant–as well as with molar and ectopic pregnancy, missed abortion, and bowel abnormalities (Exacoustos and Rosati, 1993). In some cases the use of color Doppler may be beneficial (Kessler and colleagues, 1993).

Magnetic resonance imaging serves as an adjunct to sonography. In comparative studies, MR-imaging techniques have been described that markedly improve the reliability of identifying uterine myomas (Schwartz and associates, 1998; Torashima and colleagues, 1998).

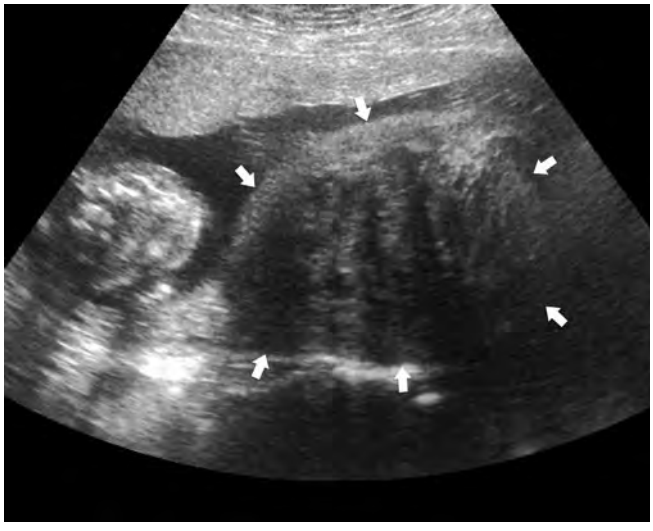

FIGURE 40-11 Sonogram of a uterine leiomyoma. The large inhomogeneous mass (*arrows*) lies beside the fetus (seen in cross section) and shows the classic appearance of a leiomyoma in pregnancy. The mass originates from the lower uterine segment and occupies greater than half of the total uterine volume.

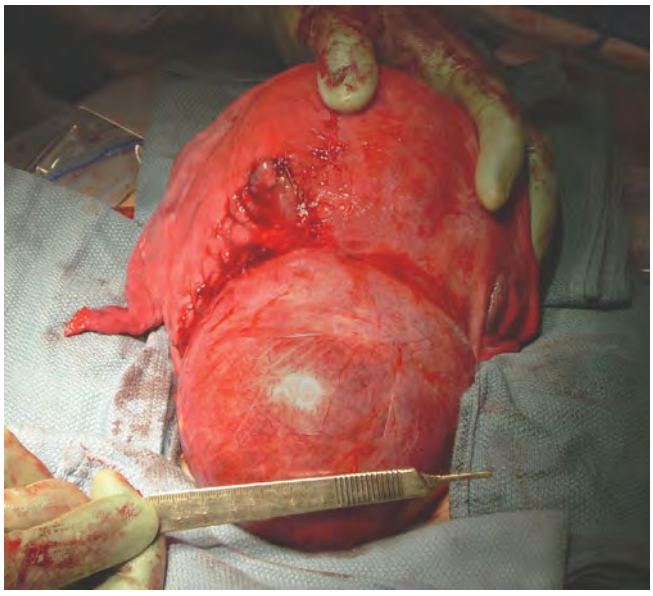

FIGURE 40-12 Cesarean delivery complicated by a large leiomyoma in the lower uterine segment. The location of the mass prompted a classical vertical uterine incision for delivery of the fetus.

Myomectomy

Resection of myomas during pregnancy is generally contraindicated. In some cases, unrelenting pain from infarction and degeneration prompts surgical treatment. We agree with most authorities that surgery should be limited to tumors with a discrete pedicle that can be clamped and easily ligated. Resection of intramural myomas during pregnancy or at the time of delivery usually stimulates profuse bleeding.

Limited data concerning indicated myomectomy during pregnancy are encouraging. De Carolis and colleagues (2001) and Celik and associates (2002) described good outcomes in 23 women. Most were between 14 and 20 weeks, and in almost half, the surgery was performed because of pain. In some of these cases, an intramural myoma was in contact with the implantation site. Except for one loss immediately following surgery at 19 weeks, most women had cesarean delivery at term. These investigators emphasize that such management is for highly selected cases. Joó and co-workers (2001) described resection at 25 weeks of a 940-g degenerating fundal myoma that caused fetal postural deformity and oligohydramnios. Postoperatively, amnionic fluid volume became normal, and later, the woman underwent cesarean delivery of a normal infant.

Intramural myomectomy in nonpregnant women can be hazardous for subsequent pregnancy. When myoma resection results in a defect into or immediately adjacent to the endometrial cavity, uterine rupture may occur remote from labor and sometimes even early in pregnancy (Golan and associates, 1990a). Prevention depends on cesarean delivery before active labor begins.

Infection of Myomas Postpartum

Although puerperal pelvic infections and myomas are both fairly common, myomas rarely become infected (Genta and colleagues, 2001). Most infections occur postpartum especially if the myoma is located immediately adjacent to the placental implantation site (Lin and associates, 2002). They also may become infected with a septic abortion or with myoma perforation by a sound or curette during dilatation and curettage.

Leiomyomatosis Peritonealis Disseminata

These are numerous subperitoneal smooth muscle tumors that at first appear to be disseminated carcinomatosis. The tumors are likely caused by estrogen stimulation of multicentric subcoelomic mesenchymal cells to become smooth muscle cells. From their review of 45 cases, Lashgari and colleagues (1994) found that half were discovered during pregnancy. Marom and associates (1998) as well as Ling and colleagues (2000) have described women who had tumors extending up the vena cava into the heart. Although surgical excision has been recommended, these tumors usually regress after pregnancy. Thomas and co-workers, (2007) described leiomyomatosis associated with uterine rupture and bone metastases that regressed spontaneously. Tanaka and colleagues (2009) reported two cases associated with assisted reproductive technology and accompanying high maternal estrogen concentrations.

ENDOMETRIOSIS AND ADENOMYOSIS

Although almost never symptomatic during pregnancy, occasionally endometriosis is problematic. For example, a ruptured endometrioma may cause bizarre clinical symptoms or labor dystocia. More commonly, symptoms subsequently develop from endometrial implants at the time of cesarean delivery or episiotomy (Bumpers and associates, 2002).

Adenomyosis is found in older women. Its acquisition may be at least partially related to disruption of the endometrial-myometrial border during sharp curettage for abortion (Curtis and co-workers, 2002). Although problems during pregnancy are rare, in an 80-year review, Azziz (1986) reported adenomyosis to be associated with uterine rupture, ectopic pregnancy, uterine atony, and placenta previa. Successful pregnancy may follow treatment of adenomyosis with gonadotropin-releasing hormone agonists or MR-guided focused ultrasound surgery (Rabinovici and colleagues, 2006; Silva and colleagues, 1994).

Ovarian Abnormalities

The incidence of ovarian masses during pregnancy varies depending on whether the population studied is from referral or primary care sources, the frequency with which prenatal sonography is used, and the threshold for the size of tumor. The studies listed in Table 40-6 show a variable incidence from about 1 in 100 pregnancies to 1 in 2000. Whitecar and associates (1999) described only those masses requiring laparotomy. The highest incidence was in the prospective population-based Italian study by Zanetta and associates (2003). They included almost 6650 pregnancies and found at least one mass larger than 3 cm in every 85 women.

Any type of ovarian mass can be encountered, but the most common are cystic (Table 40-6). Because pregnant women are usually young, malignant tumors, including those of low-

TABLE 40-6. Ovarian Masses Complicating Pregnancy

malignant potential, are relatively uncommon. That said, the proportion of malignant tumors in the studies shown in Table 40-6 varied from 4 to 13 percent. In our large obstetrical services in Dallas and Birmingham, the incidences are not so high. They are similar to those reported by Leiserowitz and colleagues (2006), who analyzed California hospital discharge data from 1991 through 1999. They found that only 1 percent of 9375 ovarian masses in pregnant women were frankly malignant, and another 1 percent were of low-malignant potential.

Tumors Unique to Pregnancy

Luteomas are unique to pregnancy and may be virilizing (Mazza and colleagues, 2002; Wang and associates, 2005). *Theca-lutein cysts* can be large and appear complex. They are usually seen in pregnancies with inordinately high hCG secretion–gestational trophoblastic disease, twins, and other situations with increased placental mass. The entity of *ovarian hyperstimulation syndrome* is usually caused by ovulation-induction therapy, but it may develop spontaneously in pregnancy. This phenomenon is thought to be caused by a mutation in the FSH receptor (Kaiser, 2003; Vasseur and associates, 2003).

Complications

Acute complications of ovarian masses during pregnancy include torsion or hemorrhage. Their incidence depends on tumor size and whether laparotomy is done preemptively for tumors more likely to undergo torsion. Whitecar (1999) and Zanetta (2003) and their colleagues identified torsion in 5 percent of their cases.

Management

Ovarian enlargement less than 6 cm found early in pregnancy usually represents corpus luteum formation. When high-resolution sonography became available, Thornton and Wells (1987) proposed a conservative management approach based on sonographic characteristics. They recommended resection of all cysts suspected of rupture or torsion, those capable of obstructing labor, and those measuring more than 10 cm in diameter because of the increased risk of cancer in large cysts. Cysts 5 cm or less could be simply observed, and indeed, most undergo spontaneous resolution.

Management of masses between 5 and 10 cm diameter is controversial. Some recommend that they be managed expectantly if they have a simple cystic appearance. Whitecar and co-workers, (1999) caution against this approach, but most recent studies support it (Schmeler and colleagues, 2005). Importantly, if cysts contain septae, nodules, papillary excrescences, or solid components, then resection is recommended (Caspi and co-workers, 2000; Fleischer and associates, 1990). Women with these 5- to 10-cm cysts who are observed have been reported to require emergency exploration for rupture, torsion, or infarction in as many as half of cases (Hess and colleagues, 1988; Platek and colleagues, 1995). In our experiences, the rate is not nearly so high.

Laparoscopy is used with increased frequency to evaluate and resect intermediate-sized cysts (see Chap. 41, p. 913). The major concern is for the unrecognized malignant tumor rupturing with intraperitoneal spillage. Soriano and colleagues (1999) described maternal and fetal outcomes in 39 women undergoing laparoscopic adnexal surgery in the first trimester and in 54 who had either first- or second-trimester laparotomy and found comparable results. Akira and associates (1999) compared gasless laparoscopy with laparotomy for ovarian cystectomy in 35 women at 12 to 16 weeks and reported advantages to the laparoscopic approach. Parker and co-workers (1996) described laparoscopic resection between 9 and 17 weeks for a benign cystic teratoma in 12 women. It is worrisome that all but two of these 5- to 13-cm tumors ruptured intraoperatively, although there were no complications. Mathevet and associates (2003b)

reported generally good outcomes for 47 pregnant women whose adnexal masses were resected via laparoscopy.

The major questions to be answered once a pelvic mass is discovered during pregnancy include the following:

1. What is the mass and what is the likelihood that it is malignant?
2. Is there a good possibility that the mass will regress?
3. If observed, will the mass undergo torsion or rupture, or will it be an obstruction to vaginal delivery?

Only time, serial sonographic surveillance, and labor will provide answers to the last two questions. As for the first question, Kier and associates (1990) reported that MR imaging correctly identified the origin of unknown pelvic masses in 17 of 17 women compared with 12 of 17 women in whom sonography was used. With the high-resolution equipment currently available, expectant management has become more common (Sherard and colleagues, 2003; Zanetta and co-workers, 2003). In some cases, transvaginal color Doppler assessment of tumor vascularity can be used for better characterization of adnexal tumors (Kurjak and Zalud, 1990).

Recommendations

It seems reasonable to remove all ovarian masses larger than 10 cm because of the substantive risk of malignancy and torsion. Tumors from 6 to 10 cm should be carefully evaluated for the possibility of neoplastic disease by sonography with color Doppler or MR imaging or both. If evaluation suggests a neoplasm, then resection is indicated. If the corpus luteum is removed before 10 weeks, then 17α-OH-progesterone, 250 mg intramuscularly, is given weekly until 10 weeks' gestation. Cystic masses that are thought to be benign or are less than 6 cm are imaged serially and are resected if they grow, begin to display malignant qualities, or become symptomatic. In general, we perform elective surgery at 14 to 20 weeks because most masses that will regress will have done so by this time.

Ovarian Carcinoma

Malignant ovarian neoplasms are unusual during pregnancy simply because of the young population involved. Measurement of ovarian tumor serum markers is rarely helpful during pregnancy (Zanetta and colleagues, 2003). Ovarian malignancies are discussed in Chapter 57 (see p. 1204).

SECTION 8

MEDICAL AND SURGICAL COMPLICATIONS

CHAPTER 41

General Considerations and Maternal Evaluation

MATERNAL PHYSIOLOGY AND ALTERATIONS IN LABORATORY VALUES 912
MEDICATIONS DURING PREGNANCY 912
SURGERY DURING PREGNANCY 913
IMAGING TECHNIQUES 915
SONOGRAPHY 921
MAGNETIC RESONANCE (MR) IMAGING 921
GUIDELINES FOR DIAGNOSTIC IMAGING DURING PREGNANCY 923

It is difficult to accurately quantify the incidence and types of medical and surgical illnesses that complicate pregnancy. Estimates have been derived from other indices of hospitalization as well as birth certificate data (Lydon-Rochelle and associates, 2005). For example, Gazmararian and colleagues (2002) reported an overall antenatal hospitalization rate of 10.1 per 100 deliveries in their managed-care population of more than 46,000 pregnant women. About a third of these were for nonobstetrical conditions such as renal, gastrointestinal, pulmonary, and infectious diseases. In a study from the 2002 Nationwide Inpatient Sample of the Healthcare Cost and Utilization Project, Kuo and associates (2007) used the International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) injury and concurrent pregnancy diagnosis codes. From these, they found the injury hospitalization rate to be 4.1 women per 1000 deliveries.

The care for some of these women with medical or surgical disorders will warrant a team effort between obstetricians and maternal-fetal medicine specialists, or with internists, surgeons, anesthesiologists, and other disciplines (American College of Obstetricians and Gynecologists, 2003). It is important that obstetricians have a working knowledge of medical and surgical diseases common to women of childbearing age. Likewise, nonobstetricians who see these women in consultation should be familiar with pregnancy-induced physiological changes that affect various diseases.

A number of generalizations concern the rational approach to management of these nonobstetrical disorders:

- A woman should never be penalized because she is pregnant.
- What management plan would be recommended if the woman was not pregnant?
- If a proposed medical or surgical management plan is altered because the woman is pregnant, what are the justifications for this?

Such an approach should allow individualization of care for most medical and surgical disorders. Moreover, it may be especially helpful when dealing with nonobstetrical consultants.

MATERNAL PHYSIOLOGY AND ALTERATIONS IN LABORATORY VALUES

Pregnancy induces physiological changes in most organ systems. Some of these are profound and may amplify or obfuscate evaluation of coexisting conditions. Results of laboratory tests can also be altered, and some of these would, in the nonpregnant woman, be considered abnormal. Conversely, some may appear to be normal but are not so in the pregnant woman. The wide ranges of pregnancy effects on normal physiology and on laboratory values are discussed in Chapter 5, in the chapters that follow, and in the Appendix.

MEDICATIONS DURING PREGNANCY

Antepartum management of nonobstetrical disorders includes administration of various drugs. Fortunately, the vast majority

necessary to treat the most commonly encountered complications can be used with relative safety. However, there are a few notable exceptions, which are considered in detail in Chapter 14, as well as with the discussions of specific disorders for which these drugs are given.

SURGERY DURING PREGNANCY

The risk of an adverse pregnancy outcome is not appreciably increased in women who undergo most uncomplicated surgical procedures. With complications, however, risks may be increased. For example, perforative appendicitis with feculent peritonitis has significant maternal and perinatal morbidity and mortality rates even if surgical and anesthetic techniques are flawless. Conversely, procedure-related complications may adversely affect outcomes. For example, a woman who has uncomplicated removal of an inflamed appendix may suffer aspiration of acidic gastric contents at the time of tracheal extubation (see Chap. 19, p. 460).

Effect of Surgery and Anesthesia on Pregnancy Outcome

The most extensive experiences regarding anesthetic and surgical risks to pregnancy are from the Swedish Birth Registry reported by Mazze and Källén (1989). The effects of 5405 nonobstetrical surgical procedures performed in 720,000 pregnant women were analyzed from 1973 to 1981 (Fig. 41-1). Surgery was performed in 41 percent of women in the first trimester, 35 percent in the second, and 24 percent in the third. Of the total, 25 percent were abdominal operations, another 20 percent were gynecological and urological procedures, and 15 percent were laparoscopic procedures. Laparoscopy was the most commonly performed first-trimester operation, and appendectomy was the most common second-trimester procedure.

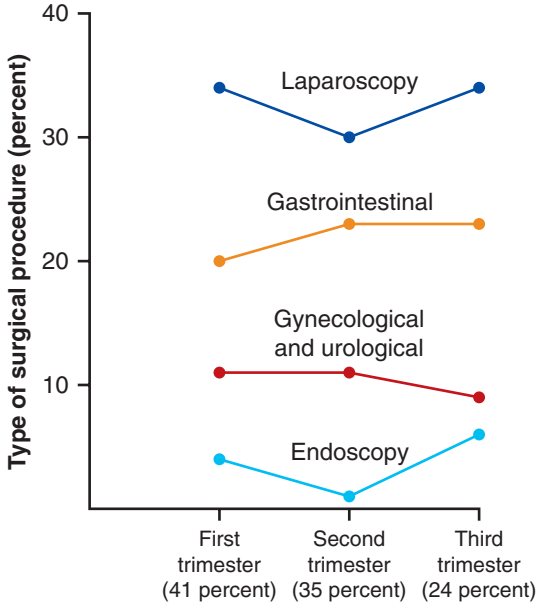

FIGURE 41-1 Selected types of surgical procedures by trimester in 3615 women. (Data from Mazze and Källén, 1989.)

TABLE 41-1. Birth Outcomes in 5405 Pregnant Women Undergoing Nonobstetrical Surgery

Outcome	Rate	*p* Value[a]
Major malformation	1.9 percent	NS
Stillbirth	7 per 1000	NS
Neonatal death by 7 days	10.5 per 1000	< 0.05
Preterm birth (< 37 wk)	7.5 percent	< 0.05
Birthweight < 1500 g	1.2 percent	< 0.05
Birthweight < 2500 g	6.6 percent	< 0.05

[a]Compared with 720,000 pregnancies in women without surgery.
NS = not significant
Data from Mazze and Källén (1989).

General anesthesia was used for 54 percent of procedures in the 5405 women in the Swedish report. This commonly involved nitrous oxide supplemented by another inhalation agent or intravenous medications.

Perinatal Outcomes

Excessive perinatal morbidity associated with nonobstetrical surgery is attributable to the disease itself rather than to adverse effects of surgery and anesthesia. Mazze and Källén (1989) compared pregnancy outcomes in the 5405 women undergoing surgery as described with perinatal outcomes in the other 720,000 pregnancies. As shown in Table 41-1, the incidence of neonates with congenital malformations or those stillborn was not significantly different from that of nonexposed newborns. There were, however, significantly increased incidences of low birthweight, preterm birth, and neonatal death in infants born to women who had undergone surgery. Increased neonatal mortality rates resulted in large part from preterm birth. These investigators concluded that these likely were due to a synergistic effect of the illness in concert with the surgical procedures. Similarly, Hong (2006) reported increased preterm delivery in 235 women undergoing adnexal mass surgery.

Källén and Mazze (1990) scrutinized 572 operations performed at 4 to 5 weeks and found a nonsignificant relationship with neural-tube defects. From the Hungarian database, Czeizel and colleagues (1998) found no evidence that anesthetic agents were teratogenic. Sylvester and co-workers (1994) performed a case-control study from the Metropolitan Atlanta Congenital Defects Program. They found an increased risk of hydrocephaly—but not neural-tube defects—in conjunction with other major defects in newborns of women exposed to general anesthesia. The study was based on questionnaire data, and we agree with Kuczkowski (2006) that there is no robust evidence that anesthetic agents are harmful to the fetus.

Laparoscopic Surgery During Pregnancy

During the past decade, laparoscopic techniques have become commonly used for diagnosis and management of a number of surgical disorders complicating pregnancy. The obvious example is management of ectopic pregnancy (see Chap. 10, p. 246). From his review, Kuczkowski (2007) reported that laparoscopy

is the most common first-trimester surgical procedure. It is used preferentially for exploration and treatment of adnexal masses (Chap. 40, p. 905), for appendectomy (Chap. 49, p. 1059), and for cholecystectomy (Chap. 50, p. 1074). In 2008, the Guidelines Committee of the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) published its recommendations concerning the use of laparoscopy in pregnant women. These guidelines are reasonable and are generally followed by most obstetricians and surgeons.

Lachman and colleagues (1999) and Fatum and Rojansky (2001) reviewed more than 800 laparoscopic procedures performed during pregnancy. The most common were cholecystectomy, adnexal surgery, and appendectomy. These generally had good outcomes, and these researchers concluded that 26 to 28 weeks was the upper gestational age limit for successful laparoscopy. Predictably, some centers are now describing laparoscopic surgery performed in the third trimester. For example, Rollins and colleagues (2004) described 59 pregnant women managed with laparoscopic procedures—31 cholecystectomies and 28 appendectomies. Of these 59 women, 30 percent underwent surgery after 26 weeks. There were no serious adverse sequelae to these procedures. There are also a number of reports of laparoscopic splenectomy, adrenalectomy, and nephrectomy done in pregnant women (Felbinger, 2007; Gernsheimer and McCrae, 2007; Kosaka, 2006; Stroup, 2007, and all their colleagues).

Maternal Effects

Hemodynamic changes from abdominal insufflation for laparoscopy are similar in pregnant and nonpregnant women as summarized in Table 41-2. Reedy and colleagues (1995) studied baboons at the human equivalent of 22 to 26 weeks' gestation. Although they found no substantive physiological changes with 10 mm Hg insufflation pressures, 20 mm Hg caused significant maternal cardiovascular and respiratory changes after 20 minutes. These included increased respiratory rate, respiratory acidosis, diminished cardiac output, and increased pulmonary artery and wedge pressures.

In women, cardiorespiratory changes are generally not severe if insufflation pressures are kept below 20 mm Hg. Steinbrook and Bhavani-Shankar (2001) performed noninvasive hemodynamic monitoring in women at midpregnancy and reported that the cardiac index decreased 26 percent by 5 minutes of insufflation and 21 percent by 15 minutes. The mean arterial pressures, systemic vascular resistance, and heart rate did not change significantly.

Perinatal Outcomes

Because precise effects of laparoscopy in the human fetus are unknown, animal studies are informative. Pregnancy outcomes in women are limited to observations.

Animal Studies

In early studies of pregnant ewes, Barnard and associates (1995) and Hunter and colleagues (1995) reported that uteroplacental blood flow decreased when intraperitoneal pressure from insufflation exceeded 15 mm Hg. This was caused by decreased perfusion pressure and increased placental vessel resistance (Table 41-2). Studies in sheep since that time have corroborated these findings, which were reviewed by Reynolds and associates (2003) and O'Rourke and Kodali (2006). And the previously cited baboon study by Reedy and colleagues (1995) produced similar results. Importantly, severity of adverse effects was related to insufflation pressures greater than 15 mm Hg.

Human Data

To study the impact of laparoscopy on perinatal outcomes, Reedy and colleagues (1997) used the updated Swedish Birth Registry described earlier. Between 1973 and 1993, data accrued from more

TABLE 41-2. Physiological Effects of CO_2 Insufflation of the Peritoneal Cavity

System	Effects	Mechanisms	Possible Maternal-Fetal Effects
Respiratory	pCO_2 increases, pH decreases	CO_2 absorption	Hypercarbia and acidosis
Cardiovascular	Increased—heart rate; systemic vascular resistance; pulmonary, central venous, and mean arterial pressures	Hypercarbia and increased intra-abdominal pressure	Uteroplacental hypoperfusion—possible fetal hypoxia, acidosis, and hypoperfusion[a]
	Decreased—cardiac output	Decreased venous return	
Blood Flow	Decreased splanchnic flow with hypoperfusion of liver, kidneys, and gastrointestinal organs	Increased intra-abdominal pressure	As above
	Decreased venous return from lower extremities	Increased intra-abdominal pressure	As above
	Increased cerebral blood flow	Hypercarbia possibly from shunting due to splanchnic tamponade	Increased CSF pressure[a]

[a]Data primarily from animal studies.
CO_2 = carbon dioxide; CSF = cerebrospinal fluid; pCO_2 = partial pressure of CO_2.
Data from reviews by O'Rourke and Kodali (2006) and Reynolds and co-workers (2003).

than 2 million deliveries. There were 2181 laparoscopic procedures, which were performed primarily during the first trimester. The perinatal outcomes in these pregnancies were compared with those of all women, and the findings confirmed previous studies. Specifically, there was an increased risk of low birthweight, preterm delivery, and fetal-growth restriction in pregnancies of women in the operative group. There were no differences when outcomes of women having laparoscopy versus laparotomy were compared.

Technique

Preparation for laparoscopy differs little from that commonly used for laparotomy. Bowel cleansing empties the large intestine and may aid visualization. Nasogastric or orogastric decompression reduces the risk of stomach trocar puncture and aspiration. Aortocaval compression is avoided by a left-lateral tilt. Positioning of the lower extremities in boot-type stirrups maintains access to the vagina for fetal sonographic assessment or *manual* uterine displacement.

Most reports describe general anesthesia after tracheal intubation and monitoring of end-tidal carbon dioxide ($EtCO_2$) (Hong, 2006; Ribic-Pucelj and associates, 2007). With controlled ventilation, $EtCO_2$ is maintained at 30 to 35 mm Hg.

Beyond the first trimester, technical modifications of standard pelvic laparoscopic entry are required to avoid uterine puncture or laceration. Many recommend *open entry* techniques to avoid perforations of the uterus, pelvic vessels, and adnexa (Akira and co-workers, 1999). The abdomen is incised at or above the umbilicus and the peritoneal cavity entered under direct visualization. At this point, the cannula is then connected to the insufflation systems, and a 10-mm Hg pneumoperitoneum is created. The initial insufflation should be conducted slowly to allow for prompt assessment and reversal of any untoward pressure-related effects. Gas leakage around the cannula is managed by tightening the surrounding skin with a towel clamp. Insertion of secondary trocars is most safely performed under direct laparoscopic visual observation through the primary port.

In more advanced pregnancies, direct entry through a left upper quadrant port in the midclavicular line, 2 cm beneath the costal margin, has been described by Stepp and Falcone (2004). Known as *Palmer Point*, this entry site is used in gynecological laparoscopy because visceroparietal adhesions uncommonly form here (Vilos and colleagues, 2007).

Gasless Laparoscopy. This alternative approach involves use of a rod with fan-blade-shaped retractors, which when opened allow the abdominal wall to be lifted in an upward direction. It avoids the cardiovascular changes with pneumoperitoneum (Phupong and Bunyavejchewin, 2007).

Complications

Risks inherent to any abdominal endoscopy are *probably* not increased during pregnancy. The obvious unique complication is perforation of the pregnant uterus with either a trocar or Veress needle. Certainly, reported complications are uncommon (Fatum and Rojansky, 2001; Lachman and colleagues, 1999; Oelsner and associates, 2003). After a Cochrane Registry review, Bunyavejchevin and Phupong (2006) concluded that randomized trials would be necessary to deduce comparative benefits and risks of laparoscopy versus laparotomy during pregnancy. Pragmatically, this seems unfeasible and common sense should dictate the approach used.

IMAGING TECHNIQUES

Imaging modalities that are used as adjuncts for diagnosis and therapy during pregnancy include sonography, radiography, and magnetic resonance imaging. Of these, radiography is the most worrisome. Inevitably, some radiographic procedures are performed prior to recognition of early pregnancy, usually because of trauma or serious illness. Fortunately, most diagnostic radiographic procedures are associated with *minimal* fetal risks. As with drugs and medications, however, these procedures may lead to litigation if there is an adverse pregnancy outcome. And x-ray exposure may lead to a needless therapeutic abortion because of patient or physician anxiety.

Ionizing Radiation

The term *radiation* is poorly understood. Literally it refers to transmission of energy, and thus it is often applied not only to x-rays, but also to microwaves, ultrasound, diathermy, and radio waves. Of these, x-rays and gamma rays have short wavelengths with very high energy and are forms of ionizing radiation. The other four energy forms have rather long wavelengths and low energy (Brent, 1999a, 2009).

The biological effects of x-rays are caused by an electrochemical reaction that can cause tissue damage. According to Brent (1999b, 2009), x- and gamma-radiation at high doses can create biological effects and reproductive risks in the fetus:

1. Deterministic effects, which may cause congenital malformations, fetal-growth restriction, mental retardation, and abortion
2. Stochastic effects—randomly determined probabilities—which may cause genetic diseases and carcinogenesis.

In this sense, ionizing radiation refers to waves or particles—photons—of significant energy that can change the structure of molecules such as those in DNA, or that can create free radicals or ions capable of causing tissue damage (Hall, 1991; National Research Council, 1990). Methods of measuring the effects of x-rays are summarized in **Table 41-3**. The standard terms used are *exposure* (in air), *dose* (to tissue), and *relative effective dose* (to tissue). In the range of energies for diagnostic x-rays, the dose is now expressed in gray (Gy), and the relative effective dose is now expressed in sievert (Sv). These can be used interchangeably. For consistency, all doses discussed subsequently are expressed in contemporaneously used units of gray (1 Gy = 100 rad) or sievert (1 Sv = 100 rem). To convert, 1 Sv = 100 rem = 100 rad.

X-Ray Dosimetry

When calculating the dose of ionizing radiation such as that from x-rays, according to Wagner and colleagues (1997) several factors to be considered include:

1. Type of study
2. Type and age of equipment

TABLE 41-3. Some Measures of Ionizing Radiation

Exposure	The number of ions produced by x-rays per kg of air Unit: roentgen (R)
Dose	The amount of energy deposited per kg of tissue Modern unit: gray (Gy) (1 Gy = 100 rad) Traditional unit: rad[a]
Relative effective dose	The amount of energy deposited per kg of tissue normalized for biological effectiveness Modern unit: sievert (Sv) (1 Sv = 100 rem) Traditional unit: rem[a]

[a]For diagnostic x-rays, 1 rad = 1 rem.

3. Distance of target organ from radiation source
4. Thickness of the body part penetrated
5. Method or technique used for the study.

Estimates of dose to the uterus and embryo for a variety of commonly used radiographic examinations are summarized in Table 41-4. Studies of maternal body parts farthest from the uterus, such as the head, result in a very small dose of radiation scatter to the embryo or fetus. Because the size of the woman, radiographic technique, and equipment performance are variable factors, data in the table serve only as a guideline. When the radiation dose for a specific individual is required, a medical physicist should be consulted. In his most recent review, Brent (2009) recommends consulting the Health Physics Society website (www.hps.org) to view some examples of questions and answers posed by patients exposed to radiation (Click on ATE—ask the expert).

Deterministic Effects of Ionizing Radiation

One potential harmful effect of radiation exposure is deterministic, which may result in abortion, growth restriction, congenital malformations, microcephaly, and mental retardation. These deterministic effects are threshold effects, and the level below which they are induced is the *NOAEL—no-adverse-effect level* (Brent, 2009).

The harmful deterministic effects of ionizing radiation have been extensively studied for cell damage with resultant dysfunction of embryogenesis. These have been assessed in animal models, as well as Japanese atomic bomb survivors and the Oxford Survey of Childhood Cancers (Sorahan and colleagues, 1995). Additional sources have confirmed previous observations and provided more information. One is the 2003 International Commission on Radiological Protection (ICRP) publication of biological fetal effects from prenatal irradiation. Another is the BEIR VII Phase 2 report of the National Research Council (2006) that discusses health risks from exposure to low levels of ionizing radiation.

Animal Studies. In the mouse model, the risk of lethality is highest during the preimplantation period—up to 10 days postconception. This is likely due to blastomere destruction caused by chromosomal damage (Hall, 1991). The NOAEL for lethality is 0.15 to 0.2 Gy. Genomic instability can be induced in some mouse models at levels of 0.5 Gy (50 rad), which greatly exceeds levels with diagnostic studies (International Commission on Radiological Protection, 2003).

During organogenesis, high-dose radiation—1 gray or 100 rad—is more likely to cause malformations and growth restriction, and less likely to have lethal effects in the mouse. Studies

of brain development suggest that there are effects on neuronal development and a "window of cortical sensitivity" in early and midfetal periods with a threshold in the range of 0.1 to 0.3 Gy or 10 to 30 rad (International Commission on Radiological Protection, 2003).

Human Data. Adverse human effects of high-dose ionizing radiation are most often quoted in atomic bomb survivors from Hiroshima and Nagasaki (Greskovich and Macklis, 2000; Otake and co-workers, 1987). The International Commission on Radiological Protection (2003) confirmed initial studies showing that the increased risk of severe mental retardation was greatest between 8 and 15 weeks (Fig. 41-2). There may be a lower threshold dose of 0.3 Gy—30 rad—a similar range of the "window of cortical sensitivity" in the mouse model discussed above. The mean decrease in intelligence quotient (IQ) scores was 25 points per Gy or 100 rad. There appears to be linear dose response, but it is not clear whether there is a threshold dose. Most estimates err on the conservative side by assuming a linear nonthreshold (LNT) hypothesis. From their review, Strzelczyk and colleagues (2007) conclude that limitations of epidemiological studies at low-level exposures, along with recent new radiobiological findings, challenge the hypothesis that any amount of radiation causes adverse effects.

Finally, there is no documented increased risk of mental retardation in humans less than 8 weeks' or greater than 25 weeks' gestation, even with doses exceeding 0.5 Gy or 50 rad (Committee on Biological Effects, BEIR V, 1990; International Commission on Radiological Protection, 2003).

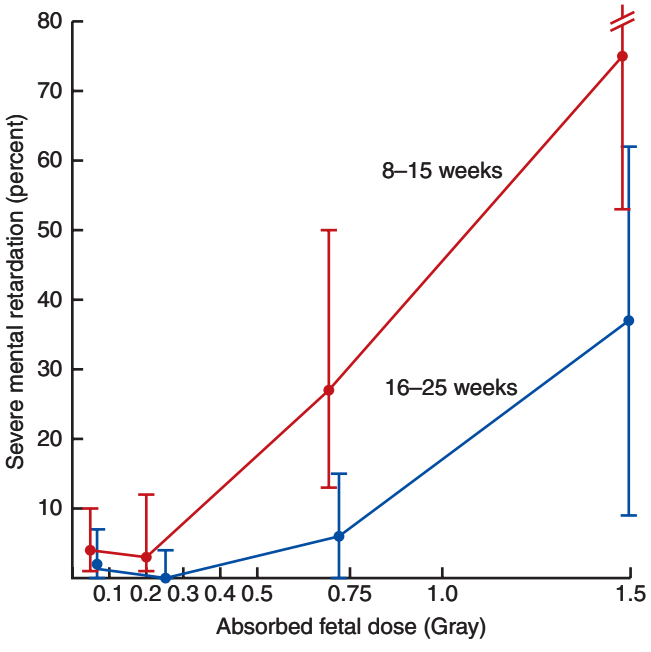

FIGURE 41-2 Follow-up of subjects from Hiroshima and Nagasaki after the atomic bomb explosion in 1945: Subsequent severe mental retardation caused by exposure to ionizing in utero radiation at two gestational age epochs to 1 Gy—or 100 rad. Mean values and 90-percent confidence levels are estimated from dosimetry calculated by two methods—T65DR and D586—used by the Radiation Effects Research Foundation of the Japanese Ministry of Health and National Academy of Sciences of the United States. (Data from Otake and associates, 1987, with permission.)

There are also reports that describe high-dose radiation given to treat women for malignancy, menorrhagia, and uterine myomas**.** In one, Dekaban (1968) described 22 infants with microcephaly, mental retardation, or both, following exposure in the first half of pregnancy to an estimated 2.5 Gy or 250 rad. Malformations in other organs were not found unless they were accompanied by microcephaly, eye abnormalities**,** or growth restriction (Brent, 1999a).

The implications of these findings seem straightforward. From 8 to 15 weeks, the embryo is most susceptible to radiation-induced mental retardation. It has not been resolved whether this is a threshold or nonthreshold linear function of dose. The Committee on Biological Effects (1990) estimates the risk of severe mental retardation to be low as 4 percent for 0.1 Gy (10 rad) and as high as 60 percent for 1.5 Gy (150 rad). But recall that these doses are 2 to 100 times higher than those from diagnostic radiation. Importantly, *cumulative doses from multiple procedures* may reach the harmful range, especially at 8 to 15 weeks. At 16 to 25 weeks, the risk is less. And again, there is no proven risk before 8 weeks or after 25 weeks.

Embryofetal risks from low-dose diagnostic radiation appear to be minimal. Current evidence suggests that there are no increased risks for malformations, growth restriction, or abortion from a radiation dose of less than 0.05 Gy (5 rad). Indeed, Brent (2009) concluded that gross congenital malformations would not be increased with exposure to less than 0.2 Gy (20 rad). Because diagnostic x-rays seldom exceed 0.1 Gy (10 rad), Strzelczyk and associates (2007) concluded that these procedures are unlikely to cause deterministic effects.

Stochastic Effects of Ionizing Radiation

This refers to random, presumably unpredictable oncogenic or mutagenic effects of radiation exposure. They concern associations between fetal diagnostic radiation exposure and increased risk of childhood cancers or genetic diseases. According to Doll and Wakeford (1997), as well as the National Research Council (2006) BEIR VII Phase 2 report, excess cancers can result from in utero exposure to doses as low as 0.01 Sv or 1 rad. Stated another way by Hurwitz and colleagues (2006), the estimated risk of childhood cancer following fetal exposure to 0.03 Gy or 3 rad doubles the background risk of 1 in 600 to that of 2 in 600.

In one report, in utero radiation exposure was determined for 10 solid cancers in adults from 17 to 45 years of age. There was a dose-response relationship as previously noted at the 0.1 Sv or 10 rem threshold. Intriguingly, nine of 10 cancers were found in females (National Research Council, 2006). These likely are associated with a complex series of interactions between DNA and ionizing radiation. They also make it more problematic to predict cancer risk from low-dose radiation of less than 0.1 Sv or 10 rem. Importantly, below doses of 0.1 to 0.2 Sv, there is no convincing evidence of a carcinogenic effect (Brent, 2009; Preston and colleagues, 2008; Strzelczyk and co-workers, 2007).

Therapeutic Radiation

In an earlier report, the Radiation Therapy Committee Task Group of the American Association of Physics in Medicine found that about 4000 pregnant women annually undergo cancer

therapy in the United States (Stovall and colleagues, 1995). Their recommendations, however, stand to date. The Task Group emphasizes careful individualization of radiotherapy for the pregnant woman (see Chap. 57, p. 1193). For example, in some cases, shielding of the fetus and other safeguards can be taken (Fenig and colleagues, 2001; Nuyttens and colleagues, 2002). In other cases, the fetus will be exposed to dangerous doses of radiation, and a carefully designed plan must be improvised (Prado and colleagues, 2000). One example is the model to estimate fetal dosage with maternal brain radiotherapy, and another is the model to calculate fetal dose with tangential breast irradiation developed by Mazonakis and colleagues (1999, 2003). The impact of radiotherapy on future fertility and pregnancy outcomes was recently reviewed by Wo and Viswanathan (2009) and is discussed in detail in Chapter 57 (p. 1194).

Diagnostic Radiation

To estimate fetal risk, approximate x-ray dosimetry must be known. According to the American College of Radiology (Hall, 1991), no single diagnostic procedure results in a radiation dose significant enough to threaten embryofetal well-being.

Radiographs. Dosimetry for standard radiographs is presented in Table 41-4. In pregnancy, the two-view chest radiograph is the most commonly used study, and fetal exposure is exceptionally small—0.0007 Gy or *0.07 mrad.* With one abdominal radiograph, because the embryo or fetus is directly in the x-ray beam, the dose is higher—0.001 Gy or 100 mrad**.** The standard intravenous pyelogram may exceed 0.005 Gy or 500 mrad because of several films. The one-shot pyelogram described in Chapter 48 (p. 1038) is useful when urolithiasis or other causes of obstruction are suspected but unproven by sonography. Most "trauma series," such as radiographs of an extremity, skull, or rib series, deliver low doses because of the fetal distance from the target area.

Fetal indications for radiographic studies are limited. Perhaps the most common is pelvimetry with a breech presentation (see Chap. 24, p. 529 and Fig. 20-4, p. 473).

Fluoroscopy and Angiography. Dosimetry calculations are much more difficult with these procedures because of variations in the number of radiographs obtained, total fluoroscopy time, and fluoroscopy time in which the fetus is in the radiation field. As shown in **Table 41-5**, the range is quite variable. Although the Food and Drug Administration limits exposure rate for conventional fluoroscopy such as barium studies, special-purpose systems such as angiography units have potential for much higher exposure.

Endoscopy is the preferred method of gastrointestinal tract evaluation in pregnancy. Occasionally, an upper gastrointestinal series or barium enema may be done before the woman realizes that she is pregnant. Most would likely be performed during the period of preimplantation or early organogenesis.

Angiography may occasionally be necessary for serious maternal disorders, and especially for trauma. As before, the greater the distance from the embryo or fetus, the less the exposure and risk.

Computed Tomography. Most computed tomography (CT) imaging is now performed by obtaining a spiral of 360-degree images that are postprocessed in multiple planes. Of these, the axial image remains the most commonly obtained. Multidetector CT (MDCT) images are now standard for common clinical indications. The most recent detectors have 16 or 64 channels. MDCT protocols may result in increased dosimetry compared with traditional CT imaging. A number of imaging parameters have an effect on exposure (Brenner and colleagues, 2007). These include pitch, kilovoltage, tube current, collimation,

TABLE 41-5. Estimated X-Ray Doses to the Uterus/Embryo from Common Fluoroscopic Procedures

Procedure	Dose to Uterus (mrad)	Fluoroscopic Exposure Time (sec)	Cinegraphic Exposure Time (sec)

TABLE 41-6. Estimated Radiation Dosimetry with 16-Channel Multidetector-Imaging Protocols

	Dosimetry (mGy)	
Protocol	**Preimplantation**	**3 Months' Gestation**
Pulmonary embolism	0.20–0.47	0.61–0.66
Renal stone	8–12	4–7
Appendix	15–17	20–40

Data from Hurwitz and co-workers (2006).

number of slices, tube rotation, and total acquisition time. If a study is performed with and without contrast, the dose is doubled because twice as many images are obtained. Fetal exposure is also dependent on factors such as maternal size as well as fetal size and position. And as with plain radiography, the closer the target area is to the fetus, the greater the dosimetry.

Hurwitz and colleagues (2006) employed a 16-MDCT to calculate fetal exposure at 0 and 3 months' gestation using a phantom model (Table 41-6). Calculations were made for three commonly requested procedures in pregnant women. The pulmonary embolism protocol has the same dosimetry exposure as the ventilation-perfusion (V/Q) lung scan discussed below. Because of the pitch used, the appendicitis protocol has the highest radiation exposure, however, it is very useful clinically (Fig. 41-3). For imaging suspected urolithiasis, the MDCT scan protocol is used if sonography is nondiagnostic (Fig. 41-4). Using a similar protocol in 67 women with suspected appendicitis, Lazarus and co-workers (2007) reported sensitivity of 92 percent, specificity of 99 percent, and a negative-predictive value of 99 percent. Here dosimetry is markedly decreased compared with appendiceal imaging because of a different pitch. Using a similar protocol, White and co-workers (2007) identified urolithiasis in 13 of 20 women at an average of 26.5 weeks. Finally, abdominal tomography should be performed if indicated in the pregnant woman with severe trauma (American College of Obstetricians and Gynecologists, 1998).

Cranial CT scanning is the most commonly requested study in pregnant women. Its use in women with neurological disorders is discussed in Chapter 55 (p. 1164) and with eclampsia in Chapter 34 (p. 723). Nonenhanced CT scanning is commonly used to detect acute hemorrhage within the epidural, subdural, or subarachnoid spaces.

Pelvimetry is used by some before attempting breech vaginal delivery (see Chap. 24, p. 529). The fetal dose approaches 0.015 Gy or 1.5 rad, but use of a low-exposure technique may reduce this to 0.0025 Gy or 0.25 rad.

Most experience with chest CT scanning is with suspected pulmonary embolism. The most recent recommendations for its use in pregnancy from the Prospective Investigation of Pulmonary Embolism Diagnosis—PIOPED—II investigators were summarized by Stein and co-workers (2007). They found that pulmonary scintigraphy—the V/Q scan—was recommended for pregnant women by 70 percent of radiologists and chest CT angiography by 30 percent. But most agree that MDCT angiography has improved accuracy because of increasingly faster acquisition times. Others have reported a higher use-rate for CT angiography and emphasize that dosimetry is similar to that with V/Q scintigraphy (Brenner, 2007; Hurwitz, 2006; Matthews, 2006, and their many colleagues). At both Parkland Hospital and the University of Alabama Hospital at Birmingham, we use MDCT scanning initially for suspected pulmonary embolism (see Chap. 47, p. 1026).

Nuclear Medicine Studies

These studies are performed by "tagging" a radioactive element to a carrier that can be injected, inhaled, or swallowed. For

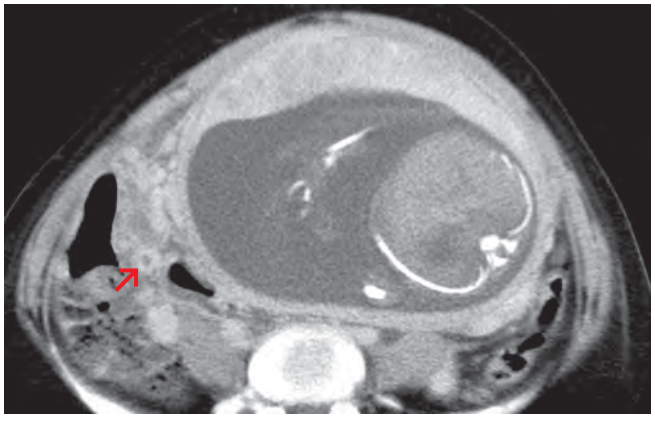

FIGURE 41-3 CT-protocol for appendix shows an enlarged, enhancing—and thus inflamed appendix (*arrow*) next to the 25-week pregnancy. (Used with permission from Dr. Jeffrey H. Pruitt.)

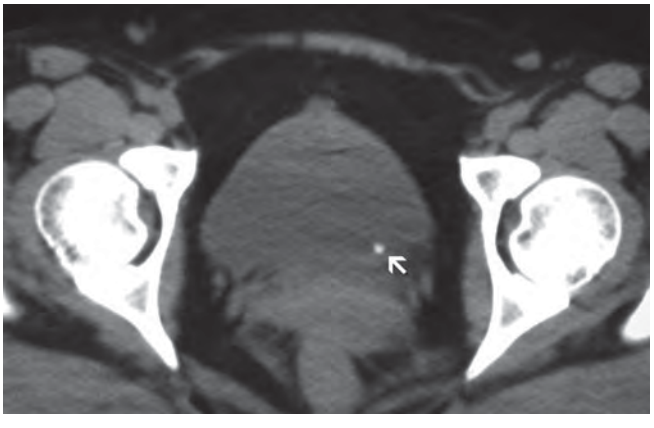

FIGURE 41-4 CT-protocol imaging for urolithiasis disclosed a renal stone in the distal ureter (*arrow*) at its junction with the bladder. (Used with permission from Dr. Jeffrey H. Pruitt.)

example, the radioisotope technetium-99m may be tagged to red blood cells, sulfur colloid, or pertechnetate. The method used to tag the agent determines fetal radiation exposure. The amount of placental transfer is obviously important, but so is renal clearance because of fetal proximity to the maternal bladder. Measurement of radioactive technetium is based on its decay, and the units used are the curie (Ci) or the becquerel (Bq). Dosimetry is usually expressed in millicuries (mCi). As shown in Table 41-3, the effective tissue dose is expressed in sievert units (Sv). As discussed, to convert: 1 Sv = 100 rem = 100 rad.

Depending on the physical and biochemical properties of a radioisotope, an average fetal exposure can be calculated (Wagner and co-workers, 1997; Zanzonico, 2000). Commonly used radiopharmaceuticals and estimated absorbed fetal doses are given in **Table 41-7**. The radionuclide dose should be kept as low as possible (Adelstein, 1999). Exposures vary with gestational age and are greatest earlier in pregnancy for most radiopharmaceuticals. One exception is the later effect of ^{131}iodine on the fetal thyroid (Wagner and associates, 1997). The International Commission on Radiological Protection (2001) has compiled dose coefficients for radionuclides. Stather and colleagues (2002) detailed the biokinetic and dosimetric models used by the Commission to estimate fetal radiation doses from maternal radionuclide exposure.

As discussed above, MDCT-angiography is being used preferentially for suspected pulmonary embolism during pregnancy. Until recently, the imaging modality was the *ventilation-perfusion lung scan* in this setting. It is used if CT angiography is nondiagnostic (see Chap. 47, p. 1026). Perfusion is measured with injected ^{99}Tc-macroaggregated albumin, and ventilation is meas-

TABLE 41-7. Radiopharmaceuticals Used in Nuclear Medicine Studies

Study	Estimated Activity Administered per Examination in Millicuries (mCi)	Weeks' Gestation[a]	Dose to Uterus/Embryo per Pharmaceutical (mSv)[b]
Brain	20 mCi ^{99m}Tc DTPA	<12	8.8
		12	7[c]
Hepatobiliary	5 mCi ^{99m}Tc sulfur colloid	12	0.45
	5 mCi ^{99m}Tc HIDA		1.5
Bone	20 mCi ^{99m}Tc phosphate	<12	4.6
Pulmonary			
Perfusion	3 mCi ^{99m}Tc-macroaggregated albumin	Any	0.45–0.57
Ventilation	10 mCi ^{133}Xe gas		(combined)
Renal	20 mCi ^{99m}Tc DTPA	<12	8.8
Abscess or tumor	3 mCi ^{67}Ga citrate	<12	7.5
Cardiovascular	20 mCi ^{99m}Tc-labeled red blood cells	<12	5
	3 mCi ^{210}Tl chloride	<12	11
		12	6.4
		24	5.2
		36	3
Thyroid	5 mCi $^{99m}TcO_4$	<8	2.4
	0.3 mCi ^{123}I (whole body)	1.5–6	0.10
	0.1 mCi ^{131}I[d]		
	Whole body	2–6	0.15
	Whole body	7–9	0.88
	Whole body	12–13	1.6
	Whole body	20	3
	Thyroid-fetal	11	720
	Thyroid-fetal	12–13	1300
	Thyroid-fetal	20	5900
Sentinel lymphoscintigram	5 mCi ^{99m}Tc sulfur colloid (1–3 mCi)		5

[a]To convert to mrad multiply x 100.
[b]Exposures are generally greater prior to 12 weeks compared with increasing gestational ages.
[c]Some measurements account for placental transfer.
[d]The uptake and exposure of ^{131}I increases with gestational age.
DPTA = diethylenetriaminepentaacetic acid; Ga = gallium; HIDA = hepatobiliary iminodiacetic acid; I = iodine; mCi = millicurie; mSv = millisievert; Tc = technetium; TcO_4 = pertechnetate; Tl = thallium. Compiled from data from Adelstein (1999), Schwartz (2003), Stather (2002), Wagner (1997), Zanzonico (2000), and all their colleagues.

ured with inhaled xenon-127 or xenon-133. Fetal exposure with either is negligible (Chan and colleagues, 2002; Mountford, 1997).

Thyroid scanning with iodine-123 or iodine-131 seldom is indicated in pregnancy. With trace doses used, however, fetal risk is minimal. **Importantly, therapeutic radioiodine in doses to treat Graves disease or thyroid cancer may cause fetal thyroid ablation and cretinism.**

The *sentinel lymphoscintigram,* which uses ^{99m}Tc-sulfur colloid to detect the axillary lymph node most likely to have metastases from breast cancer, is a commonly used preoperative study in nonpregnant women (Newman and Newman, 2007; Spanheimer and associates, 2009; Wang and co-workers, 2007). As shown in Table 41-7, the calculated dose is approximately 0.014 mSv or 1.4 mrad, which should not preclude its use during pregnancy.

SONOGRAPHY

Of all of the major advances in obstetrics, the development of sonography for study of the fetus and mother certainly is one of the greater achievements. The technique has become virtually indispensable in everyday practice. The wide range of clinical uses of sonography in pregnancy is further discussed in Chapter 16 and in most other sections of this book.

Safety

Diagnostic sonography uses sound wave transmission at certain frequencies. Recall that ultrasound is a form of radiation that transmits energy. At very high intensities, there is a *potential* for tissue damage from heat and cavitation (Callen, 2000). That said, with the low-intensity range of real-time imaging, no fetal risks have been demonstrated in more than 35 years of use (Maulik, 1997; Miller and colleagues, 1998). An example is the study done by Naumburg and associates (2000). They performed a case-control study of 578 children with leukemia compared with healthy controls. In each cohort, a third of the children had been exposed to ultrasound in utero.

Advances in technology have introduced Doppler-shift imaging coupled with gray-scale imaging to localize spectral waveforms and superimpose color mapping. Higher energy intensities are used with this duplex Doppler imaging. Again, however, these should have no embryo or fetal effects if low-level pulses are used (Kossoff, 1997).

Ultrasound equipment must have a video display of acoustic output to safeguard against exceeding standards set by a number of organizations including the American College of Obstetricians and Gynecologists (2009). Acoustic outputs are displayed as an index. The *thermal index* is an estimate of temperature increases from acoustic output. If the index is below 1.0, then no potential risk is expected (Miller and associates, 1998). Adverse effects reflected in thermal index changes have not been demonstrated with Doppler use in clinical applications (Maulik, 1997). The *mechanical index* is used to estimate the potential risk of cavitation from heat generated by real-time imaging.

As long as sonographic contrast agents are not used, there is no hypothetical fetal risk. Prolonged exposure of animal fetuses suggest that it is possible to induce cellular alterations. For example, prolonged exposure to ultrasound impeded migration of brain cells in fetal mice (Ang and co-workers, 2007). At this time, the American Institute of Ultrasound in Medicine (2007) and other organizations agree that these findings should not alter the use of ultrasound in pregnant women.

MAGNETIC RESONANCE (MR) IMAGING

Like sonography, magnetic resonance technology has proven extremely useful for maternal and fetal imaging studies because it does not use ionizing radiation. Its application is cited throughout this book. Advantages include high soft-tissue contrast, ability to characterize tissue, and acquisition of images in any plane—particularly axial, sagittal, and coronal. With MR imaging, powerful magnets are used to temporarily alter the state of protons. The hydrogen proton is used for imaging because of its abundance, especially in water and fat. Radio waves are then used to deflect the magnetic vector. When the radiofrequency source is turned off, hydrogen protons return to their normal state. In doing so, they emit radio waves of different frequencies, which are received by radio coils wrapped around the body part. The relative intensity of these signals is plotted on a gray scale. A series of pulse sequences in all planes can be obtained, and each acquisition includes information about the location and characteristics of the sequences. From this, an image is constructed. Technological advances have significantly reduced scan times and improved image quality.

Safety

The most recent update of the Blue Ribbon Panel on MR safety of the American College of Radiology was summarized by Kanal and colleagues (2007). The panel concluded that there are no reported harmful human effects from MR imaging. Chew and colleagues (2001) found no differences in blastocyst formation exposure of early murine embryos to MR imaging with 1.5 tesla strength. Vadeyar and associates (2000) noted no demonstrable fetal heart rate pattern changes during MR imaging in women. Chung (2002) has reviewed these safety issues.

In their report, the Panel described above decided that each request for MR imaging in a pregnant woman should be approved by the attending radiologist. Indicated imaging should be performed at any gestational age if no other imaging studies can be performed, or if MR imaging would provide information that would otherwise require radiation exposure. Contraindications to MR imaging include internal cardiac pacemakers, neurostimulators, implanted defibrillators and infusion pumps, cochlear implants, shrapnel or other metal in biologically sensitive areas, some intracranial aneurysm clips, and any metallic foreign body in the eye. Of more than 51,000 nonpregnant patients scheduled for MR imaging, Dewey and colleagues (2007) found that only 0.4 percent had an absolute contraindication to the procedure.

Contrast Agents

A number of elemental *gadolinium chelates* are used to create paramagnetic contrast. Some are gadopentetate, gadodiamide, gadoteridol, and gadoterate. These cross the placenta and are found in

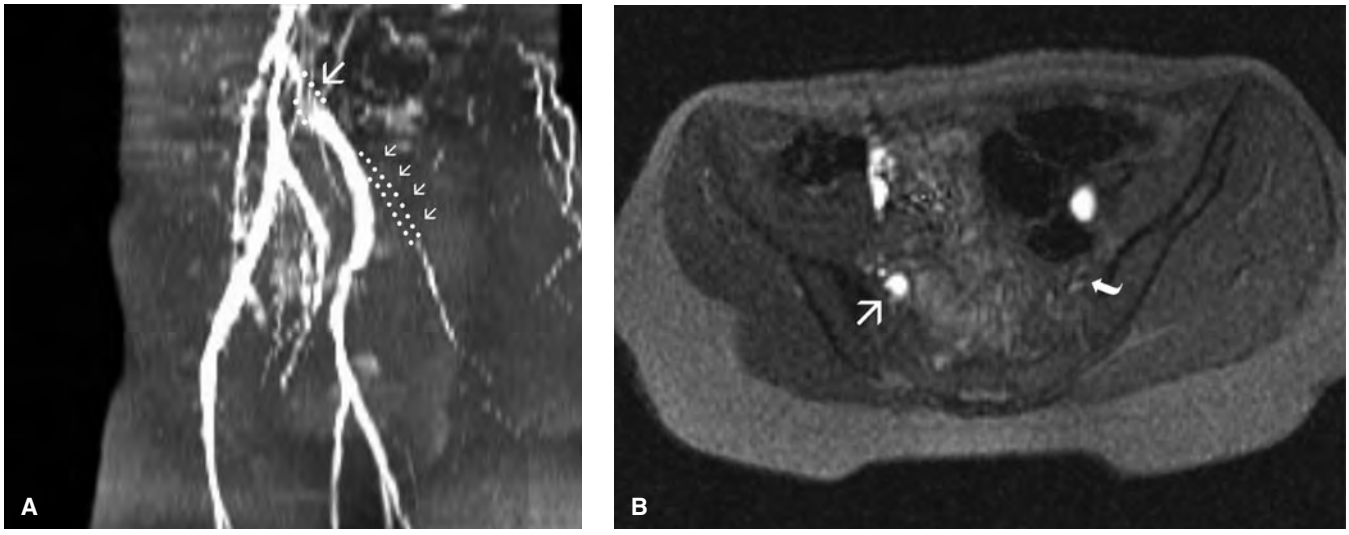

FIGURE 41-5 MR images of a pelvic vein thrombosis in a 15-week pregnant woman who presented with left leg pain but no symptoms of a pulmonary embolus. **A.** Reconstructed magnetic resonance venogram demonstrates partial chronic occlusion of the left common iliac vein (*large arrow*) and thrombosis and complete occlusion of the left internal iliac vein (*small arrows*). **B.** From the axial images, there is normal flow in the right (*arrow*) and no flow in the left internal iliac vein (*curved arrow*). (Courtesy of Dr. R. Douglas Sims.)

amnionic fluid. In doses approximately 10 times the human dose, gadopentetate caused slight developmental delay in rabbit fetuses. De Santis and associates (2007) described 26 women given a gadolinium derivative in the first trimester without adverse fetal effects. According to Briggs and colleagues (2005), as well as the Panel, these contrast agents currently are not recommended unless there are overwhelming benefits. This is because of the uncertain nature of the gadolinium ion in amnionic fluid.

Maternal Indications

With maternal disorders unrelated to pregnancy, MR imaging technology has advantages over CT scanning because there is no ionizing radiation. In some cases, MR imaging may be complementary to CT, and in others, MR imaging is preferable. Maternal central nervous system abnormalities, such as brain tumors or spinal trauma, are more clearly seen with MR imaging. As discussed in Chapter 34 (p. 723), MR imaging has provided valuable insights into the pathophysiology of eclampsia (Twickler and Cunningham, 2007; Zeeman and associates, 2003, 2009). *Magnetic-resonance angiography* provides imaging of the cerebral vasculature and can also be used to calculate flow of the middle and posterior cerebral arteries (Zeeman and colleagues, 2004a, b).

MR imaging is a superb technique to evaluate the maternal abdomen and retroperitoneal space in a pregnant woman. It has

TABLE 41-8. Guidelines for Diagnostic Imaging During Pregnancy

1. Women should be counseled that x-ray exposure from a single diagnostic procedure does not result in harmful fetal effects. Specifically, exposure to less than 5 rads has not been associated with an increase in fetal anomalies or pregnancy loss.
2. Concern about possible effects of high-dose ionizing radiation exposure should not prevent medically indicated diagnostic X-ray procedures from being performed on a pregnant woman. During pregnancy, other imaging procedures not associated with ionizing radiation (e.g., ultrasonography, MRI) should be considered instead of x-rays when appropriate.
3. Ultrasonography and MRI are not associated with known adverse fetal effects.
4. Consultation with an expert in dosimetry calculation may be helpful in calculating estimated fetal dose when multiple diagnostic x-rays are performed on a pregnant patient.
5. The use of radioactive isotopes of iodine is contraindicated for therapeutic use during pregnancy.
6. Radiopaque and paramagnetic contrast agents are unlikely to cause harm and may be of diagnostic benefit, but these agents should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

been used for detection and localization of adrenal tumors, renal lesions, gastrointestinal lesions, and pelvic masses in pregnancy. It has particular value in evaluating neoplasms of the chest, abdomen, and pelvis in pregnancy (Oto and co-workers, 2007). MR imaging may be used to confirm pelvic and vena caval thrombosis—a common source of pulmonary embolism in pregnant women (**Fig. 41-5**). As discussed in Chapter 31 (p. 666), CT and MR imaging is useful for evaluation of puerperal infections, but MR imaging provides better visualization of the bladder flap area following cesarean delivery (Brown and associates, 1999; Twickler and colleagues, 1997). Recently, MR imaging use has been expanded to include evaluation of right lower quadrant pain in pregnancy, specifically appendicitis (Pedrosa and co-workers, 2007, 2009; Singh and colleagues, 2007). Investigators have found disorders of the gastrointestinal tract, especially appendicitis, to be easily diagnosed with MR imaging (see Chap. 49, p. 1058).

Fetal Indications

Fetal MR imaging as a complement to sonography has been used with increasing frequency (De Wilde, 2005; Laifer-Narin, 2007; Sandrasegaran, 2006, and all their colleagues). According to Zaretsky and associates (2003a), MR imaging can be used to image almost all elements of the standard fetal anatomical survey. Bauer (2009), Reichel (2003), Twickler (2002), Weisz (2009) and their associates have validated its use for fetal central nervous system anomalies and biometry (**Fig. 41-6**). Caire and associates (2003) described its merits for fetal genitourinary anomalies. Hawkins and colleagues (2008) reported use of MR imaging in 21 fetuses with renal anomalies and oligohydramnios. Zaretsky and co-workers (2003b) reported that fetal weight estimation was more accurate using MR imaging than with sonography. Fast acquisition sequencing has solved problems with fetal movement to improve imaging. The technique is termed *HASTE*—*H*alf-Fourier *A*cquisition *S*ingle slow *T*urbo spin *E*cho, or *SSFSE*—*S*ingle *S*hot *F*ast *S*pin *E*cho. Levine and colleagues (2001) reported that HASTE protocols do not generate significant heat in the uterus or fetus of pigs. The most common fetal indications for MR imaging are for evaluation of complex abnormalities of the brain, chest, and genitourinary system. A more extensive discussion of fetal indications and findings of MR imaging are discussed in Chapter 16 and throughout the book.

GUIDELINES FOR DIAGNOSTIC IMAGING DURING PREGNANCY

The American College of Obstetricians and Gynecologists (2004) has reviewed the effects of radiographic, sonographic, and magnetic-resonance exposure during pregnancy. Its suggested guidelines are shown in **Table 41-8**.

SEPSIS SYNDROME 932
TRAUMA 936
THERMAL INJURY 941
CARDIOPULMONARY RESUSCITATION 942

Women with a broad spectrum of pathophysiological conditions—some of which in the past precluded pregnancy—benefit from the technology and expertise of *critical care obstetrics*. Common medical and surgical problems such as serious heart disease, acute or chronic pulmonary disorders, and trauma complicating pregnancy are just a few examples. Included also are severe obstetrical complications such as preeclampsia, hemorrhage, and sepsis syndrome. It is imperative that obstetricians and other members of the healthcare team have a working knowledge of the unique considerations for pregnant women. Because these women are usually young and in good health, their prognosis should be better than that of many other patients admitted to an intensive care unit.

OBSTETRICAL INTENSIVE CARE

Depending on methods and protocols at various institutions, approximately 1 percent of obstetrical patients need some type of intensive observation and management. Women with complications specific to pregnancy have the greatest need for obstetrical intensive care (Kuklina and associates, 2009; Madan and co-workers, 2008). As shown in Table 42-1, nearly half of these women need critical care for hypertensive disorders, hemorrhage, sepsis, or cardiopulmonary complications. With life-threatening hemorrhage, surgical procedures may be necessary, and close proximity to a delivery-operating room is advantageous. When admitted, a fourth of these women with serious medical or surgical disorders are still pregnant, and concerns for fetal well-being are usually better served by this close proximity. In our experiences from Parkland Hospital, Zeeman and colleagues (2003) reported that the most common nonobstetrical reasons for intensive care were usually encountered antepartum and included patients with diabetes, pneumonia or asthma, heart disease, chronic hypertension, pyelonephritis, or thyrotoxicosis.

Organization of Critical Care

The concept and development of critical care began in the 1960s. In 1983, the National Institutes of Health had its first Consensus Conference on this subject, and in 1988, the Society for Critical Care Medicine promulgated definitions and established guidelines for intensive care units (ICUs). These continue to be refined by certifying organizations (Manthous, 2004).

Because of high costs incurred by medical and surgical ICUs, a step-down *intermediate care unit* evolved. These units were designed for patients who did not require intensive care, but who needed a higher level of care than provided on a general ward. In 1998, the American College of Critical Care Medicine and the Society of Critical Care Medicine published guidelines for intermediate care units (Table 42-2).

Obstetrical Critical Care

Although the evolution of critical care for obstetrical patients has generally followed developments described above, there are no specific guidelines. Most hospitals employ a blend of

TABLE 42-1. Indications for Admission to Intensive Care Units for Obstetrical Patients

Factor	Dallas, Texas[a]	Houston, Texas[b]	Leiden, The Netherlands[c]	Weighted Average
Number	483	58	142	683
Antepartum	20%	30%	31%	23%
Postpartum	80%	70%	69%	77%
Diagnosis[d]				
Hypertensive disorders	45%	24%	62%	47%
Hemorrhage	18%	16%	18%	18%

[c]Keizer and associates (2006): Multidisciplinary Intensive Care Unit.
[d]Columns do not total 100 percent–other diagnoses not listed.

these concepts, and in general, those can be divided into three types:

1. Medical or surgical ICU—in most hospitals, severely ill women are transferred to a unit operated by medical and surgical "intensivists." Triage to one of these depends on the acuity of care needed and the ability of that facility to provide it. In most obstetrical units, women who require ventilatory support, invasive monitoring, or pharmacological support of circulation are transferred to a specialized ICU. In her review of reports from more than 25 tertiary-care referral institutions, Zeeman (2006) found that about 0.5 percent of obstetrical patients are transferred to these types of ICUs.
2. Obstetrical Intermediate Care Unit—sometimes referred to as High-Dependency Care Unit (HDU)—examples of this system have been developed at both Parkland and at the University of Alabama at Birmingham Hospitals. These units are within the labor and delivery suites in specialized areas with experienced personnel available. The two-tiered system incorporates the guidelines for intermediate and intensive care. Care is provided by specially trained maternal-fetal medicine specialists and nurses with experience in critical care obstetrics. The team should include clinicians with special expertise sufficient to deal with all problem areas. These typically include other obstetricians and anesthesiologists with readily available pulmonologists, cardiologists, and other medical and surgical specialists. Many tertiary-care centers have developed such intermediate care units and use selected triage to other ICUs. For smaller hospitals, transfer to a medical or surgical ICU is preferable, and sometimes transfer to another hospital is necessary. In either case, there must be collaboration between obstetricians, intensivists, and other specialists.
3. Obstetrical Intensive Care Unit—these units are full-care ICUs as described above, but are operated by obstetrical and anesthesia personnel in labor and delivery. Very few units have these capabilities (Zeeman, 2006).

Recently the American College of Obstetricians and Gynecologists (2009) summarized implementation of concepts of critical obstetrical care depending on hospital size and technical facilities. Somewhat related, Gosman and colleagues (2008)

TABLE 42-2. Guidelines for Conditions That Could Qualify for Intermediate Care

Cardiac: exclude infarction, stable infarction, stable arrhythmias, mild-to-moderate congestive heart failure, hypertensive urgency without end-organ damage
Pulmonary: stable patients for weaning and chronic ventilation, patients with potential for respiratory failure who are otherwise stable
Neurological: stable central nervous system, neuromuscular, or neurosurgical conditions that require close monitoring
Drug overdose: hemodynamically stable
Gastrointestinal: stable bleeding, liver failure with stable vital signs
Endocrine: diabetic ketoacidosis, thyrotoxicosis that requires frequent monitoring
Surgical: postoperative from major procedures or complications that require close monitoring
Miscellaneous: early sepsis, patients who require closely titrated intravenous fluids, pregnant women with severe preeclampsia or other medical problems

Reprinted from Nasraway SA, Cohen IL, Dennis RC, et al: Guidelines on admission and discharge for adult intermediate care units, *Critical Care Medicine*, 1998, vol. 26, no. 3, pp. 607–610, with permission.

TABLE 42-3. Formulas for Deriving Various Cardiopulmonary Parameters

Mean arterial pressure (MAP) (mm Hg) = [SBP + 2 (DBP)] ÷ 3
Cardiac output (CO) (L/min) = heart rate × stroke volume
Stroke volume (SV) (mL/beat) = CO/HR
Stroke index (SI) (mL/beat/m^2) = stroke volume/BSA
Cardiac index (CI) (L/min/m^2) = CO/BSA
Systemic vascular resistance (SVR) (dynes × sec × cm^{-5}) = [(MAP − CVP)/CO] × 80
Pulmonary vascular resistance (PVR) (dynes × sec × cm^{-5}) = [(MPAP − PCWP)/CO] × 80

BSA = body surface area (m^2); CO = cardiac output (L/min); CVP = central venous pressure (mm Hg); DBP = diastolic blood pressure; HR = heart rate (beats/min); MAP = mean systemic arterial pressure (mm Hg); MPAP = mean pulmonary artery pressure (mm Hg); PCWP = pulmonary capillary wedge pressure (mm Hg); SBP = systolic blood pressure.

have explored the concept of a *medical emergency team*—*MET*—for rapid response to emergent obstetrical critical care situations.

Pulmonary Artery Catheter (PAC)

Use of the pulmonary artery catheter has contributed immensely to understanding of normal pregnancy hemodynamics as well as pathophysiology of common obstetrical conditions. These include severe preeclampsia-eclampsia, acute respiratory distress syndrome (ARDS), and amnionic fluid embolism (Clark, 1988, 1995, 1997; Cunningham, 1986, 1987; Hankins, 1984, 1985, and all their co-workers). That said, in our extensive experiences, invasive hemodynamic monitoring is seldom necessary for critically ill obstetrical patients.

After years of use, randomized trials of more than 3700 medical and surgical patients described no benefits with pulmonary artery catheter monitoring (Harvey, 2005; Richard, 2003; Sandham, 2003, and their numerous colleagues). A recent randomized trial conducted by the National Heart, Lung, and Blood Institute (2006b) assessed catheter-guided therapy in 1000 patients with acute respiratory distress syndrome (ARDS). PAC monitoring did not improve survival or organ function, and there were more complications than with central venous pressure monitoring. A retrospective analysis of the National Trauma Data Bank by Friese and co-workers (2006) showed a survival advantage for catheter monitoring in patients with the highest injury severity scores (ISS). Its uses in obstetrics are limited (Martin and Foley, 2006). One example might be sepsis syndrome complicated by pulmonary edema and hypotension.

Hemodynamic Changes in Pregnancy

Formulas for deriving some hemodynamic parameters are shown in Table 42-3. These measurements can be corrected for body size by dividing by body surface area (BSA) to obtain *index values*. Nomograms for nonpregnant adults are used. As emphasized by Van Hook and Hankins (1997), this information does not always reflect uteroplacental perfusion.

In a landmark investigation, Clark and colleagues (1989) used PAC to obtain cardiovascular measurements in healthy pregnant women and again in these same women when nonpregnant, to serve as their own controls (Table 42-4). When plotted on a *ventricular function curve*, performance remains unchanged during pregnancy because increased blood volume and cardiac output are compensated by decreased vascular resistance and increased pulse rate (Fig. 42-1). A working knowledge of these changes is

TABLE 42-4. Hemodynamic Changes in Normal Nonpregnant Women Compared with Those When Pregnant at Term

Measurement	Nonpregnant	Term Pregnant	Change (%)
Cardiac output (L/min)	4.3 ± 0.9	6.2 ± 1.0	+44
Heart rate (beats/min)	71 ± 10	83 ± 10	+17
Mean arterial pressure (mm Hg)	86 ± 7.5	90 ± 5.8	+4
Systemic vascular resistance (dynes/cm/sec^{-5})	1530 ± 520	1210 ± 266	−21
Pulmonary vascular resistance (dynes/cm/sec^{-5})	199 ± 47	78 ± 22	−35
Pulmonary capillary wedge pressure (mm Hg)	6.3 ± 2.1	7.5 ± 1.8	+18
Central venous pressure (mm Hg)	3.7 ± 2.6	3.6 ± 2.5	−2
Left ventricular stroke work index (g/m/m^{-2})	41 ± 8	48 ± 6	+17
Colloid oncotic pressure (mm Hg)	20.8 ± 1.0	18.0 ± 1.5	−14
Colloid oncotic/wedge pressure gradient (mm Hg)	14.5 ± 2.5	10.5 ± 2.7	−28

This table was published in *American Journal of Obstetrics & Gynecology,* Vol. 161, No. 6, pt. 1, SL Clark, DB Cotton, W Lee, et al., Central hemodynamic assessment of normal term pregnancy, pp. 1439–1442, Copyright Elsevier 1989.

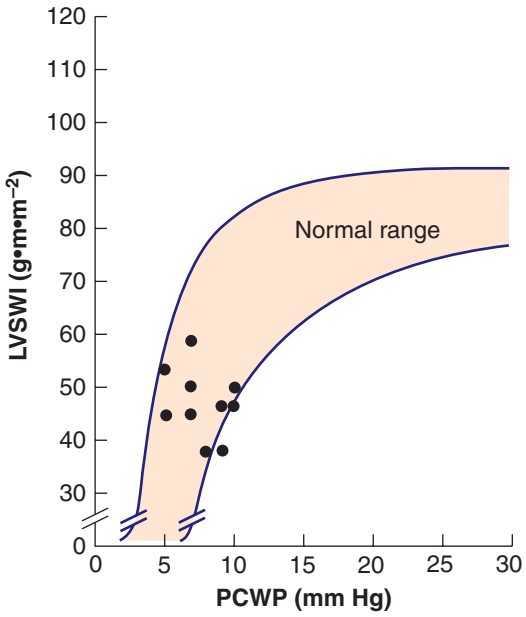

FIGURE 42-1 Ventricular function in 10 healthy pregnant women at term. Individual values are plotted and all but one fall between the lines that define normal function. (LVSWI = left ventricular stroke work index; PCWP = pulmonary capillary wedge pressure.) (Plotted data points from Clark and colleagues, 1989.)

paramount to understanding the pathophysiology of pregnancy complications discussed throughout this book.

ACUTE PULMONARY EDEMA

The incidence of pulmonary edema complicating pregnancy averages about 1 in 500 to 1000 deliveries at tertiary referral centers. The two general causes are: (1) *cardiogenic*—hydrostatic edema caused by high pulmonary capillary hydraulic pressures and (2) *noncardiogenic*—permeability edema caused by capillary endothelial and alveolar epithelial damage. In pregnancy, pulmonary edema frequently is due to a combination of these two. Taken in toto, studies in pregnant women indicate that more than half who develop pulmonary edema have some degree of sepsis syndrome in conjunction with tocolysis, severe preeclampsia, or obstetrical hemorrhage combined with vigorous fluid therapy.

Cardiogenic pulmonary edema is involved in fewer than half of cases, but resuscitation for hemorrhage and vigorous treatment for preterm labor are common precipitating causes. Sciscione and colleagues (2003) reported that among 51 cases of pulmonary edema, approximately one fourth each were due to cardiac failure, tocolytic therapy, iatrogenic fluid overload, or preeclampsia. In 25 cases described by Hough and Katz (2007), more than half were associated with preeclampsia, and there was equal distribution of the other three causes. DiFederico and associates (1998) reported that 40 percent of 84 cases of pulmonary edema were associated with tocolytic therapy. And in the report by Jenkins and colleagues (2003), tocolytic therapy caused 15 percent of cases of pulmonary edema and one maternal death in 51 women who required assisted ventilation.

Noncardiogenic Increased Permeability Edema

Endothelial activation associated with preeclampsia, sepsis syndrome, or acute hemorrhage—or more likely combinations of these—are the most common predisposing factors to pulmonary edema in pregnant women (Table 42-5). As discussed, these are often associated with vigorous fluid replacement and tocolytic therapy for preterm labor. Parenteral β-agonists such as terbutaline are undisputedly related to pulmonary edema. And although Samol and Lambers (2005) reported that pulmonary edema developed in 8 percent of 789 women given magnesium sulfate for preterm labor, half of these were also given terbutaline. In our extensive experiences with the use of magnesium sulfate for treatment of severe preeclampsia, we are dubious that magnesium *per se* causes pulmonary edema. Martin and Foley (2006) arrived at a similar conclusion after their review.

Cardiogenic Hydrostatic Edema

Most cases of cardiogenic pulmonary edema during pregnancy are associated with some form of gestational hypertension. Acute systolic hypertension exacerbates diastolic dysfunction, causing pulmonary edema (Gandhi and associates, 2001). Common causes of diastolic heart failure are chronic hypertension and obesity with left ventricular hypertrophy (Jessup and Brozena, 2003; Kenchaiah and colleagues, 2002). And such hypertrophy is two- to threefold more common in black women compared with white women (Drazner and co-workers, 2005). Other causes are congenital or acquired anatomical defects (see Chap. 44, p. 963, and Appendix). Even so, heart failure is commonly precipitated acutely by preeclampsia, hemorrhage and anemia, and puerperal sepsis (Cunningham and associates, 1986; Sibai and colleagues, 1987). In many of these, when echocardiography is done later, there is a normal ejection fraction, and evidence for diastolic dysfunction can be found (Aurigemma and Gaasch, 2004). Determination of serum levels of *brain natriuretic peptide (BNP)* has not been reported extensively in pregnancy (see Chap. 5, p. 121). This is a cardiac neurohormone that is secreted from cardiac ventricle myocytes and fibroblasts, and its plasma concentrations are increased in congestive

TABLE 42-5. Some Causes and Associated Factors for Pulmonary Edema in Pregnancy

Noncardiogenic permeability edema—endothelial activation with capillary-alveolar leakage:

heart failure. In general, values less than 100 pg/mL have an excellent negative-predictive value, and levels exceeding 500 pg/mL have an excellent positive-predictive value. But those often recorded—100 to 500 pg/mL—are nondiagnostic (Ware and Matthay, 2005). Assays for both N-terminal BNP and atrial natriuretic peptide (ANP) are elevated with preeclampsia compared with normotensive pregnancy (Tihtonen and co-workers, 2007).

ACUTE RESPIRATORY DISTRESS SYNDROME

The most common cause of respiratory failure in pregnancy is from severe permeability pulmonary edema—the acute respiratory distress syndrome (ARDS). This pathophysiological manifestation of acute lung injury is a continuum from clinical pulmonary edema with mild pulmonary insufficiency as discussed earlier to dependence on high-inspired oxygen concentrations and mechanical ventilation. Because there are no uniform criteria for the diagnosis of ARDS, its incidence is variably reported. In a review, Catanzarite and associates (2001) computed it to be 1 in 3000 to 6000 deliveries. Severe disease requiring ventilatory support has a mortality rate for all patients of 45 percent, which has remained constant since the mid-1990s (Phua and co-workers, 2009). It is as high as 90 percent if caused or complicated by sepsis. Although they are younger and healthier than the overall population, pregnant women still have mortality rates of 25 to 40 percent (Catanzarite and co-workers, 2001; Cole and associates, 2005). Women who are still pregnant with ARDS have correspondingly high perinatal mortality rates.

Definitions

Physiological criteria required for diagnosis of ARDS differ, but clinically it is important to remember that the syndrome covers a wide spectrum. For studies, most investigators define ARDS as radiographically documented pulmonary infiltrates, a ratio of arterial oxygen tension to the fraction of inspired oxygen (PaO_2:FiO_2) of less than 200, and no evidence of heart failure (Martin and Foley, 2006). For most interventional studies, a working diagnosis of *acute lung injury* is made when the PaO_2:FiO_2 ratio is less than 300 along with dyspnea, tachypnea, oxygen desaturation, and radiographic pulmonary infiltrates (Wheeler and Bernard, 2007).

Pathophysiology

ARDS is a pathophysiological description and not necessarily a diagnosis. With acute lung injury from a variety of causes, there is recruitment of neutrophils to the site of inflammation by chemokines. As neutrophils accumulate, they initiate further tissue injury by cytokine elaboration. There is widespread injury to microvascular endothelium, including the pulmonary vasculature, and there is also alveolar epithelial injury. These result in increased pulmonary capillary permeability, surfactant loss or inactivation, diminished lung volume, and vascular shunting with resultant arterial hypoxemia. The second phase of the syndrome usually begins 3 to 4 days later. It involves development of *fibrosing alveolitis* and subsequent repair. Despite this, the long-term prognosis for pulmonary function is surprisingly good (Herridge and colleagues, 2003). This subject has been reviewed by Wheeler and Bernard (2007).

Etiology

A number of disorders have been associated with acute pulmonary injury and permeability edema during pregnancy (**Table 42-6**). Although many are coincidental, others are unique to pregnancy. For example, in nonpregnant patients, sepsis and diffuse infectious pneumonia are the two most common single-agent causes and together account for 60 percent of cases. In pregnancy, however, pyelonephritis, chorioamnionitis, and puerperal pelvic infection are the most frequent causes of sepsis. Severe preeclampsia and obstetrical hemorrhage are also commonly found with ARDS. Importantly, more than half of pregnant women have some combination of sepsis, shock, trauma, and fluid overload. The contribution of *transfusion-related acute lung injury (TRALI),* as described by Kopko and colleagues (2002), is unclear in obstetrical patients (see Chap. 35, p. 794). This subject has been reviewed by Bux and Sachs (2007) and by Stroncek (2007).

Clinical Course

With pulmonary injury, the clinical condition depends largely on the magnitude of the insult, the ability to compensate for it, and the stage of the disease. For example, soon after the initial injury, there commonly are no physical findings except perhaps hyperventilation. And at first, arterial oxygenation usually is adequate. Pregnancy-induced mild metabolic alkalosis may be accentuated by hyperventilation. With worsening, clinical and radiological evidence for pulmonary edema, decreased lung compliance,

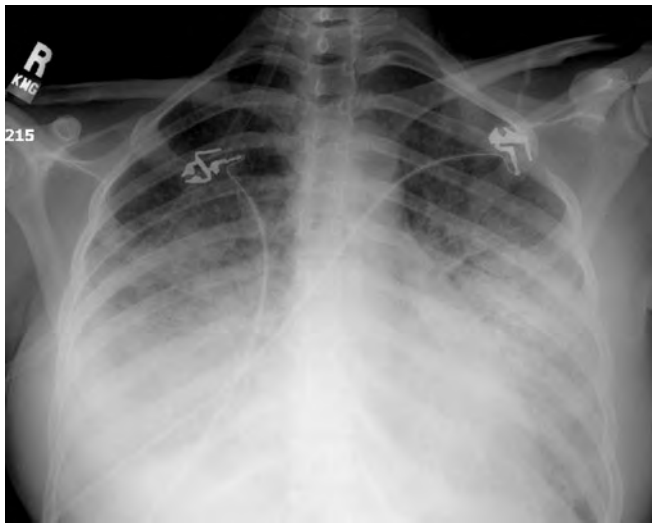

FIGURE 42-2 Anterior-posterior projection chest radiograph of a second-trimester pregnant woman. Marked bilateral parenchymal and pleural opacification secondary to acute respiratory distress syndrome (ARDS) are seen.

and increased intrapulmonary blood shunting become apparent. Progressive alveolar and interstitial edema develop with extravasation of inflammatory cells and erythrocytes.

Ideally, pulmonary injury is identified at this early stage, and specific therapy is directed at the insult if possible. Further progression to acute respiratory failure is characterized by marked dyspnea, tachypnea, and hypoxemia. Further loss of lung volume results in worsening of pulmonary compliance and increased shunting. There are now diffuse abnormalities by auscultation, and a chest radiograph characteristically demonstrates bilateral lung involvement (Fig. 42-2). At this phase, the injury ordinarily would be lethal in the absence of high inspired-oxygen concentrations and positive airway pressure by mask or by intubation. When shunting exceeds 30 percent, severe refractory hypoxemia develops along with metabolic and respiratory acidosis that can result in myocardial irritability, dysfunction, and cardiac arrest.

Management

In acute and severe lung injury, attempts are made to provide adequate oxygenation of peripheral tissues while ensuring that therapeutic maneuvers do not further aggravate lung injury. At least intuitively, increasing oxygen delivery should produce a corresponding increase in tissue uptake, but this is difficult to measure (Evans and Smithies, 1999). Support of systemic perfusion with intravenous crystalloid and blood is imperative. In this regard, a randomized trial by the National Heart, Lung, and Blood Institute (2006b) showed that pulmonary artery catheterization did not improve outcomes. Because sepsis is commonplace in lung injury, vigorous antimicrobial therapy is given for infection. Oxygen delivery can be greatly improved by correction of anemia—each gram of hemoglobin carries 1.25 mL of oxygen when 90-percent saturated. By comparison, increasing the arterial P_{O_2} from 100 to 200 mm Hg results in the transport of only 0.1 mL of additional oxygen for each 100 mL of blood.

Reasonable goals in caring for the woman with severe lung injury are to obtain a Pa_{O_2} of 60 mm Hg or 90-percent saturation at an inspired oxygen content of less than 50 percent, and with positive end-expiratory pressures less than 15 mm Hg. It remains controversial whether delivery of the fetus improves maternal oxygenation (Cole and associates, 2005; Jenkins and co-workers, 2003). Further discussion of the possible effects of delivery during cardiopulmonary resuscitation is found on p. 942).

Oxyhemoglobin Dissociation Curve

The propensity of the hemoglobin molecule to release oxygen is described by the oxyhemoglobin dissociation curve. Simplistically, the curve can be divided into an upper oxygen association curve representing the alveolar-capillary environment and a lower oxygen dissociation portion representing the tissue-capillary environment (Fig. 42-3). Shifts of the curve have their greatest impact at the steep portion because they affect oxygen delivery. A rightward shift is associated with decreased hemoglobin affinity for oxygen and hence increased tissue-capillary oxygen interchange. Rightward shifts are produced by hypercapnia, metabolic acidosis, fever, and increased 2,3-diphosphoglycerate levels. During pregnancy, the erythrocyte concentration of 2,3-diphosphoglycerate is increased by approximately 30 percent. This favors oxygen delivery to both the fetus and peripheral maternal tissues (Rorth and Bille-Brahe, 1971).

Fetal hemoglobin has a higher oxygen affinity than adult hemoglobin. As seen in Figure 42-3, its curve is positioned to the left of the adult curve. To achieve 50-percent hemoglobin saturation in the mother, the Pa_{O_2} must be 27 mm Hg compared with only 19 mm Hg in the fetus. Under normal physiological conditions, the fetus is constantly on the dissociation, or tissue,

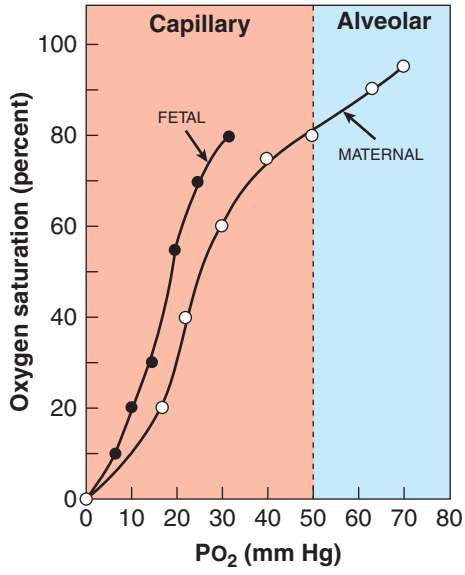

FIGURE 42-3 Oxyhemoglobin dissociation curve. With higher oxygen tension (Pa_{O_2}) in the pulmonary alveoli, adult hemoglobin is maximally saturated compared with that at the lower oxygen tension in the tissue capillaries. Note that at any given oxygen tension, fetal hemoglobin carries more oxygen than adult hemoglobin, as indicated by percent saturation.

portion of the curve. Even with severe maternal lung disease and very low PaO_2 levels, oxygen displacement to fetal tissues is favored. This has been confirmed by studies of pregnant women and their fetuses at high altitude, where despite a maternal PaO_2 of only 60 mm Hg, the fetal PaO_2 is equivalent to that at sea level (Subrevilla and colleagues, 1971).

Mechanical Ventilation

In some patients, positive pressure ventilation by face mask may be effective in early stages of pulmonary insufficiency (Roy and colleagues, 2007). In an attempt to maximize the fetal environment, early intubation is preferred in the pregnant woman if respiratory failure is more likely than not, and especially if it appears to be imminent. The use of *low tidal volume ventilation*—≤ 6 mL/kg body weight—with plateau pressures of < 30 cm H_2O has been proven most beneficial to survival (Girard and Bernard, 2007). Ventilation is adjusted to obtain a PaO_2 greater than 60 mm Hg, or a hemoglobin saturation of 90 percent and a $PaCO_2$ of 35 to 45 mm Hg. Lower levels for PaO_2 should be avoided, because placental perfusion may be impaired (Levinson and co-workers, 1974).

Across the board, the maternal mortality rate is about 20 percent for pregnant women who require ventilation for any length of time. Jenkins and associates (2003) described 51 such women, of whom almost half had severe preeclampsia. Most were intubated postpartum, but 11 were delivered while being ventilated, and another six were discharged undelivered. The maternal mortality rate was 14 percent, and this included a woman who died as a complication of tocolytic treatment. Schneider and colleagues (2003) described a 17-percent maternal mortality rate in 53 women who delivered while receiving ventilatory support. Chen and co-workers (2003) reported four maternal deaths among 16 pregnant women—25 percent—who required mechanical ventilation. None of these investigators concluded that delivery improved maternal outcome.

Positive End-Expiratory Pressure

With severe lung injury and high intrapulmonary shunt fractions, it may not be possible to provide adequate oxygenation with usual ventilatory pressures, even with 100-percent oxygen. Positive end-expiratory pressure is usually successful in decreasing the shunt by recruiting collapsed alveoli. At low levels of 5 to 15 mm Hg, positive pressure can typically be used safely. At higher levels, impaired right-sided venous return can result in decreased cardiac output, decreased uteroplacental perfusion, alveolar overdistension, falling compliance, and barotrauma.

Extracorporeal Membrane Oxygenation (ECMO)

This is not usually used in adults. But in a few pregnant women with respiratory failure, ECMO has been used successfully to allow time for lung healing. Cunningham and colleagues (2006) reviewed outcomes in five such women. The duration of support in the four survivors was 2 to 28 days.

Intravenous Fluids

Some pregnancy-induced physiological changes may predispose to greater risk of permeability edema from fluid therapy. For example, colloid oncotic pressure (COP) is determined by serum albumin concentration, and 1 g/dL exerts about 6 mm Hg pressure. As discussed in Chapter 5 (p. 126), serum albumin concentrations normally decrease in pregnancy. This results in a decline from 28 mm Hg in the nonpregnant woman to 23 mm Hg at term and to 17 mm Hg in the puerperium (Benedetti and Carlson, 1979; Robertson, 1969). With preeclampsia, endothelial activation with leakage causes extravascular albumin loss and decreased serum albumin levels. As a result, oncotic pressure averages only 16 mm Hg antepartum and 14 mm Hg postpartum (Zinaman and co-workers, 1985). These changes have a significant clinical impact on the *colloid oncotic pressure/wedge pressure gradient.* Normally, this gradient exceeds 8 mm Hg: however, when it is 4 mm Hg or less, there is an increased risk for pulmonary edema.

Other Therapy

There were no benefits from *artificial or replacement surfactant therapy* in 725 nonpregnant patients with sepsis-induced lung failure reported by Anzueto and colleagues (1996). Although inhalation of *nitric oxide* was found to cause early improvement, mortality rates were unchanged in two studies (Taylor and co-workers, 2004; Wheeler and Bernard, 2007). In a randomized trial conducted by the National Heart, Lung, and Blood Institute (2006), *prolonged methylprednisolone* therapy did not reduce mortality rates when begun in patients who had no improvement by day 7.

SEPSIS SYNDROME

The sepsis syndrome is induced by a systemic inflammatory response to bacteria or their by-products such as endotoxins or exotoxins. The severity of the syndrome is a continuum or spectrum (Fig. 42-4). Infections that most commonly cause the sepsis syndrome in obstetrics are pyelonephritis (see Chap. 48, p. 1036), chorioamnionitis and puerperal sepsis (see Chap. 31, p. 661), septic abortion (see Chap. 9, p. 220), and necrotizing fasciitis (see Chap. 31, p. 669). In more than 4000 nonpregnant patients, the mortality rate at 28 days with severe sepsis was 30 to 40 percent (Abraham and colleagues, 1997; Bernard and associates, 2001). When there is septic shock, mortality rates are higher regardless of the etiology. Mabie and associates (1997) reported a 28-percent mortality rate in 18 pregnant women with sepsis and shock.

Etiopathogenesis

The sepsis syndrome in obstetrics may be caused by a number of pathogens. Although pelvic infections are usually polymicrobial, bacteria that cause severe sepsis syndrome are frequently endotoxin-producing Enterobacteriaceae, most commonly *Escherichia coli.* Other pathogens are aerobic and anaerobic streptococci, *Bacteroides* species, and *Clostridium* species. As recently reviewed by Filbin and colleagues (2009), some strains of group A β-hemolytic streptococci and *Staphylococcus aureus*—including community-acquired methicillin-resistant strains (CA-MRSA)—produce virulent exotoxins that can rapidly cause all features of

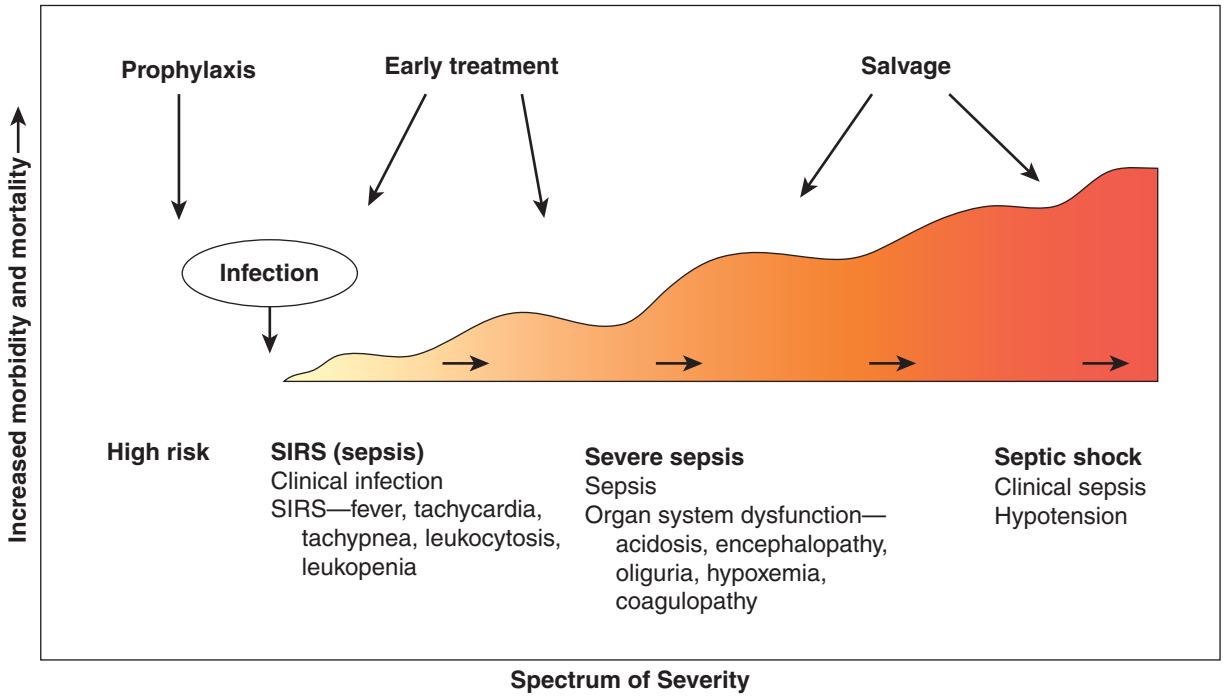

FIGURE 42-4 The sepsis syndrome begins with a systemic inflammatory response syndrome (SIRS) in response to infection that may progress to septic shock. (Redrawn with permission from Dr. Robert S. Munford.)

the sepsis syndrome, which is then termed the *toxic shock syndrome* (see Chap. 31, p. 670). Other virulent streptococci produce proteases that degrade interleukin-8 (IL-8) (Hidalgo- Grass and associates, 2004). Pyelonephritis complicating pregnancy caused by *E. coli* and *Klebsiella* species commonly is associated with bacteremia and sepsis syndrome (Cunningham and associates, 1987; Mabie and colleagues, 1997).

Endotoxin is a lipopolysaccharide released upon lysis of the cell walls of gram-negative bacteria. A number of potent bacterial *exotoxins* can also cause severe sepsis syndrome. Examples include exotoxins from *Clostridium perfringens*, toxic shock syndrome toxin (TSST-1) from *S. aureus,* and toxic shock-like exotoxin from group A β-hemolytic streptococci (Adem and associates, 2005; Daif and co-workers, 2009). As described by Nathan and colleagues (1993), these exotoxins cause rapid and extensive tissue necrosis and gangrene, especially of the postpartum uterus, and may cause profound cardiovascular collapse and maternal death.

Sequelae of the sepsis syndrome begin with an inflammatory response that is directed against microbial endotoxins and exotoxins. These and other toxins stimulate CD4 T cells and leukocytes to produce proinflammatory compounds that include tumor necrosis factor-α (TNF-α), a number of interleukins, other cytokines, proteases, oxidants, and bradykinin (Russell, 2006). For example, a very small amount of TSST-1 activates 5 to 30 percent of T cells that result in a "cytokine storm" (Que and associates, 2005). A myriad of cellular reactions follow that include stimulation of pro- and anti-inflammatory compounds, procoagulant activity, gene activation, receptor regulation, and immune suppression (Filbin and colleagues, 2009; Hotchkiss and Karl, 2003). It is also likely that IL-6 mediates myocardial suppression (Pathan and associates, 2004).

The pathophysiological response to this cascade is selective vasodilation with maldistribution of blood flow. Leukocyte and platelet aggregation causes capillary plugging. Vascular endothelial injury causes profound capillary leakage and interstitial fluid accumulation. Depending on the injury and inflammatory response, which are likely related to the virulence and dose of toxin, there is a spectrum of clinical response (see Fig. 42-4). Thus, sepsis syndrome is a clinical as well as pathophysiological continuum, the most severe result of which is *septic shock*. In its early stages, clinical shock results primarily from decreased systemic vascular resistance that is not compensated fully by increased cardiac output. Hypoperfusion results in lactic acidosis, decreased tissue oxygen extraction, and end-organ dysfunction such as renal failure (Schrier and Wang, 2004). Ultimately, *multiple organ failure* may follow (**Table 42-7**).

Hemodynamic Changes with Sepsis

The pathophysiology of the sepsis syndrome has been elucidated by Parker (1987) and Parrillo (1990) and their colleagues from the National Institutes of Health. They observed that capillary leakage initially causes hypovolemia. If circulating volume is restored with intravenous crystalloid at this point, sepsis is a high cardiac output, low systemic vascular resistance condition. Concomitantly, pulmonary hypertension develops. This is often referred to as the *warm phase* of septic shock. These findings are the most common cardiovascular manifestations of early sepsis, and they often have prognostic significance. Paradoxically, despite the high cardiac output, patients with severe sepsis likely have myocardial depression (Ognibene and co-workers, 1988).

Most previously healthy pregnant women with sepsis at this stage respond well to fluid resuscitation, intensive antimicrobial

TABLE 42-7. Multiple Organ Effects with Sepsis and Shock

Central nervous system	
Cerebral	Confusion, somnolence, coma, combativeness
Hypothalamic	Fever, hypothermia
Cardiovascular	
Blood pressure	Hypotension (vasodilation)
Cardiac	Increased cardiac output with fluid replacement; myocardial depression with diminished cardiac output
Pulmonary	Shunting with dysoxia and hypoxemia; diffuse infiltrates from endothelial and epithelial damage
Gastrointestinal	Gastritis, toxic hepatitis, hyperglycemia
Renal	Hypoperfusion with oliguria; acute tubular necrosis
Hematological	Thrombocytopenia, leukocytosis, activation of coagulation

therapy, and if indicated, removal of infected tissue. Conversely, if hypotension is not corrected following vigorous fluid infusion, then the prognosis is more guarded. At this juncture, if there also is no response to β-adrenergic inotropic agents, this indicates severe and unresponsive extracellular fluid extravasation with vascular insufficiency, overwhelming myocardial depression, or both. Oliguria and continued peripheral vasoconstriction characterize a secondary, *cold phase* of septic shock, survival of which is uncommon. Another poor prognostic sign is continued renal, pulmonary, and cerebral dysfunction once hypotension has been corrected. The average risk of death increases by 15 to 20 percent with failure of each organ system (Wheeler and Bernard, 1999). If three systems are involved, mortality rates are 70 percent (Martin and colleagues, 2003).

Management

In the early 2000s, after a review of various protocols for managing sepsis, an internationally directed consortium launched the Surviving Sepsis Campaign. The cornerstone of management was termed *early goal-directed management* and patterned after the protocol of Rivers and colleagues (2001). The protocol, recently updated by Dellinger and colleagues (2008), stresses prompt recognition of serious bacterial infection and close monitoring of vital signs and urine flow. In obstetrics, hypotension or oliguria should immediately prompt consideration for septicemia or hemorrhage.

One algorithm for management of sepsis syndrome is shown in **Figure 42-5**. The three steps are performed as simultaneously as possible. Prompt and aggressive evaluation and treatment are initiated. Rapid infusion with 2 L and sometimes as many as 4 to 6 L of crystalloid fluids may be required to restore renal perfusion in severely affected women. Because of the capillary leak, there is hemoconcentration. To combat this, blood is given along with crystalloid to maintain the hematocrit at approximately 30 percent (Rivers and colleagues, 2001). According to Ware and Matthay (2000), the use of colloid solution such as 5-percent human albumin is controversial. We do not recommend its use.

If aggressive volume replacement is not promptly followed by urinary output of at least 30 and preferably 50 mL/hr, as well as other indicators of improved perfusion, then consideration is given for vasoactive drug therapy. Mortality rates are high when sepsis is further complicated by respiratory or renal failure. With severe sepsis, damage to pulmonary capillary endothelium and alveolar epithelium causes alveolar flooding and pulmonary edema. This may occur even with low or normal pulmonary capillary wedge pressures. With continued inflammation, this progresses to the *acute respiratory distress syndrome* as discussed on page 930.

Broad-spectrum antimicrobials are administered in maximal doses after appropriate cultures are taken of blood, urine, or exudates not contaminated by normal flora. In severe sepsis, appropriate empirical coverage results in better survival rates (MacArthur and colleagues, 2004). For women with an infected abortion or deep fascial infections, a Gram-stained smear may be helpful in identifying *Clostridium perfringens* or group A streptococcal organisms. Generally, empirical coverage with regimens such as ampicillin plus gentamicin plus clindamycin suffices for pelvic infections (see Chap. 31, p. 664). Wound and other soft-tissue infections are increasingly likely to be caused by methicillin-resistant *S. aureus* (Klevens and associates, 2007; Rotas and colleagues, 2007).

Surgical Treatment

Continuing sepsis may prove fatal, and debridement of necrotic tissue or drainage of purulent material is crucial. Of 18 pregnant women with septic shock, Mabie and colleagues (1997) reported that eight required surgical therapy to control the source of infection. A meticulous search is made for such foci. With an infected abortion, uterine contents must be removed promptly by curettage. Hysterectomy is seldom indicated unless gangrene has resulted, such as in the case shown in **Figure 42-6**.

For women with pyelonephritis, continuing sepsis should prompt a search for obstruction caused by calculi or a perinephric or intrarenal phlegmon or abscess. Renal sonography or "one-shot" pyelography may be used to diagnose obstruction and calculi, whereas computed tomography (CT) may be helpful to diagnose a phlegmon or abscess. With obstruction, ureteral catheterization, percutaneous nephrostomy, or flank exploration may be lifesaving (see Chap. 48, p. 1038).

Most cases of puerperal sepsis are clinically manifested in the first several days postpartum, and tissue debridement is not usually indicated this early. There are several exceptions:

- Necrotizing fasciitis of the episiotomy site or abdominal surgical incision. As described by Gallup and colleagues (2002), this is a surgical emergency, and aggressive management is discussed in Chapter 31 (pp. 665 and 669).
- Massive uterine myonecrosis caused by group A β-hemolytic streptococcal infections (Fig. 42-6). The mortality rate in

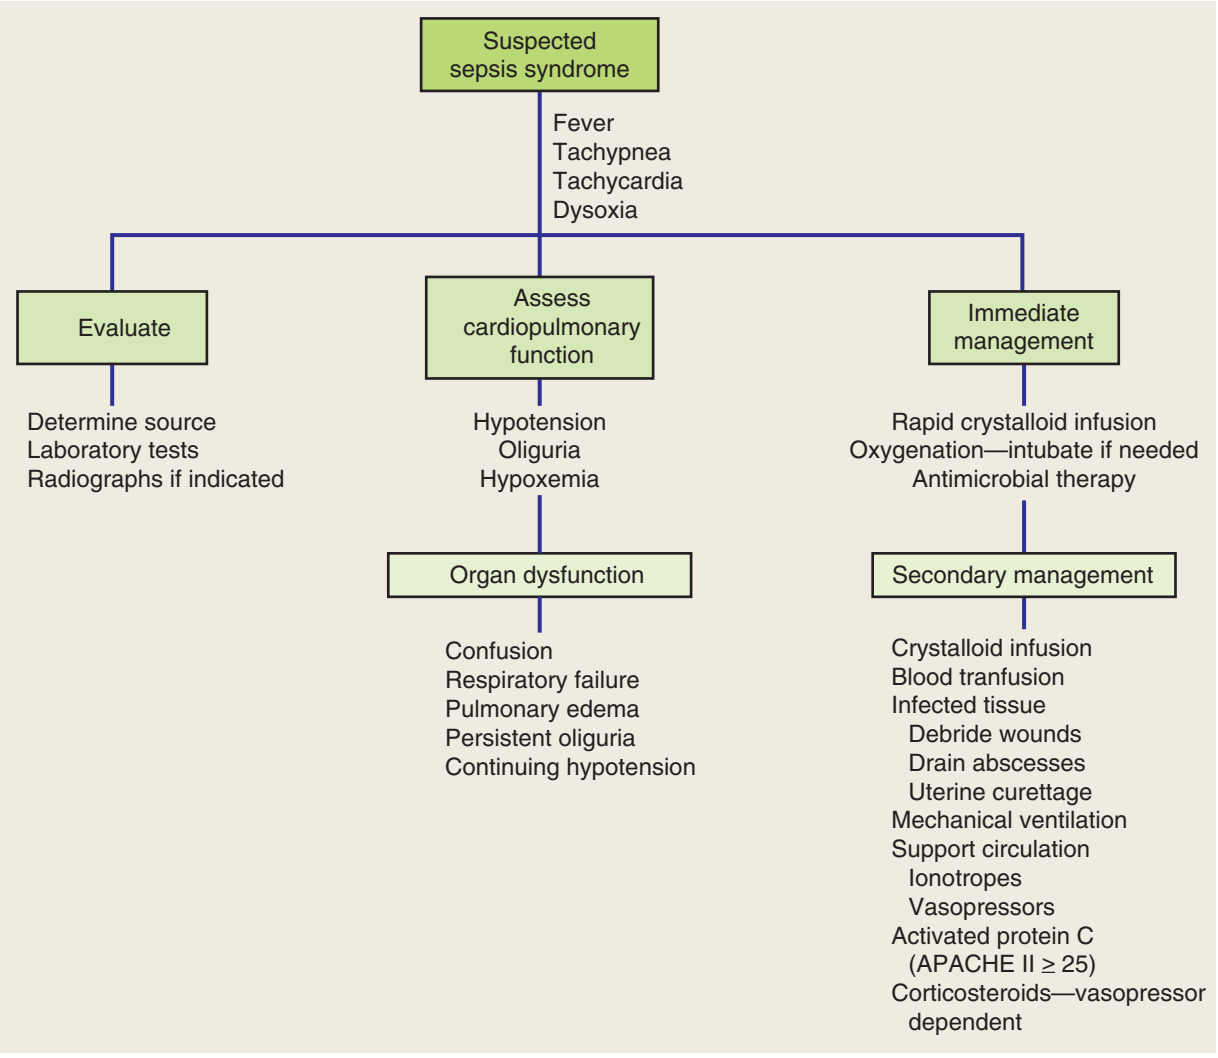

FIGURE 42-5 Algorithm for evaluation and management of sepsis syndrome. Rapid and aggressive implementation is paramount for success. The three steps—Evaluate, Assess, and Immediate management—are done as simultaneously as possible.

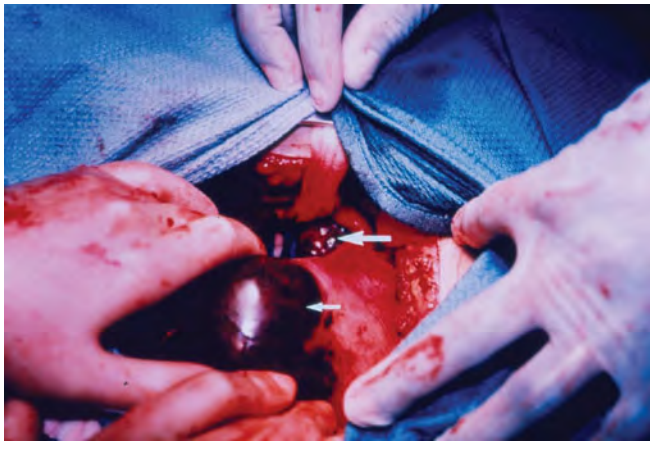

FIGURE 42-6 Group A β-hemolytic *Streptococcus pyogenes* puerperal infection that caused uterine gangrene, overwhelming sepsis syndrome, and maternal death. Arrows point to overtly "ballooned-out" gangrenous areas of postpartum uterus.

these women is high, and prompt hysterectomy may be lifesaving (Mabie and co-workers, 1997; Nathan and colleagues, 1993). Other overwhelmingly infected tissues or other virulent organisms can produce similar findings (Clad and associates, 2003; Daif and co-workers, 2009).

- Persistent or aggressive uterine infection with necrosis and dehiscence of the uterine incision with severe peritonitis (see Chap. 31, p. 666). **Any woman with infection following cesarean delivery who is suspected of having peritonitis should be carefully evaluated for uterine incisional necrosis or bowel perforation.** Prompt surgical exploration, and frequently hysterectomy, may be necessary. An abdominopelvic CT scan of the pelvis is useful to characterize these infections.

Peritonitis and sepsis much less commonly may result from a ruptured parametrial, intra-abdominal, or ovarian abscess (see Chap. 31, p. 665).

Adjunctive Therapy

Vasoactive drugs are not given unless aggressive fluid treatment fails to correct hypotension and perfusion abnormalities. First-line agents are norepinephrine, epinephrine, dopamine, dobutamine, or phenylephrine. Russell and colleagues (2008) recently showed that low-dose vasopressin combined with norepinephrine infusion did not lower 28-day mortality rates.

The use of corticosteroids is controversial. Serum cortisol levels are typically elevated in sepsis, and higher levels are associated with increased mortality rates (Sam and associates, 2004). Some but not all studies have shown a salutary effect of steroid administration, and these drugs are considered for use in patients who are vasopressor dependent (Dellinger and co-workers, 2008).

Endotoxin stimulates endothelial cells to upregulate tissue factor and thus procoagulant production. At the same time, it decreases the anticoagulant action of activated protein C. Because of this, agents were developed that block coagulation, however, *antithrombin III* and *tissue factor pathway inhibitor* did not improve outcomes (Abraham and co-workers, 2003; Warren and colleagues, 2001).

In a landmark study by Bernard and associates (2001), recombinant activated protein C—*drotrecogin alfa*—was shown to improve 28-day mortality rates from sepsis. This effect was limited to the subset of patients with severe sepsis and a high risk of death as determined by an Acute Physiology and Chronic Health Evaluation II (APACHE II) score of 25 or greater. The APACHE II score is computed from 12 physiological assessments in the ICU—scores range from 0 to 71. Subsequent trials confirmed this and again showed no advantages for patients with severe sepsis and an APACHE II score of less than 25 (Abraham and colleagues, 2005; Payen and associates, 2007). The Surviving Sepsis campaign guidelines call for recombinant human activated protein C infusion for 96 hours in patients whose APACHE II score is 25 or higher (Dellinger and colleagues, 2008). A major drawback is a 10-percent risk of serious hemorrhage (Kanji and co-workers, 2007). Importantly, its use in pregnancy is limited, although Medve and associates (2005) described its use in a woman with urosepsis at 18 weeks.

There are a number of other therapies that have proven ineffective. Some of these include *antiendotoxin antibody* and *E5 murine monoclonal IgM antiendotoxin antibody; anticytokine antibodies* and *competitive blockers of TNF-α binding;* and a *nitric oxide synthase inhibitor* (Russell, 2006). Active searches focused on novel targets continue.

TRAUMA

Trauma, homicide, and similar violent events are a leading cause of death in young women. As many as 10 to 20 percent of pregnant women suffer physical trauma (American College of Obstetricians and Gynecologists, 1998; Rickert and associates, 2003). Injury-related deaths are the most commonly identified cause of maternal morbidity in Maryland, Utah, and North Carolina (Harper and Parsons, 1997; Horon and Cheng, 2001; Jacob and colleagues, 1998). And in a California study of 4.8 million pregnancies by El Kady and co-workers (2004, 2005), almost 1 in 350 women were hospitalized for injuries from assaults. In an audit from Parkland Hospital, Hawkins and associates (2007) studied 1682 pregnant women who presented to the trauma service. Motor vehicle accidents and falls accounted for 85 percent of injuries, whereas 10 percent were due to assaults.

A number of reports of pregnancy-associated deaths have established homicide as a major cause of maternal deaths (Chang and associates, 2005; Christiansen and Collins, 2006; Shadigian and Bauer, 2005). In the 10-city case-control study by McFarlane and associates (2002), 5 percent of female homicide victims were pregnant. Finally, there is evidence that intimate partner violence may be linked to suicide in pregnancy (Martin and associates, 2007).

Blunt Trauma

Many forms of blunt trauma are encountered in pregnancy. Their common theme concerns immediate assessment of maternal effects of trauma, emergency treatment, and then evaluation of collateral effects on the fetus.

Physical Abuse—Intimate Partner Violence

According to the Department of Justice, women who are aged 16 to 24 years have the highest per capita rates of intimate partner violence—19.4 per 1000 (Rennison and Welchans, 2000). It is estimated that 5 million women each year are physically assaulted by their male partners (American College of Obstetricians and Gynecologists, 2006a). One goal in violence prevention for Healthy People 2010 is reduction of physical abuse directed at women by male partners. The *Pregnancy Risk Assessment Monitoring Systems—PRAMS*—report from 2000 to 2003 showed some improvement in these areas (Suellentrop and coworkers, 2006).

Even more appalling is that pregnant women are not immune to this physical violence. Most supporting data have been accrued by public institutions, and according to the American College of Obstetrics and Gynecology (2006a), abuse rates range from 1 to 20 percent during pregnancy. In Phoenix, more than 13 percent of women who enrolled for prenatal services had a history of physical or sexual abuse (Coonrod and colleagues, 2007). Abuse is linked to poverty, poor education, and use of tobacco, alcohol, and illicit drugs (Centers for Disease Control and Prevention, 2008). Unfortunately, abused women tend to remain with their abusers, and the major risk factor for intimate partner homicide is prior domestic violence (Campbell and colleagues, 2007). Finally, women seeking pregnancy termination have a higher incidence of intimate partner violence (Bourassa and Bérubé, 2007).

The woman who is physically abused tends to present late, if at all, for prenatal care. For pregnant women hospitalized in California as a result of assault, perinatal morbidity rates were significantly increased (El Kady and co-workers, 2005). Immediate sequelae included uterine rupture, maternal death, fetal death, and preterm delivery. Later, there were increased rates of placental abruption, preterm and low-birthweight infants, and other adverse outcomes. Similar results were reported by Silverman and colleagues (2006) from PRAMS, which included more than 118,000 pregnancies in 26 states. Importantly, Rodrigues

TABLE 42-8. Guidelines for Prophylaxis against Sexually Transmitted Disease in Victims of Sexual Assault

Prophylaxis Against	Regimen	Alternative
Neisseria gonorrhoeae	Ceftriaxone 125 mg IM single dose	Cefixime 400 mg orally single dose *or* Ciprofloxacin 500 mg orally single dose
Chlamydia trachomatis	Azithromycin 1 g orally single dose[a]	Erythromycin-base 500 mg orally four times daily for 7 days *or* Ofloxacin 300 mg orally twice daily for 7 days
Bacterial vaginosis	Metronidazole 500 mg orally twice daily for 7 days	Metronidazole gel, 0.75% 5 g intravaginally daily for 5 days *or* Clindamycin cream, 2%, 5 g intravaginally daily for 7 days
Trichomonas vaginalis	Metronidazole as given above	Tinidazole 2 g orally single dose[b]
Hepatitis B (HBV)	If not previously vaccinated, give first dose HBV vaccine, repeat at 1–2 and 4–6 months	
Human immunodeficiency virus (HIV)	Consider retroviral prophylaxis if risk for HIV exposure is high	

[a] For nonpregnant women, doxycycline, 100 mg orally twice daily for 7 days, can be given instead.
[b] Pregnancy category C.
From Centers for Disease Control and Prevention (2006).

and associates (2008) found that preterm delivery was increased three- to fivefold in abused women, but that it was not related to the severity of abuse. Women who are abused are also twice as likely to be depressed than unabused women—41 versus 19 percent (Rodriguez and co-workers, 2008).

Screening and Prevention. A case-finding approach based on clinical suspicion of *intimate partner violence* is recommended by some (Wathen and MacMillan, 2003). Others take a more aggressive approach, and the American College of Obstetricians and Gynecologists (2005a, 2006a) recommends universal screening at the initial prenatal visit, during each trimester, and again at the postpartum visit (see Chap. 8, p. 197).

Sexual Assault

According to the U.S. Department of Justice (2006), 17 percent of adult women will be sexually assaulted sometime during their lives. More than 90 percent of the nearly 200,000 rape victims in the United States in 2006 were women; 80 percent were younger than 30 years; and 44 percent were younger than 18. Satin and co-workers (1992) reviewed more than 5700 female sexual assault victim cases in Dallas County during 6 years and reported that 2 percent of victims were pregnant. Associated physical trauma occurs in approximately half of all women (Sugar and colleagues, 2004). From a forensic standpoint, evidence collection protocol is not altered.

The importance of psychological counseling for the rape victim and her family cannot be overemphasized. In addition to attention to physical and psychological injuries, exposure to sexually transmitted diseases must be considered. The current recommendations for prophylaxis are shown in Table 42-8. If the woman is not pregnant, another very important aspect is emergency contraception as recommended by the American College of Obstetricians and Gynecologists (2005b) and discussed in detail in Chapter 32 (p. 692).

Automobile Accidents

At least 3 percent of pregnant women are involved in motor vehicle accidents each year in the United States. Using PRAMS, Sirin and colleagues (2007) estimated that 92,500 pregnant women are injured annually. Motor-vehicle crashes are the most common causes of serious, life-threatening, or fatal blunt trauma during pregnancy (Patteson and co-workers, 2007; Schiff and Holt, 2005). They are also the leading cause of traumatic fetal deaths (Mattox and Goetzl, 2005). Between 1995 and 2008, 10 of 12 fetal deaths from maternal trauma were caused by motor-vehicle accidents at Parkland Hospital (Hawkins and colleagues, 2007). Up to half of accidents are associated with lack of seat belt use, and many of these deaths might be preventable with use of three-point restraints shown in Figure 42-7 (Duma and associates, 2006; Metz and Abbott, 2006). Another associated risk factor is alcohol use.

Effects of airbag deployment in pregnant drivers or passengers have not been widely studied. Sims and associates (1996) reported no injuries in three women in their third trimester whose driver-side airbag deployed in 10- to 25-mph collisions. Metz and Abbott (2006) described 30 such women from 20 to 37 weeks whose airbag deployed in accidents with a median speed of 35 mph. A third were not using seat belts, and there

FIGURE 42-7 Illustration showing correct use of three-point automobile restraint. The upper belt is *above* the uterus and the lower belt fits snugly across the upper thighs and well *below* the uterus.

was one fetal death from the single case of placental abruption. Almost 75 percent had contractions, half had abdominal pain, and in 20 percent, there were abnormal fetal heart rate tracings. Even less is known about passenger-side bags or door bags (Moorcroft and co-workers, 2003).

Other Blunt Trauma

Some other common causes of blunt trauma are falls and aggravated assaults. In the California reports by El Kady and co-workers (2004, 2005), intentionally inflicted injuries were present in approximately one third of pregnant women who were hospitalized for trauma. Less common are blast or crush injury (Schoenfeld and colleagues, 1995). With blunt trauma, there can be serious intra-abdominal injuries. Even so, bowel injuries are less frequent because of the protective effect of the large uterus. Still, diaphragmatic, splenic, liver, and kidney injuries may also be sustained. Particularly worrisome is the specter of amnionic fluid embolism, which has been reported even with mild trauma (Ellingsen and co-workers, 2007; Pluymakers and colleagues, 2007). Retroperitoneal hemorrhage is encountered more commonly than usual.

Orthopedic injuries are also encountered with some regularity (Desai and Suk, 2007). In the experiences from the Parkland Hospital trauma unit, 6 percent of 1682 pregnant women evaluated had orthopedic injuries. This subset was also at increased risk for placental abruption, preterm delivery, and perinatal mortality (Cannada and associates, 2008). Leggon and associates (2002) reviewed 101 pelvic fractures during pregnancy and found a 9-percent maternal and 35-percent fetal mortality rate. Almog and co-workers (2007) described their experience with pelvic and acetabular fractures during 15 pregnancies. There was one maternal death, and four of 16 fetuses died.

Finally, head trauma and neurosurgical care is an issue with some cases (Qaiser and Black, 2007).

Fetal Injury and Death

As expected, fetal mortality rates increase with the severity of maternal injuries. Specifically, fetal death is more likely when there is direct fetoplacental injury, maternal shock, pelvic fracture, maternal head injury, or hypoxia (Ikossi and co-workers, 2005; Pearlman and colleagues, 2008). In a 16-state review of fetal deaths from trauma, Weiss and associates (2001) found that motor vehicle accidents caused 82 percent. There was placental injury in almost half, and uterine rupture in 4 percent of these fetal deaths. Patteson and colleagues (2007) reported similar findings.

Although uncommon, fetal skull and brain injuries are more likely if the head is engaged and the maternal pelvis is fractured (Palmer and Sparrow, 1994). Conversely, fetal head injuries, presumably from a *contrecoup* effect, may be sustained in unengaged vertex or nonvertex presentations. Sequelae include intracranial hemorrhage (Green-Thompson and Moodley, 2005). A newborn with paraplegia and contractures associated with a motor vehicle accident sustained several months before birth was described by Weyerts and colleagues (1992). Other injuries include fetal decapitation and another of incomplete midabdominal fetal transection at midpregnancy (Rowe and associates, 1996; Weir and colleagues, 2008).

Placental Abruption and Uterine Rupture

Two catastrophic events from blunt trauma are placental abruption and uterine rupture. These often are life-threatening to both mother and fetus. Another is a placental tear or "fracture" that can result in fetal hemorrhage and exsanguination, either into the amnionic sac or as fetomaternal hemorrhage.

Traumatic Placental Abruption. Placental separation from trauma is likely caused by deformation of the elastic myometrium around the relatively inelastic placenta (Crosby and associates, 1968). This may result from a deceleration injury as the large uterus meets the immovable steering wheel or seat belt (Fig. 42-8). Some degree of abruption complicates 1 to 6 percent of "minor" injuries and up to 50 percent of "major" injuries (Pearlman and co-workers, 1990; Schiff and associates, 2002). In one study, Reis and colleagues (2000) reported that abruption was more likely if vehicle speed exceeded 30 mph.

Clinical findings with traumatic abruption may be similar to those for spontaneous placental abruption (see Chap. 35, p. 761). Kettel and co-workers (1988) emphasized that traumatic abruption may be occult and unaccompanied by uterine pain, tenderness, or bleeding. Stettler and associates (1992) reviewed our experiences with 13 such women at Parkland Hospital and

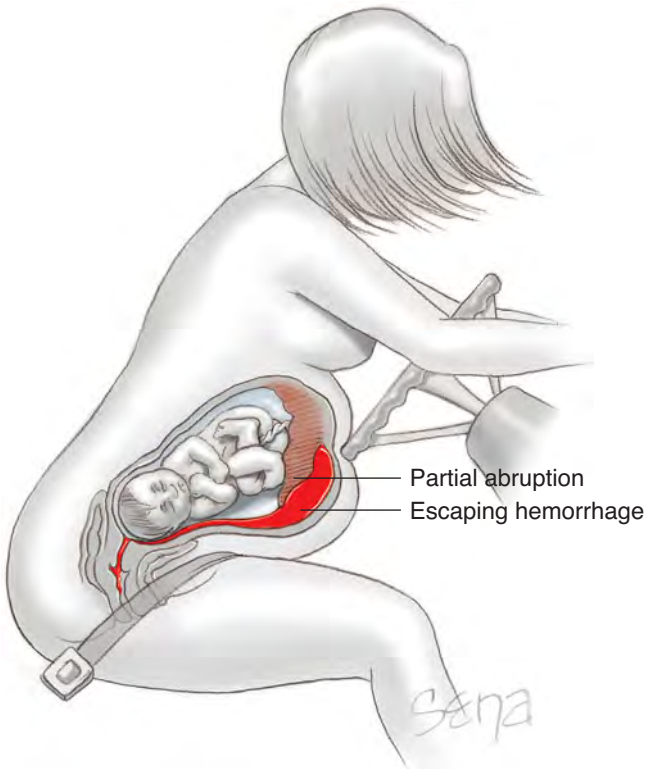

FIGURE 42-8 Acute deceleration injury when the elastic uterus meets the steering wheel, and as it stretches, the inelastic placenta shears from the decidua basalis. Intrauterine pressures as high as 550 mm Hg are generated.

reported that 11 had uterine tenderness, but only five had vaginal bleeding. Because traumatic abruption is more likely to be concealed and generate higher intrauterine pressures, associated coagulopathy is more likely than with nontraumatic abruption. Other common findings are uterine contractions; evidence of fetal compromise such as fetal tachycardia, late decelerations, and acidosis; and fetal death.

Another indication of partial separation is uterine activity. Pearlman and associates (1990) found that if contractions were fewer than every 10 minutes during 4 hours of electronic monitoring, then an abruption is unlikely. Women with contractions of greater frequency, however, have a 20-percent chance of an abruption. If tocolytics are used, they may obfuscate these findings, and we do not recommend them.

Uterine Rupture. Blunt trauma results in uterine rupture in less than 1 percent of severe cases (American College of Obstetricians and Gynecologists, 1998). Rupture is more likely in a previously scarred uterus and is usually associated with a direct impact of substantive force. Decelerative forces following a 25-mph collision can generate up to 500 mm Hg of intrauterine pressure in a properly restrained woman (Crosby and associates, 1968). Findings may be identical to those for placental abruption with an intact uterus, and maternal and fetal deterioration are soon inevitable. Pearlman and Cunningham (1996) described uterine fundal "blow out" with fetal decapitation in a 20-week pregnancy following a high-speed collision. Similarly, Weir and colleagues (2008) described supracervical uterine avulsion and fetal transection at 22 weeks. It may be particularly difficult to diagnose uterine rupture with a dead fetus even using CT scanning (Dash and Lupetin, 1991).

Fetal-Maternal Hemorrhage

If there is considerable abdominal force associated with trauma, and especially if the placenta is lacerated, or "fractured," then life-threatening fetal-maternal hemorrhage may be encountered (Pritchard and associates, 1991). If there is ABO compatibility, fetomaternal hemorrhage can be estimated using a Kleihauer-Betke stain of maternal blood. A small amount of fetal-maternal bleeding has been described in up to one third of trauma cases, but in 90 percent of these, the volume is less than 15 mL (Goodwin and Breen, 1990; Pearlman and associates, 1990). Nontraumatic placental abruption is seldom associated with fetomaternal hemorrhage because there is no fetal bleeding into the intervillous space. Still, massive fetomaternal hemorrhage may coexist with traumatic abruption (Stettler and associates, 1992). In these cases, fetomaternal hemorrhage associated with trauma is caused by a placental tear or "fracture" caused by stretching of the inelastic placenta (Fig. 42-9). Muench and colleagues (2004) reported a 20-fold risk of associated uterine contractions and preterm labor if there is evidence for a fetomaternal bleed.

Penetrating Trauma

Knife and gunshot wounds are the most common penetrating injuries and may be associated with aggravated assaults, suicide attempts, or attempts to cause abortion. The incidence of maternal visceral injury with penetrating trauma is only 15 to 40 percent compared with 80 to 90 percent in nonpregnant individuals (Stone, 1999). When the uterus sustains penetrating wounds, the fetus is more likely than the mother to be seriously injured. Indeed, although the fetus sustains injury in two thirds of such cases, maternal visceral injuries are seen in only 20 percent.

Awwad and colleagues (1994) reported unique experiences with high-velocity penetrating wounds of the pregnant uterus during 16 years of civil war in Lebanon. Two of 14 women died, but neither as a direct result of intra-abdominal injury. They concluded that:

1. When the entrance wound was in either the upper abdomen or back, there were visceral injuries
2. When the entry wound site was anterior and below the uterine fundus, six of women had no visceral injuries
3. The perinatal mortality rate was 50 percent and due to maternal shock, uteroplacental injury, or direct fetal injury.

Management of Trauma

Maternal and fetal outcomes are directly related to the severity of injury. That said, commonly used methods of severity scoring do not take into account significant morbidity and mortality rates related to placental abruption and thus to pregnancy outcomes. For example, Schiff and Holt (2005) evaluated 582 pregnant women hospitalized for injuries. The injury severity score did not accurately predict adverse pregnancy outcomes.

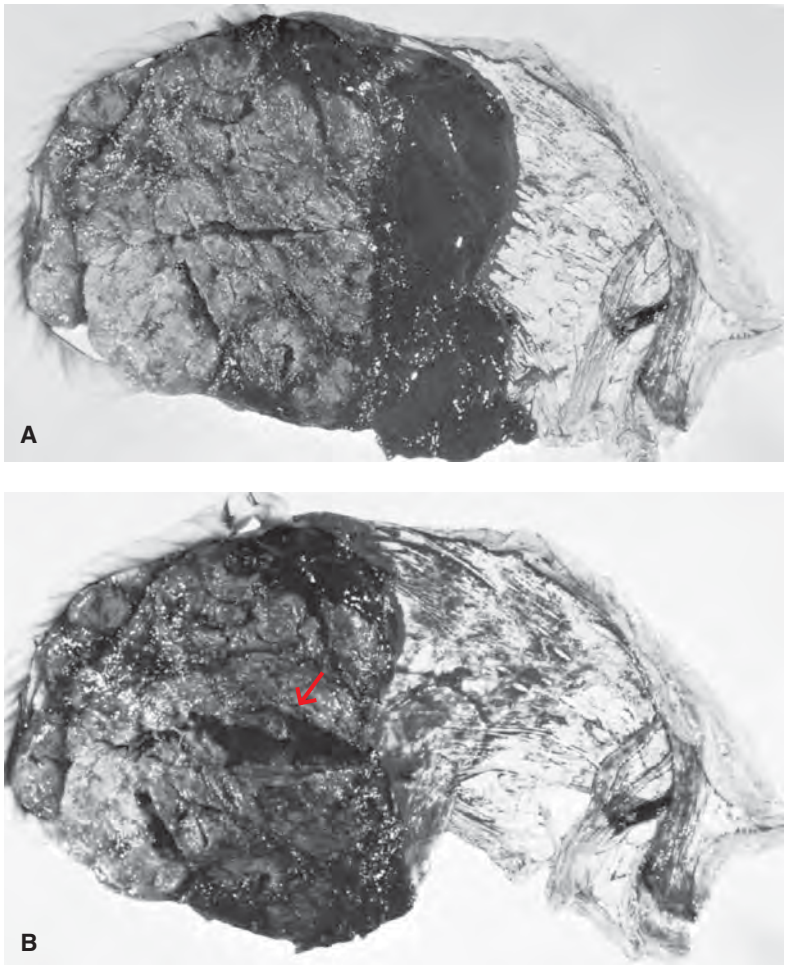

FIGURE 42-9 **A.** Partial placental abruption with adherent blood clot. The fetus died from massive hemorrhage, chiefly into the maternal circulation. **B.** The adherent blood clot has been removed. Note the laceration of the placenta *(arrow)*. **C.** Kleihauer–Betke stain of a smear of maternal blood after fetal death. The dark cells that constituted 4.5 percent of peripheral cells are fetal in origin, whereas the empty cells are of maternal origin.

Importantly, relatively minor injuries were associated with preterm labor and placental abruption. Biester and co-workers (1997) reached similar conclusions with the revised trauma score. Ikossi and colleagues (2005) found that scores indicating severe trauma did correlate with fetal death. But Cahill and associates (2008) studied 317 pregnant women 24 weeks or more who had "minor trauma." Only 14 percent had clinically significant uterine contractions requiring extended fetal evaluation past 4 hours. Adverse perinatal outcomes for all women were not increased. The problem, of course, is that there is no agreed-upon definition for "minor trauma."

With few exceptions, treatment priorities in injured pregnant women are directed as they would be in nonpregnant patients (Meroz and associates, 2007; Petrone and Asensio, 2006). Primary goals are evaluation and stabilization of maternal injuries. Attention to fetal assessment during the acute evaluation may divert attention from life-threatening maternal injuries (American College of Obstetricians and Gynecologists, 1998). Basic rules are applied to resuscitation, including establishing ventilation, arrest of hemorrhage, and treatment of hypovolemia with crystalloid and blood products. **An important aspect of management is repositioning of the large uterus away from the great vessels to diminish its effect on decreased cardiac output.**

Following emergency resuscitation, evaluation is continued for fractures, internal injuries, bleeding sites, and placental, uterine, and fetal injuries. Overall, Ylagan and co-workers (2009) reported that pregnant trauma victims have less radiation exposure than nonpregnant controls. Brown and colleagues (2005) advocate screening abdominal sonography followed by CT scanning for positive sonographic findings. In some cases, open peritoneal lavage may be informative (Tsuei, 2006). Penetrating injuries in most cases must be evaluated using radiography. Because clinical response to peritoneal irritation is blunted during pregnancy, an aggressive approach to exploratory laparotomy is pursued. Whereas exploration is mandatory for abdominal gunshot wounds, some clinicians advocate close observation for selected stab wounds.

Cesarean Delivery

The necessity for cesarean delivery of a live fetus depends on several factors. Laparotomy itself is not an indication for hysterotomy. Some considerations include gestational age, fetal condition, extent of uterine injury, and whether the large uterus

hinders adequate treatment or evaluation of other intra-abdominal injuries (Tsuei, 2006).

Electronic Monitoring

As for many other acute or chronic maternal conditions, fetal well-being may reflect the status of the mother, and thus, fetal monitoring is another "vital sign" that helps evaluate the extent of maternal injuries. Even if the mother is stable, electronic monitoring may be predictive of placental abruption. In the study by Pearlman and associates (1990), no woman had an abruption if uterine contractions were less often than every 10 minutes within the 4 hours after trauma was sustained. **Almost 20 percent of women who had contractions more frequently than every 10 minutes in the first 4 hours had an associated placental abruption.** In these cases, abnormal tracings were common and included fetal tachycardia and late decelerations. Connolly and co-workers (1997) reported no adverse outcomes in women who had normal monitor tracings.

Because placental abruption usually develops early following trauma, fetal monitoring is begun as soon as the mother is stabilized. The duration for which posttrauma monitoring should be performed is not precisely known. From data cited above, an observation period of 4 hours is reasonable with a normal tracing and no other sentinel findings such as contractions, uterine tenderness, or bleeding. Certainly, monitoring should be continued as long as there are uterine contractions, nonreassuring fetal heart patterns, vaginal bleeding, uterine tenderness or irritability, serious maternal injury, or ruptured membranes (American College of Obstetricians and Gynecologists, 1998). In very rare cases, placental abruption has developed days after trauma (Higgins and Garite, 1984).

Fetal-Maternal Hemorrhage

Routine use of the Kleihauer-Betke or an equivalent test in pregnant trauma victims is controversial (Pak and associates, 1998). It is unclear if their routine use will modify adverse outcomes associated with fetal anemia, cardiac arrhythmias, and death. In a retrospective review of 125 pregnant women with blunt injuries, Towery and co-workers (1993) reported that the Kleihauer-Betke test had a sensitivity of 56 percent, a specificity of 71 percent, and an accuracy of 27 percent. They concluded that the test was of little use with acute trauma management. They also concluded that electronic fetal monitoring or sonography, or both, are more useful in detecting fetal or pregnancy-associated complications. Although Dupre and associates (1993) found evidence for fetal-maternal hemorrhage in 22 percent of women studied, it was of no prognostic significance. Connolly and co-workers (1997) reached similar conclusions. According to Muench and colleagues (2003, 2004), however, a Kleihauer-Betke test showing fetal cells of 0.1 percent or greater was predictive of uterine contractions or preterm labor.

For the woman who is D-negative, administration of anti-D immunoglobulin should be considered. This may be omitted if the test for fetal bleeding is negative. Isoimmunization may still develop if the fetal-maternal hemorrhage exceeds 15 mL of fetal cells.

Another important aspect of care for the pregnant trauma patient is to ensure that her tetanus immunization is current. It is recommended that pregnant women receive a tetanus and diphtheria toxoids vaccine (Td) for protection when indicated (Murphy and colleagues, 2008).

THERMAL INJURY

Although Parkland Hospital is a major burn center for the United States, we have not seen a large number of pregnant women with severe burns. Fetal prognosis is poor with severe burns. Usually the woman enters labor spontaneously within a few days to a week and often delivers a stillborn infant. Contributory factors are hypovolemia, pulmonary injury, septicemia, and the intensely catabolic state associated with burns. Treatment of burned pregnant women is similar to that for nonpregnant patients and was reviewed by Pacheco and associates (2005).

Prognosis

It is generally agreed that pregnancy does not alter maternal outcome from thermal injury compared with that of nonpregnant women of similar age. As perhaps expected, maternal and fetal survival parallels the percentage of burned surface area. Karimi and colleagues (2009) reported higher rates for both with suicidal attempts and with inhalational injuries. In the 211 pregnant burned victims shown in Figure 42-10, as the burn area reaches or exceeds 50 percent, both maternal and fetal morbidity become formidable.

Skin Contractures

Following serious abdominal burns, skin contractures that develop may be painful during a subsequent pregnancy and may even necessitate surgical decompression and split skin autografts (Matthews, 1982). Widgerow and colleagues (1991) described two women in whom surgical release of contractures without covering the resulting defect was sufficient. McCauley and colleagues (1991) followed seven women with severe circumferential truncal burns sustained at a mean age of 7.7 years. All of 14 subsequent pregnancies were delivered at term without major complications. Loss or distortion of nipples may cause problems

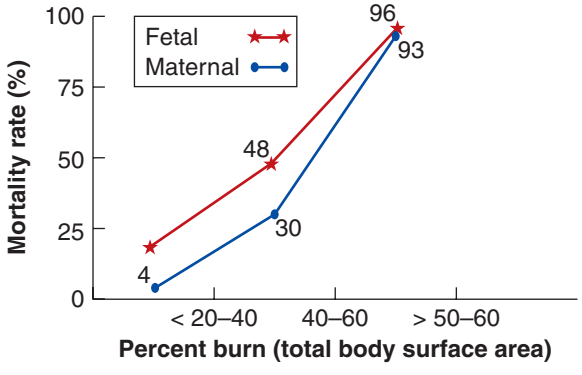

FIGURE 42-10 Maternal and fetal morbidity by burn severity in 211 women. (Data from Akhtar, 1994; Amy, 1985; Mabrouk and el-Feky, 1997; Maghsoudi, 2006; Rayburn, 1984; Rode, 1990, and all their colleagues.)

FIGURE 42-11 This 22-year-old nullipara sustained severe burns at age 12 years, and massive scarring followed. Both breasts were replaced by scar tissue. Following delivery, a few drops of colostrum were expressed from the left nipple, but no breast engorgement was detected. (Photo courtesy of Drs. A. R. Mahale and A. P. Sakhare, Maharashtra, India.)

in breast feeding (Fig. 42-11). Interestingly, normal abdominal tissue expansion due to pregnancy appears to be an excellent source for obtaining skin grafts postpartum to correct scar deformities at other body sites (Del Frari and colleagues, 2004).

Electrical Injury and Burns

Earlier case reports were suggestive of a high fetal mortality rate with electric shock (Fatovich, 1993). In a prospective cohort study, however, Einarson and colleagues (1997) showed similar perinatal outcomes in 31 injured women compared with those of pregnant controls. They concluded that traditional 110-volt North American electrical current likely is less dangerous than 220-volt currents available in Europe. Sozen and Nesin (2004) described a woman with iliofemoral thrombosis at 29 weeks that *may* have been related to a mild electrical shock at 22 weeks. Thermal burns may be extensive and require expert wound care.

Lightning Injuries

The pathophysiological effects of lightning injuries can be devastating. García Gutiérrez and associates (2005) found 12 case reports of injuries during pregnancy. They described another case and reviewed the effects of lightning injuries on the mother and fetus.

CARDIOPULMONARY RESUSCITATION

Cardiac arrest is rare during pregnancy. General considerations regarding planning and equipment were reviewed by the American College of Obstetricians and Gynecologists (2006b). There are special considerations for cardiopulmonary resuscitation (CPR) conducted in the second half of pregnancy. In nonpregnant women, external chest compression results in a cardiac output of only about 30 percent of normal (Clark and colleagues, 1997). In late pregnancy, however, cardiac output may be even less with CPR because uterine aortocaval compression may diminish forward flow as well as venous return. **Thus, uterine displacement is paramount to accompany other resuscitative efforts.** Left lateral displacement can be accomplished manually by tilting the operating table laterally, by placing a wedge under the right hip—an example is the Cardiff resuscitation wedge. Rees and Willis (1988) showed with a manikin that resuscitation with the Cardiff wedge was as efficient as resuscitation in the supine position. If no equipment is available, such as in an out-of-hospital arrest, an individual kneels on the floor with the woman's back on the thighs to form a "human wedge" (Whitty, 2002).

Over the past few years, the recommendation by many authors is to perform cesarean delivery within 4 to 5 minutes of beginning CPR if the fetus is viable (Moise and Belfort, 1997). Certainly, there is an inverse correlation between neurologically intact neonatal survival and the cardiac arrest-to-delivery interval in women delivered by perimortem cesarean. According to Clark and co-workers (1997), of newborns delivered within 5 minutes of arrest, 98 percent are neurologically intact; within 6 to 15 minutes, 83 percent are intact; within 16 to 25 minutes, 33 percent are intact; and within 26 to 35 minutes, only 25 percent are intact.

Because delivery *may* also enhance maternal resuscitative efforts, the American College of Obstetricians and Gynecologists (2009) advises *consideration* for cesarean delivery within 4 minutes of cardiac arrest in third-trimester pregnancy. Katz and associates (2005) reviewed the literature that included 38 perimortem cesarean deliveries with a "large selection bias." They concluded that these reports supported—but "fell far from proving"—that perimortem cesarean delivery within 4 minutes of maternal cardiac arrest improves maternal and fetal outcomes. Even so, as emphasized by Clark and associates (1997), and in our experiences, these goals rarely can be met in actual practice. Whitten and Irvine (2000) and Whitty (2002) have reviewed indications for postmortem and perimortem cesarean delivery.

Maternal Brain Death

Occasionally a pregnant woman with a supposedly healthy intact fetus will be kept on somatic support to await fetal viability or maturity. This is discussed in Chapter 55 (p. 1175).

CHAPTER 43

Obesity

DEFINITIONS 946
MORBIDITY AND MORTALITY ASSOCIATED WITH OBESITY 948
TREATMENT OF OBESITY 949
PREGNANCY AND OBESITY 949

Excessive weight has become one of the major health problems in affluent societies. Because of its medical importance and its multifaceted effects on pregnancy, it is discussed separately in this chapter. The prevalence of obesity in the United States has increased steadily as economic prosperity has increased. For a number of years, obesity has been termed *epidemic*—strictly defined, this implies a *temporary* widespread outbreak of greatly increased frequency and severity. Unfortunately, obesity more correctly is *endemic*—a condition that is habitually present. Moreover, its prevalence has continued to increase since 1960. By 1991, approximately a third of adults in the United States were overweight, and almost 300,000 deaths were attributed annually to obesity (Allison and co-workers, 1999). Sadly, the problem is not limited to adults, and 15 percent of children aged 6 through 11 years are reported to be overweight (Ogden and associates, 2002). The prevalence in adolescents is similar.

Public health authorities began to address the problem of obesity in the late 1980s. A stated goal of *Healthy People 2000* was to reduce the prevalence of overweight people to 20 percent or less by the end of the 20th century (Public Health Service, 1990). Not only was this goal not achieved, but by 2000, more than half of the population was overweight, and nearly a third of adults were obese (Flegal and colleagues, 2002; Hedley and associates, 2004).

There are many obesity-related diseases, including diabetes, heart disease, hypertension, stroke, and osteoarthritis. Together they result in a decreased life span. The worldwide diabetes epidemic that Bray (2003) predicted would follow the worldwide obesity epidemic has already begun. Obese women who become pregnant—and their fetuses—are predisposed to a variety of serious pregnancy-related complications. Long-term maternal effects include significant and increased rates of morbidity and mortality. Moreover, recent studies show that the offspring of obese women also suffer long-term morbidity.

DEFINITIONS

A number of systems have been used to define and classify obesity. The *body mass index* (*BMI*), also known as the *Quetelet index,* is currently in use. The BMI is calculated as weight in kilograms divided by height in square meters (kg/m^2). Calculated BMI values are available in various chart and graphic forms, such as the one shown in Figure 43-1. According to the National Heart, Lung, and Blood Institute (1998), a *normal* BMI is 18.5 to 24.9 kg/m^2; *overweight* is a BMI of 25 to 29.9 kg/m^2; and *obesity* is a BMI of 30 kg/m^2 or greater. According to Freedman and colleagues (2002), obesity is further categorized as class I (BMI: 30 to 34.9 kg/m^2), class II (BMI: 35 to 39.9 kg/m^2), and class III (BMI: 40-plus kg/m^2).

Prevalence

Pleis and colleagues (2003) reported that by 2000, 34 percent of adults in the United States were overweight, and another 27 percent were obese. This is an increase of 75 percent compared with 1980 statistics. **Thus, by 2000, more than half of adults in the United States were either overweight or obese.** Moreover, 2.8 percent of women and 1.7 percent of men were extremely obese (class III), with a BMI of 40 kg/m^2 or more (Mokdad and associates, 2003). Prevalence data through 2004 for women aged 20 to 39 are shown in Figure 43-2. As shown in Figure 43-3, there is a disparate prevalence of obesity in Mexican-American and

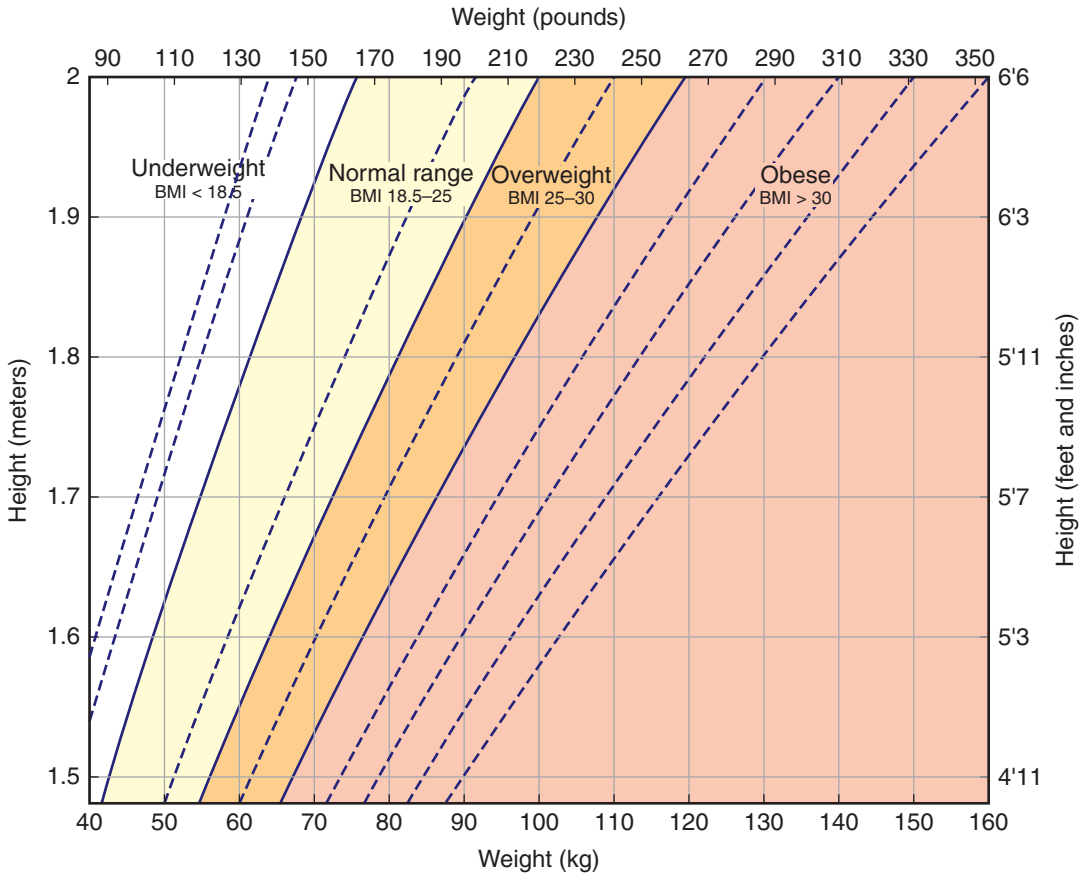

FIGURE 43-1 Chart for estimating body mass index (BMI). To find the BMI category for a particular subject, locate the point at which the height and weight intersect.

black women ages 20 to 39. This is also true among indigent individuals (Drewnowski and Specter, 2004). The prevalence of obese adults in 2006 was less than 20 percent in only four states (Centers for Disease Control and Prevention, 2007, 2008).

The Metabolic Syndrome

In some people, obesity interacts with inherited factors and leads to the onset of *insulin resistance*. This metabolic abnormality in turn is responsible for altered glucose metabolism and a predisposition to type 2 diabetes. In addition, it causes a number of subclinical abnormalities that predispose to cardiovascular disease and accelerate its onset. The most important among these are type 2 diabetes, dyslipidemia, and hypertension. When clustered together with other insulin resistance–related subclinical abnormalities, these are referred to as the *metabolic syndrome* (Abate, 2000). Virtually all obese women with hypertension demonstrate elevated plasma insulin levels. Levels are even higher in women with excessive fat in the abdomen—an apple shape, compared with those whose fat is in the hips and thighs—a pear shape (American College of Obstetricians and Gynecologists, 2003). In fact, Gus and associates (2004) reported that for women, a waist circumference greater than 88 cm was more predictive of hypertension than a BMI greater than 30 kg/m^2.

Criteria used by the National Institutes of Health (2001) to define the metabolic syndrome are shown in **Table 43-1**. Of interest, the American Diabetes Association eschews the

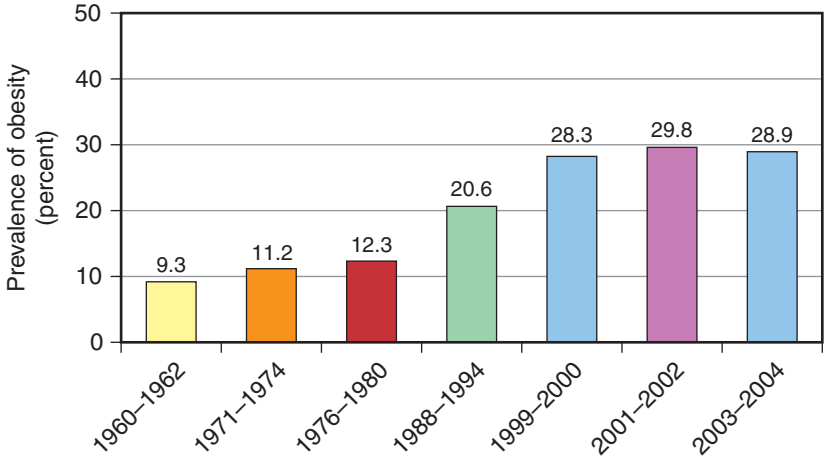

FIGURE 43-2 Prevalence (percent) of obesity among 20- to 39-year-old nonpregnant U.S. women. Obesity is defined as a body mass index of greater than 30 kg/m^2 (Redrawn with permission from *Influence of Pregnancy Weight on Maternal and Child Health Workshop Report,* 2007, by the National Academy of Sciences, Courtesy of the National Academies Press, Washington, D.C.)

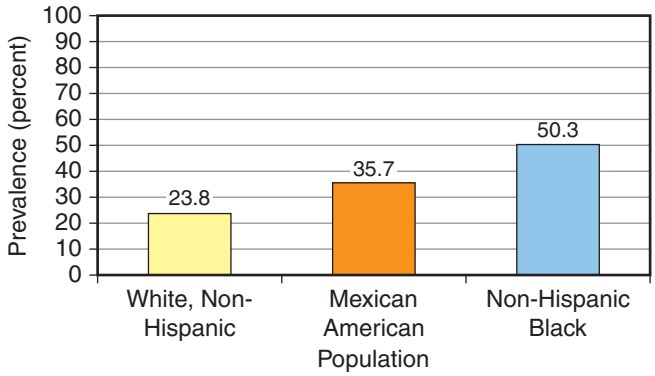

FIGURE 43-3 Prevalence (percent) of obesity among U.S. nonpregnant women, aged 20 to 39, by race/ethnicity for 2003-2004. Obesity is defined as a body mass index of greater than 30 kg/m^2. (Redrawn with permission from *Influence of Pregnancy Weight on Maternal and Child Health Workshop Report,* 2007, by the National Academy of Sciences, Courtesy of the National Academies Press, Washington, D.C.)

"syndrome" designation and urges consideration for these and other cardiovascular-disease risk factors that occur singly or in combination (Kahn and colleagues, 2005).

Prevalence

Because the metabolic syndrome is newly defined, prevalence data have been calculated from a study in progress. Ford and colleagues (2002) did a follow-up study of men and women enrolled in the Third National Health and Nutrition Survey (NHANES III). They found an overall prevalence of the metabolic syndrome in 24 percent of women and 22 percent of men. As expected, prevalence increased with age. For women, prevalence was about 6 percent in those 20 to 29 years of age; 14 percent in those 30 to 39 years of age; 20 percent in those 40 to 49 years of age; and 30 percent for women older than 50 years.

MORBIDITY AND MORTALITY ASSOCIATED WITH OBESITY

Obesity is costly—not only in morbidity and mortality, but also in healthcare dollars. Colditz (1999) estimated that 300,000 adults die each year from obesity-related causes. He estimated direct costs of obesity and physical inactivity to be 9.4 percent of annual healthcare expenditures in the United States.

TABLE 43-1. Adult Treatment Panel III (ATP III): Criteria for Diagnosis of the Metabolic Syndrome

Patients with three or more of the following:

1. Abdominal obesity: waist circumference > 88 cm (34.7 in) in women or > 102 cm (40.2 in) in men
2. Hypertriglyceridemia: ≥ 150 mg/dL
3. High-density lipoprotein (HDL): < 50 mg/dL in women or < 40 mg/dL in men
4. High blood pressure: ≥ 130/85 mm Hg[a]
5. High fasting glucose: ≥ 110 mg/dL[a]

[a]Those with normal values while taking medications are considered to meet these criteria.
From the National Institutes of Health (2001).

TABLE 43-2. Long-term Complications of Obesity

Disorder	Possible Cause(s)
Type 2 diabetes mellitus	Insulin resistance
Hypertension	Increased blood volume and cardiac output
Coronary heart disease	Hypertension, dyslipidemia, type 2 diabetes
Obesity cardiomyopathy	Eccentric left ventricular hypertrophy
Sleep apnea/pulmonary dysfunction	Pharyngeal fat deposition
Ischemic stroke	Atherosclerosis, decreased cerebral blood flow
Gallbladder disease	Hyperlipidemia
Liver disease—nonalcoholic steatohepatitis (NASH)	Increased visceral adiposity; elevated serum, free fatty acids; hyperinsulinemia
Osteoarthritis	Stress on weight-bearing joints
Subfertility	Hyperinsulinemia
Cancer—endometrium, colon, breast	Hyperestrogenemia
Carpal tunnel syndrome	
Deep-venous thrombosis	
Poor wound healing	

Compiled from Alpert (2001); Calle (2003); Chinali (2004); Flegal (2007); Kenchaiah (2002); Mokdad (2003); Must (1999); Ninomiya (2004), and all their colleagues; National Task Force on the Prevention and Treatment of Obesity (2000).

Individuals who are overweight are at increased risk for an imposing number of complications (Table 43-2). The direct link between obesity and type 2 diabetes mellitus is well known (Mokdad and associates, 2003). According to Hossain and colleagues (2007), 90 percent of type 2 diabetes is attributable to excess weight. Heart disease due to obesity—*adipositas cordis*—is caused by hypertension, hypervolemia, and dyslipidemia. Higher rates of abnormal left ventricular function, heart failure, myocardial infarction, and stroke have been noted (Chinali, 2004; Kenchaiah, 2002; Ninomiya, 2004, and all their colleagues).

Excessive weight is associated with increased early mortality rates, as shown by Peeters (2003) and Fontaine (2003) and their colleagues in follow-up studies from both the Framingham Heart Study and the NHANES III cohort. Results from a prospective study conducted by the American Cancer Society are shown in Figure 43-4. In this and other studies, mortality risk from cardiovascular disease and cancer increased directly with increasing BMI.

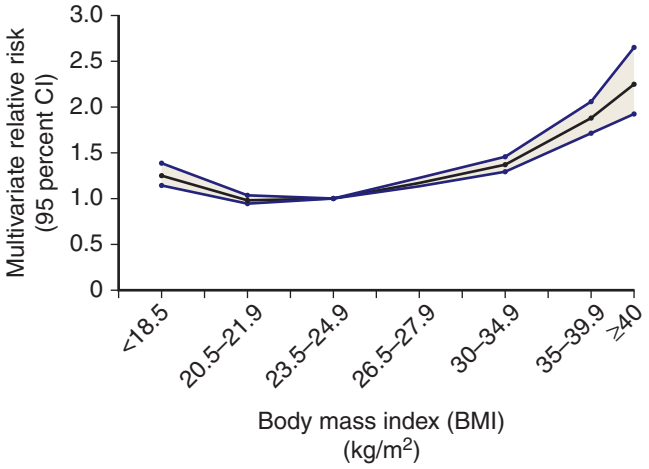

FIGURE 43-4 Relative risk of death from all causes from 1998 to 2002 in 317,875 persons entered into the Cancer Prevention Study II begun in 1982 by the American Cancer Society (Calle and colleagues, 1999, 2003). Relative risks were adjusted for age, race, sex, education, physical activity, alcohol use, marital status, aspirin use, fat and vegetable consumption, and estrogen use. The tan area represents the 95-percent confidence intervals. (Data from Calle and associates, 2005.)

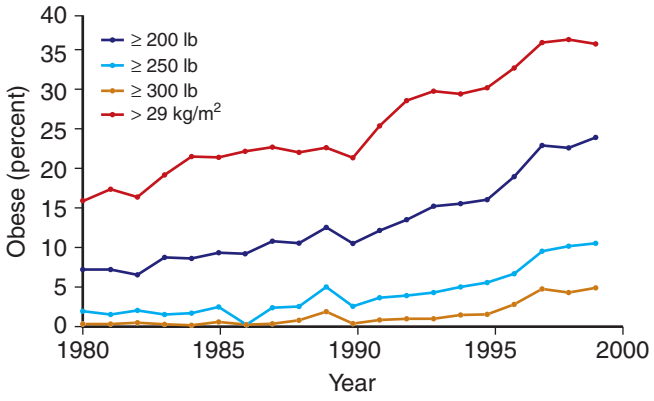

FIGURE 43-5 Increasing prevalence of obesity during 20 years in pregnant women classified at the time of their first prenatal visit at the University of Alabama at Birmingham. All women were classified into the first three categories shown on the graph. In approximately half of the women, height was available, and they were classified by body mass index. (Reprinted from *American Journal of Obstetrics & Gynecology,* Vol. 185, No. 4, GC Lu, DJ Rouse, M DuBard, et al., The effect of the increasing prevalence of maternal obesity on perinatal morbidity, pp. 845–849, Copyright 2001, with permission from Elsevier.)

TREATMENT OF OBESITY

Weight loss is tremendously difficult for obese individuals to accomplish. If achieved, long-term maintenance poses equivalent or even more daunting difficulties. There are innumerable methods espoused to help or even directly cause weight loss. Most are charlatan schemes designed to extract money from overweight individuals. That said, even the most legitimate nonsurgical methods are fraught with frequent failure. If they are successful, slow and inexorable return to preintervention weight usually follows (Yanovski, 2005). Legitimate weight loss approaches include behavioral, pharmacological, and surgical techniques, or a combination of these methods. The American College of Obstetricians and Gynecologists (2005b) encourages the role of obstetrician-gynecologists in assessment and management of obesity in adult women.

PREGNANCY AND OBESITY

Obesity is associated with subfertility due to increased insulin resistance (see Table 43-2). In their review, Neill and Nelson-Piercy (2001) linked impaired fecundity in women with a BMI in excess of 30 kg/m^2. In 6500 in vitro fertilization-intracytoplasmic sperm injection cycles, Bellver and associates (2009) found that implantation, pregnancy, and live-birth rates were progressively and significantly reduced with each unit of maternal BMI. In a case-control study, Lashen and colleagues (2004) found that obesity is associated with increased risk of first-trimester and recurrent miscarriage. In the many overweight and obese women who achieve pregnancy, there are a number of increased and interrelated adverse perinatal outcomes. **Marked obesity is unequivocally hazardous to the pregnant woman and her fetus**. Moreover, Chu and colleagues (2008) have provided evidence that obese pregnant women have a disparately increased use of healthcare services.

Prevalence

Obesity complicating pregnancy has also increased along with the overall prevalence of obesity. Before adoption of the BMI, investigators used a variety of definitions of obesity to assess risks during pregnancy. For example, in the study shown in **Figure 43-5**, four definitions were used. But, regardless of how obesity was defined, all groups showed substantive increases in its prevalence during the 20-year period. Ehrenberg and colleagues (2002) reported similar findings in a 15-year study in Cleveland.

Maternal Weight Gain and Energy Requirement

The 2007 National Research Council and Institute of Medicine (IOM) Workshop Report provides a current and comprehensive review of the determinants of maternal weight gain in relation to biological, metabolic, and social predictors. This report was a follow-up that supported the 1990 IOM recommendations for gestational weight gain, which are based on the prepregnancy BMI as shown in **Table 43-3**. The IOM (2009) recently amended these guidelines slightly. Fat deposition is greater in women with high BMI, and thus, energy costs are significantly lower (Butte and colleagues, 2004). Kinoshita and Itoh (2006) studied regional fat distribution changes across pregnancy using sonography. They found that during the third trimester increases were predominantly in visceral fat. Despite these stores, maternal catabolism is—at least intuitively—not good for fetal growth and development. Thus, it is recommended that even obese women should not attempt weight loss during pregnancy but should limit weight gain to 20 pounds (see also Chap. 8, p. 200).

Cogswell and associates (2006) reviewed gestational weight gain across BMI categories from 1990 through 2003. They reported that a third of pregnant women gained weight within the IOM recommendations, and these patterns were stable over

TABLE 43-3. Institute of Medicine Recommended Total Weight Gain Ranges for Pregnant Women by Prepregnancy Body Mass Index (BMI)

	Recommended Total Gain[a]	
Category	Kilograms	Pounds
Underweight—BMI <18.5 kg/m^2	12.5 to 18	28 to 40
Normal—BMI 18.5 to 24.9 kg/m^2	11.5 to 16	25 to 35
Overweight—BMI 25 to 29.9 kg/m^2	7 to 11.5	15 to 25
Obese—BMI >30 kg/m^2	5 to 9.1	11 to 20

[a]Young adolescents and black women should strive for gains at the upper end of the recommended range. Short women (<157 cm or 62 in) should strive for gains at the lower end of this range.

time. Similar to the overall U.S. trend from 1990, Chu and associates (2009) reported in the U.S. in 2004-2005 that 40 percent of normal-weight and 60 percent of overweight women gained excessive weight during pregnancy. Rooney and Schauberger (2002) followed 540 women after delivery for a mean of 8.5 years, during which time, the average weight gained was 6.3 kg. Women who had gained less pregnancy weight than the recommended amount were on average 4.1 kg heavier at the end of the follow-up period. Women who gained the recommended amount were 6.5 kg heavier. Finally, women who gained more than the recommended amount were 8.4 kg heavier.

Maternal Morbidity

Obesity causes excess maternal morbidity (Table 43-4). Various definitions have included more than 150 percent of ideal body weight, BMI > 35 kg/m^2, BMI > 40 kg/m^2, and >150 pounds over ideal body weight (Bianco, 1998; Cedergren, 2004; Denison, 2008; Isaacs, 1994; Kabiru and Raynor, 2004; Kumari, 2001, and all their colleagues). The significantly increased incidences of many disorders are listed in Table 43-4. Weiss and associates (2004) reported similar adverse outcomes and maternal morbidity in a prospective multicenter study of more than 16,000 women with class I—BMI 30–35—and class II—BMI

TABLE 43-4. Adverse Pregnancy Effects in Overweight and Obese Women

		Increased Complications (Odds Ratio[a])	
Complication	Prevalence in Percent in Women With Normal BMI 20–24.9 (n = 176,923)	Overweight BMI 25–29.9 (n = 79,014)	Obese BMI > 30 (n = 31,27)
Gestational diabetes	0.8	1.7	3.6
Preeclampsia	0.7	1.5	2.1
Postterm pregnancy	0.13	1.2[b]	1.7
Emergency cesarean	7.8	1.3	1.8
Elective cesarean	4.0	1.2	1.4
Postpartum hemorrhage	10.4	1.2	1.4
Pelvic infection	0.7	1.2	1.3
Urinary infection	0.7	1.2	1.4
Wound infection	0.4	1.3	2.2
Macrosomia	9.0	1.6	2.4
Stillbirth	0.4	1.1[b]	1.4

[a]Odds ratios (99% CI) are significant except when denoted.
[b]Not significantly different.
Data from Sebire and colleagues (2001).

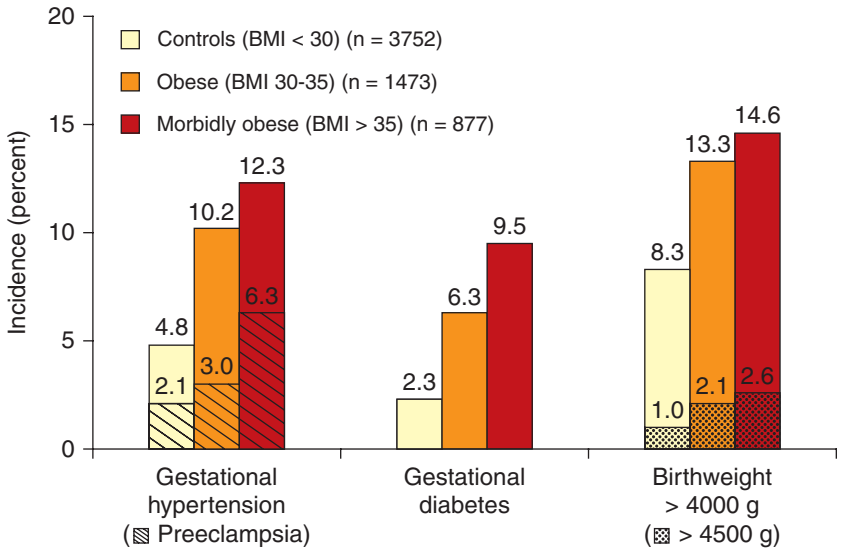

FIGURE 43-6 Incidence of selected pregnancy outcomes in 16,102 women enrolled in the FASTER (First and Second trimester Evaluation of Risk) trial according to body mass index (BMI) status. (Data from Weiss and colleagues, 2004.)

35–40—obesity within the FASTER—First- and Second-Trimester Evaluation of Risk trial. Some of these are shown in Figure 43-6. Especially striking are the marked increases in gestational hypertension and diabetes. Not shown are the cesarean delivery risks of 33.8 percent for obese and 47.4 for morbidly obese women compared with 20.7 percent for the control group. Haeri and co-workers (2009) also found increased rates of cesarean delivery and gestation diabetes in obese adolescents. More worrisome is that obese women also have increased rates of *emergency* cesarean delivery. (Lynch and associates, 2008; Poobalan and colleagues, 2009).

There are also reports of increased adverse pregnancy outcomes in overweight women whose BMI is 25 to 29.9 kg/m^2 (Hall and Neubert, 2005). Results of the study by Sebire and associates (2001) that included more than 285,000 singleton pregnancies are shown in Table 43-4. Almost all complications are significantly increased in women whose BMI is above normal.

Other morbidity associated with maternal obesity includes a higher incidence of failed trial of labor with a prior cesarean delivery (Bujold, 2005; Goodall, 2005; Hibbard, 2006; Robinson, 2005, and all their colleagues). Obesity and hypertension are common cofactors in causing peripartum heart failure (Cunningham and associates, 1986). And obese women present anesthesia challenges that include difficult epidural and spinal analgesia placement and complications from failed or difficult intubations (Hood and Dewan, 1993). Second-trimester dilatation and evacuation was reported to take longer and be more difficult in women whose BMI was 30 kg/m^2 or greater (Dark and co-workers, 2002).

Obese women are less likely to breast feed than normal-weight women (Li and colleagues, 2003). They also have greater weight retention 1 year after delivery (Catalano, 2007; National Research Council and Institute of Medicine, 2007; Rode and colleagues, 2005). Finally, there is evidence that quality-of-life measures are negatively affected by obesity during pregnancy (Amador and co-workers, 2008). LaCoursiere and Varner (2009) found that postpartum depression was significantly increased in obese women and also in relation to the degree of obesity—class 1 (22.6 percent), class 2 (32.4 percent), and class 3 (40 percent).

Preeclampsia

There is no doubt that obesity is a consistent risk factor for preeclampsia (Cedergren, 2004; Jensen, 2003; Sebire, 2001; Weiss, 2004, and all their colleagues). In a review of studies that included more than 1.4 million women, O'Brien and associates (2003) found that the preeclampsia risk doubled with each 5 to 7 kg/m^2 increase in prepregnancy BMI.

Obesity is also associated with low-grade inflammation and endothelial activation. Endothelial activation also plays an integral role in preeclampsia (see Chap. 34, p. 712). Wolf and co-workers (2001) linked these two conditions by providing intriguing evidence that inflammation may explain, at least partly, the association of obesity with preeclampsia. Ramsay and co-workers (2002) confirmed that obese pregnant women had significantly elevated serum levels of interleukin-6 and C-reactive protein as well as evidence of impaired endothelial function. These investigators found that obese gravid women had significantly higher levels of triglycerides, very-low-density lipoprotein cholesterol, insulin, and leptin compared with normal-weight pregnant woman.

Contraception

Most studies report that oral contraceptive failure is more likely in overweight women. In reviewing general studies on hormonal contraceptive efficacy, it is apparent that the typical study subject is not representative of the average American woman. As discussed earlier, at least 50 percent of American women are overweight with a BMI > 25 kg/m^2. In contraceptive studies, however, most subjects have a BMI between 18 and 28 kg/m^2 (Holt and co-workers, 2002; Zieman and colleagues, 2002).

Holt and colleagues (2002) studied oral contraceptive use and found that women in the highest weight quartile—70.5 kg—had a 1.6-fold increased pregnancy risk. Importantly, women in this quartile who used very-low-dose oral contraceptives had a four- to fivefold increased pregnancy rate (see Chap. 32, p. 673). A recent report from the National Survey of Family Growth did not find an increased rate of unintended pregnancy (Kaneshiro and associates, 2008). Zieman and colleagues (2002) studied efficacy of the Ortho-Evra patch and found a significant association between increasing body weight and contraceptive failure.

Perinatal Mortality

An increased incidence of otherwise inexplicable late-pregnancy stillbirths has been associated with obesity. Cnattingius and colleagues (1998) found a significant 1.6-fold increase in the stillbirth rate in women whose BMI was 25 to 29.9 kg/m^2. The

rate increased 2.6-fold for women with a BMI ≥ 30 kg/m^2. In addition, the early neonatal death rate was nearly doubled in nulliparous women with a BMI ≥ 30 kg/m^2. With the same database, Stephansson and associates (2001) confirmed an almost threefold late-stillbirth rate in women with a BMI > 25 kg/m^2. From their meta-analysis, Chu and co-workers (2007) found 1.5-fold increased risks for stillbirth in overweight and 2.1-fold in obese women. The recent Scottish study of more than 186,000 nulliparas described an almost fourfold increased stillbirth rate in women with a BMI ≥ 35 kg/m^2 compared with women whose BMI was 20 to 25 kg/m^2 (Denison and colleagues, 2008).

Huang and colleagues (2000) found increased prepregnancy weight to be the factor most strongly associated with 196 unexplained fetal deaths even after adjusting for maternal age and excluding women with diabetes and hypertensive disorders. Nohr and associates (2005) confirmed this association in 54,000 births from 1998 to 2001. Compared with normal-weight women, the fetal death rate among obese women increased with gestational age. The hazard ratio was 2.1 at 28 to 36 weeks, 3.5 at 37 to 39 weeks, and 4.6 at 40 or more weeks. The stillbirth rate was 240-percent greater in obese compared with normal-weight women.

Perinatal Morbidity

Both fetal and neonatal complications are increased in obese women. Earlier studies by Shaw and colleagues (1996, 2000) reported that women with a BMI > 30 kg/m^2 had a twofold increased incidence of neural-tube defects compared with that of control women. In their recent meta-analysis, Rasmussen and associates (2008) found 1.2-, 1.7-, and 3.1-fold increased risks in overweight, obese, and severely obese women compared with controls of normal weight (see also Chap. 13, p. 287). In addition to increased neural-tube defects, in a case-control study from the Atlantic Birth Defects Risk Factor Surveillance Study, Watkins and associates (2003) reported a 3.5-fold increase in rates of neural-tube defects in obese women. They also found a two- to threefold increased incidence in omphalocele, heart defects, and multiple anomalies in obese women. The last two were also increased twofold in overweight women whose BMI was 25 to 29.9 kg/m^2. In a meta-analysis, Stothard and colleagues (2009) found that maternal obesity was significantly associated with an increased risk of a wide range of fetal/newborn structural anomalies. Of appreciable concern are the many reports of unreliable fetal anatomy sonographic screening in obese gravidas (Dashe, 2009; Grace, 2009; Hendler, 2005; Thornburn, 2009, and all their co-workers).

Two important and interrelated cofactors that contribute to excessive rates of perinatal morbidity and mortality are chronic hypertension and diabetes mellitus, both of which are associated with obesity. Chronic hypertension is a well-known cause of fetal-growth restriction (see Chap. 45, p. 987). Pregestational diabetes increases the rate of birth defects, and gestational diabetes is complicated by excessive numbers of large-for-gestational age and macrosomic fetuses (see Chap. 52, p. 1104). And even without diabetes, the prevalence of macrosomic newborns is increased in obese women (Bianco and co-workers, 1998; Cedergren, 2004; Isaacs and associates, 1994).

The group from MetroHealth Medical Center in Cleveland has conducted studies of prepregnancy obesity, gestational weight gain, and prepregnancy and gestational diabetes and their relationship to newborn weight and fat mass (Catalano, 2005, 2007; Ehrenberg, 2004; Sewell, 2006, and all their co-workers). They concluded that although each of these variables is associated with larger and more corpulent newborns, prepregnancy BMI exhibits the strongest influence on the prevalence of these neonates. They attributed this increased prevalence of macrosomic infants to the marked frequency of overweight or obese women in pregnancy—46.7 percent—compared with only 4 percent of pregnant women with diabetes.

Maternal obesity is linked with increased childhood obesity. Combined with sociological and dietary factors, Armstrong and colleagues (2002) reported that breast feeding decreases the risk of childhood obesity. At the same time, recall that Ruowei and co-workers (2003) reported that obese women were less likely to breast feed.

Morbidity in Children Born to Obese Women

There seems to be no doubt that obese women beget obese children, who themselves become obese adults. Just a few studies are cited that confirm this association. Whitaker (2004) studied low-income children in the Special Supplemental Food Program for Women, Infants, and Children (WIC) and found a linear association between early pregnancy maternal BMI and prevalence of overweight children at 2, 3, and 4 years. From Denmark, Schack-Nielson and colleagues (2005) found a direct association between maternal, newborn, and childhood BMI. This association strengthened as offspring progressed to adulthood. Catalano and colleagues (2005) studied offspring at a median age of 7 and found a direct association with maternal prepregnancy obesity and childhood obesity. They also reported associations with central obesity, elevated systolic blood pressure, increased insulin resistance, and decreased high-density lipoprotein (HDL) cholesterol levels—all elements of the metabolic syndrome discussed on page 947. Boney and co-workers (2005) studied 84 large-for-gestational age (LGA) and 95 appropriate-for-gestational age (AGA) offspring of women with or without gestational diabetes. These investigators followed these cohorts longitudinally from age 6 to 11 years. They observed that children who were LGA at birth and whose mothers were either obese or had gestational diabetes had significantly increased risks for subsequently developing metabolic syndrome.

It also appears that excessive maternal weight gain in pregnancy may prognosticate adulthood obesity. Schack-Nielsen and colleagues (2005) found a linear association of maternal weight gain with the subsequent BMI in their study children. Analyzing data from Project Viva, Oken (2006) suggests a linear association between maternal weight gain and the risk of an overweight child at age 3. Not all studies concur. For example, Whitaker and colleagues (2004) analyzed a large population of children in the WIC program and found no obvious linear association between gestational weight gain and childhood obesity.

Fetal Programming and Childhood Morbidity

Epidemiological studies have addressed the association of childhood, adolescent, and even adult adverse health outcomes in relation to the fetal environment. Adverse health outcomes include obesity, diabetes, hypertension, and the metabolic syndrome. Variables studied have included maternal prepregnancy BMI, obesity, gestational weight gain, and pregestational or gestational diabetes. The most robust evidence suggests a direct association between children born to women who had prepregnancy obesity or gestational diabetes and the occurrence of a higher BMI in childhood and adulthood.

The potential biological causes and mechanisms of these associations are not clear at this time. It is a complex issue greatly confounded by insufficient data with consideration for all potential maternal—including genetic—predisposing factors. There also is insufficient data regarding the environment of the infant and child in relation to diet and activity. The science of *epigenetics* has provided some support for the possibility that perturbations of the maternal-fetal environment can adversely alter postdelivery events. For example, Aagard-Tillery and colleagues (2006) reported that diet supplementation with essential nutrients, unaltered in caloric content, prevented adult obesity and insulin resistance in a heritable transgenerational model of fetal-growth restriction. Perhaps more likely is the contributions of the maternal-child environment subsequent to birth. Gluck and colleagues (2009) found that maternal influence, not diabetic intrauterine environment, predicts children's energy intake. This is further discussed in Chapters 38 (p. 842) and 52 (p. 1109).

Management

A program of weight reduction is probably unrealistic during pregnancy. If such a regimen is chosen, however, it is mandatory that the quality of the diet be monitored closely and that ketosis be avoided (Rizzo and associates, 1991). It is more pragmatic to *limit* weight gain in obese or overweight women. The goal of 15 pounds, discussed previously, is an ideal target.

Polley and colleagues (2002) randomized women to an intensive behavioral intervention versus usual obstetrical care to prevent excessive pregnancy weight gain. For normal-weight women randomized to usual prenatal care, 58 percent exceeded the guidelines shown in Table 43-3, compared with 33 percent of those randomized to behavioral intervention. Among overweight women, however, this difference was just the opposite. Specifically, 59 percent of women in the intervention group gained excessive weight compared with only 32 percent in the usual-care group. Thus, behavioral modification programs to limit excessive weight gain require intensive efforts, and they have had only modest success (Olson and colleagues, 2004). Asbee and associates (2009) randomized 100 women to receive either additional intensive dietary and lifestyle counseling during gestation or to receive routine prenatal care. Women assigned to routine prenatal care had significantly more weight gain during pregnancy and higher cesarean delivery rates.

Close prenatal surveillance detects most early signs of diabetes or hypertension. Standard screening tests for fetal anomalies are sufficient. However, several investigators caution that detection of fetal anomalies in obese women is more difficult (Dashe and colleagues, 2009; Hendler and associates, 2005). Accurate assessment of fetal growth usually requires serial sonography. Antepartum and intrapartum fetal heart rate monitoring are likewise more difficult, and sometimes these are even impossible.

Surgical and Anesthetic Concerns

Evaluation by anesthesia personnel is performed at a prenatal visit or on arrival at the labor unit (American College of Obstetricians and Gynecologists, 2002). Anesthetic risks and complications faced by obese women are discussed in Chapter 19 (p. 460). Special attention is given to complications that might arise during labor and delivery.

For cesarean delivery, forethought is given to optimal placement and type of abdominal incision to allow access the fetus and to effect the best wound closure with the least intervening tissue (Alexander and Liston, 2006). One technique is shown in **Figure 43-7**. Individual differences in maternal body habitus preclude naming any one approach as superior (Gilstrap and colleagues, 2002). Wall and colleagues (2003) reported a fourfold wound complication rate when a vertical abdominal incision was compared with a transverse incision—31 versus 8 percent. Conversely, Houston and Raynor (2000) reported similar wound complications with either incision.

Attention to closure of the subcutaneous layer is important. Chelmow and associates (2004) performed a meta-analysis of subcutaneous closure in 887 women undergoing cesarean delivery and whose wound thickness was greater than 2 centimeters. Subcutaneous closure resulted in a modest but significant 6-percent decrease in wound disruption. Walsh and colleagues (2009) have reviewed the prevention and management of surgical site infections in morbidly obese women.

Graduated compression stockings, hydration, and early mobilization after cesarean delivery in obese women is recommended by the American College of Obstetricians and Gynecologists (2005a). Some recommend "mini-dose" heparin prophylaxis, but we do not routinely use this.

Pregnancy Following Surgical Procedures for Obesity

A number of surgical procedures have been designed to treat morbid obesity by either decreasing gastric volume or bypassing gastrointestinal absorption (Adams and co-workers, 2007; Saber and colleagues, 2008). In a meta-analysis of these procedures in nonpregnant patients, Buchwald and associates (2007) found them to improve or resolve diabetes, hyperlipidemia, hypertension, and obstructive sleep apnea. Kini and associates (2007) reported that the metabolic syndrome also improves.

Indeed, these procedures are common, and Catalano (2007) estimates that more than 150,000 are done annually in this country. Although these are not performed during pregnancy, many women are becoming pregnant following weight-reduction surgery (Abodeely and associates, 2008). Guelinckx and co-workers (2009) found improved fertility and reduced risks of obstetrical complications in those following bariatric surgery compared with morbidly obese controls. The three procedures commonly performed currently are vertical gastroplasty, gastric banding, and Roux-en-Y gastric bypass. Older procedures no longer in use include the jejunoileal bypass and upper gastrojejunostomy bypass.

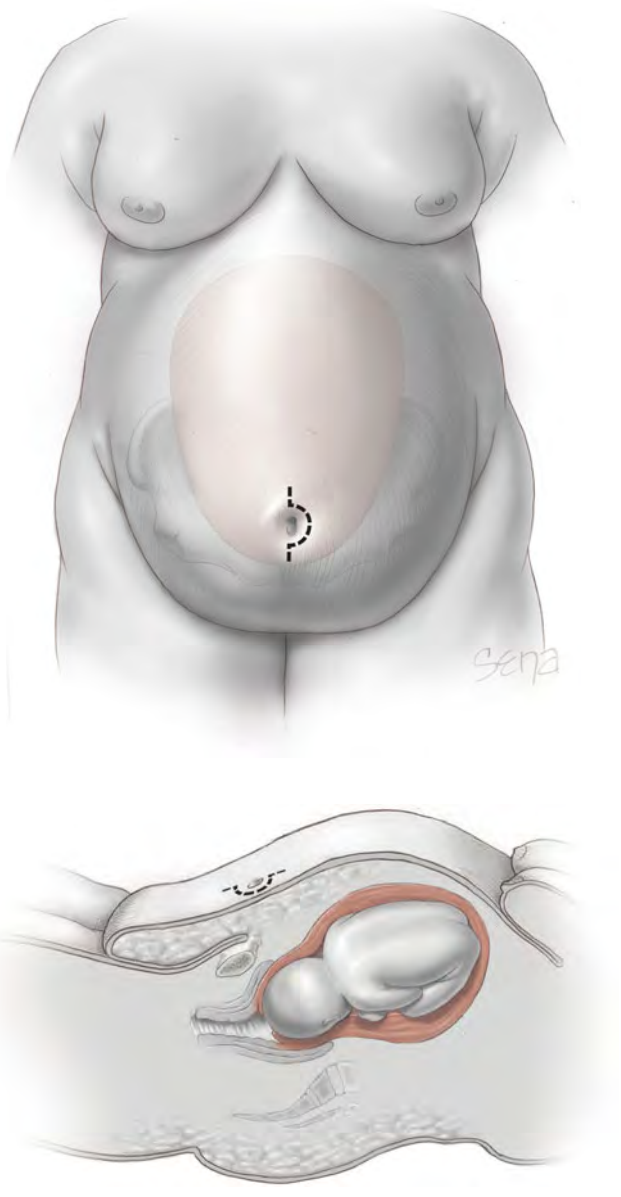

FIGURE 43-7 Abdominal incision for the obese woman. **A.** Frontal view. The dotted line indicates an appropriate skin incision for abdominal entry relative to panniculus. As shown by the uterus in the background, selection of this periumbilical site permits access to the lower uterine segment. **B.** Sagittal view.

Vertical Gastroplasty. A narrow channel is created through the stomach using stapling devices. The small gastric pouch empties through a narrow outlet into the remainder of the stomach. Subsequent pregnancy outcomes were described by Bilenka and colleagues (1995). There were 14 pregnancies in nine women who had undergone the procedure. Their mean weight loss was 80 pounds, and the women had fewer complications compared with their preprocedure pregnancies.

Gastric Banding. An adjustable band is placed 2 cm below the gastroesophageal junction to create a small pouch, as described above. Of 23 pregnancies in women subsequent to the procedure, Martin and co-workers (2000) reported that in three there was excessive nausea and vomiting, and band adjustment to decrease obstruction was successful. Dixon and associates (2005) described the outcomes in 79 women following laparoscopic adjustable banding. Pregnancy outcomes were compared with those in 40 pregnancies delivered of these women preprocedure, as well as with a matched cohort of 79 obese women. In the 79 pregnancies following banding, the incidences of gestational hypertension—10 versus 45 percent—and gestational diabetes—6 versus 15 percent—were significantly lower compared with preprocedure pregnancies. Incidences in banded patients were also significantly lower than those in the obese cohort, whose rates for hypertension were 38 percent, and for diabetes, 19 percent. The results from these and other studies are shown in Table 43-5.

Roux-en-Y Bypass. This type of bypass is the most effective bariatric procedure currently in use (Brunicardi and associates, 2001). It most often is performed laparoscopically (Dao and colleagues, 2006). The proximal stomach is completely transected to leave a 30-mL pouch. A gastroenterotomy is then created by connecting the proximal end of the distal jejunum to the pouch. A Roux-en-Y enteroenterostomy is also completed 60 cm distal to this gastrojejunostomy to allow drainage of the unused stomach and proximal small intestine.

Brunicardi and colleagues (2001) summarized four series totaling almost 400 men and nonpregnant women. Mean weight loss at 1 year in the four series ranged from 21 to 43 kg. In the largest study, at 1 year, 300 patients had lost a mean of 80 percent of their excessive weight. At 5 years, 50 to 75 percent of the weight loss had been maintained, and at 14 years, maintenance of lost weight still exceeded 50 percent (American Society for Bariatric Surgery, 2003).

As with other bariatric procedures, pregnancy outcomes are changed remarkably following Roux-en-Y bypass. Wittgrove and associates (1998) described 49 pregnancies in 36 women after these procedures. When 17 prior pregnancy outcomes were compared with those after bypass, there was a dramatic reduction in hypertension—40 versus 0 percent, diabetes—24 versus 0 percent, and infant weight > 4000 g—30 versus 5 percent. Results of pregnancy outcomes from studies summarized by Abodeely and co-workers (2008) are shown in Table 43-5. Serious complications are uncommon, but intussusception occurs, and at least one maternal death from herniation and obstruction has been reported (Moore and colleagues, 2004; Wax and associates, 2007).

Recommendations. The American College of Obstetricians and Gynecologists (2005a) recommends the following counseling before and during pregnancy in women who have undergone bariatric surgery:

- Patients with adjustable gastric banding should be advised that they are at risk of becoming pregnant unexpectedly after weight loss following surgery
- All patients are advised to delay pregnancy for 12 to 18 months after surgery to avoid pregnancy during the rapid-weight-loss phase
- Women with a gastric band should be monitored by their bariatric team during pregnancy because adjustments of the band may be necessary
- Patients should be evaluated for nutritional deficiencies, and vitamin supplementation should be given when indicated.

TABLE 43-5. Pregnancy Outcomes Following Gastric Banding Surgery and Roux-en-Y Gastric Bypass

Outcome	Gastric Banding[a] (n = 227)	Roux-en-Y Gastric Bypass[b] (n = 164)
Hypertension	~8%	6%
Gestational diabetes	~12%	4%
Cesarean delivery	~25%	23%
Mean birthweight	—	~3300 g
Small for gestational age	8%	—
Stillbirth	4/1000	6/1000

CHAPTER 44

Cardiovascular Disease

PHYSIOLOGICAL CONSIDERATIONS IN PREGNANCY 958
DIAGNOSIS OF HEART DISEASE 959
GENERAL MANAGEMENT 961
SURGICALLY CORRECTED HEART DISEASE 963
VALVULAR HEART DISEASE 965
CONGENITAL HEART DISEASE 968
PULMONARY HYPERTENSION 970
OTHER CARDIOVASCULAR CONDITIONS 971
DISEASES OF THE AORTA 976
ISCHEMIC HEART DISEASE 977

According to the Centers for Disease Control and Prevention, heart disease is the leading cause of death in women who are 25 to 44 years old (Kung and colleagues, 2008). Cardiac disorders of varying severity complicate approximately 1 percent of pregnancies and contribute significantly to maternal morbidity and mortality rates. For example, Chang and co-workers (2003) reported that cardiomyopathy alone was responsible for 8 percent of 4200 pregnancy-related deaths in the United States from 1991 to 1999. From Brazil, Avila and associates (2003) reported the maternal mortality rate to be 2.7 percent in 1000 pregnancies complicated by heart disease. In addition to maternal mortality, cardiac disorders accounted for 7.6 percent of severe obstetrical morbidities diagnosed during hospitalization for delivery in the United States from 1991 to 2003 (Callaghan and associates, 2008).

PHYSIOLOGICAL CONSIDERATIONS IN PREGNANCY

The marked pregnancy-induced hemodynamic alterations can have a profound effect on underlying heart disease. These are further detailed in Chapter 5 (p. 118). The most important is that cardiac output is increased by as much as 50 percent during pregnancy. Capeless and Clapp (1989) have shown that almost half of this total increase takes place by 8 weeks, and it is maximized by midpregnancy. The early increase stems from augmented stroke volume that results from decreased vascular resistance. Later in pregnancy, resting pulse and stroke volume increase even more because of increased diastolic filling from pregnancy hypervolemia. These changes are even more profound in multifetal pregnancy (Kametas and colleagues, 2003).

An important study by Clark and colleagues (1989) contributed greatly to the understanding of cardiovascular physiology during pregnancy. Using right-sided heart catheterization, these investigators measured hemodynamic function in 10 healthy primigravid women. Pregnancy values were compared with those measured again at 12 weeks postpartum. As shown in **Table 44-1**, near term the cardiac output in the lateral recumbent position increased 43 percent because of increased pulse rate and augmented stroke volume as the result of ventricular dilatation. Systemic and pulmonary vascular resistance were concomitantly decreased. Importantly, there was no change in intrinsic left ventricular contractility. Despite these changes, normal left ventricular function is maintained during pregnancy—specifically, hyperdynamic function or a high cardiac-output state does not develop (see Fig. 5-10, p. 120).

Recent noninvasive studies have elucidated further the maternal adaptation to the "natural volume overload state." For example, possible controlling-gene expression/function of signaling molecules that mediate reversible eccentric hypertrophy have been described (Eghbali and co-workers, 2006). These may be

TABLE 44-1. Hemodynamic Changes in 10 Normal Pregnant Women at Term Compared with Their 12-Week Postpartum Values

Parameter	Change (Percent)
Cardiac output	+43
Heart rate	+17
Left ventricular stroke work index	+17
Vascular resistance	
Systemic	−21
Pulmonary	−34
Mean arterial pressure	+4
Colloid osmotic pressure	−14

Data from Clark and colleagues (1989).

activated by estrogens or other G-protein-coupled receptor agonists such as endothelin-1 or angiotensin II (see Chap. 5, p. 120).

Women with underlying cardiac disease may not accommodate these changes, and ventricular dysfunction leads to cardiogenic heart failure. A few women with severe cardiac dysfunction may experience evidence of heart failure before midpregnancy. In others, heart failure may develop after 28 weeks when pregnancy-induced hypervolemia and cardiac output reach their maximum. In most, however, heart failure develops peripartum when a number of common obstetrical conditions place undue burdens on cardiac function. In the 542 women with heart disease reported by Etheridge and Pepperell (1977), eight of 10 maternal deaths were during the puerperium.

DIAGNOSIS OF HEART DISEASE

The physiological adaptations of normal pregnancy can induce symptoms and alter clinical findings that may confound the diagnosis of heart disease. For example, in normal pregnancy, functional systolic heart murmurs are common; respiratory effort is accentuated and at times suggests dyspnea; edema in the lower extremities after midpregnancy is common; and fatigue and exercise intolerance develop in most women. Some systolic flow murmurs may be loud, and normal changes in the various heart sounds depicted in **Figure 44-1** may suggest cardiac disease. Listed in **Table 44-2** are a number of clinical findings that may suggest heart disease. Pregnant women who have none of these rarely have serious heart disease.

Diagnostic Studies

In most women, noninvasive cardiovascular studies such as electrocardiography, echocardiography, and chest radiography will provide data necessary for evaluation. In some situations, for example, suspected pulmonary embolism with biventricular dysfunction, CT angiography has become commonplace. Albumin or red cells tagged with technicium-99 are rarely needed during pregnancy to evaluate ventricular function. Even so, the estimated fetal radiation exposure for a 20-mCi dose is only about 200 mrad, well below the accepted level (see Chap. 41, p. 920). Regional coronary perfusion is measured with thallium-201 chloride with a typical fetal exposure of 300 to 1100 mrad that is inversely proportional to gestational age. If indicated, right-sided heart catheterization can be performed with limited fluoroscopy. On rare occasions, it may be necessary to perform left-sided heart catheterization. In women with clear indications, any minimal theoretical risk is outweighed by maternal benefits.

Electrocardiography

As the diaphragm is elevated in advancing pregnancy, there is an average 15-degree left-axis deviation in the electrocardiogram (ECG), and mild ST changes may be seen in the inferior leads. Atrial and ventricular premature contractions are relatively frequent (Carruth and colleagues, 1981). Pregnancy does not alter voltage findings.

Chest Radiography

Anteroposterior and lateral chest radiographs are useful, and when a lead apron shield is used, fetal radiation exposure is minimal (see Chap. 41, p. 918). Gross cardiomegaly can usually be excluded, but slight heart enlargement cannot be detected accurately because the heart silhouette normally is larger in pregnancy.

Echocardiography

The widespread use of echocardiography has allowed accurate diagnosis of most heart diseases during pregnancy. It allows noninvasive evaluation of structural and functional cardiac factors. Some normal pregnancy-induced changes include slightly but significantly increased tricuspid regurgitation, left atrial end-diastolic dimension, and left ventricular mass. Normal morphological and functional echocardiographic parameters associated with pregnancy have been provided by Yuan and associates (2006).

Clinical Classification of Heart Disease

There is no clinically applicable test for accurately measuring functional cardiac capacity. The clinical classification of the New York Heart Association (NYHA) was first published in 1928, and it was revised for the eighth time in 1979. This classification is based on past and present disability and is uninfluenced by physical signs.

- **Class I.** *Uncompromised—no limitation of physical activity:* These women do not have symptoms of cardiac insufficiency or experience anginal pain.
- **Class II.** *Slight limitation of physical activity:* These women are comfortable at rest, but if ordinary physical activity is undertaken, discomfort in the form of excessive fatigue, palpitation, dyspnea, or anginal pain results.
- **Class III.** *Marked limitation of physical activity:* These women are comfortable at rest, but less than ordinary activity causes excessive fatigue, palpitation, dyspnea, or anginal pain.
- **Class IV.** *Severely compromised—inability to perform any physical activity without discomfort*: Symptoms of cardiac insufficiency or angina may develop even at rest. If any physical activity is undertaken, discomfort is increased.

Siu and associates (2001) expanded the NYHA classification and developed a scoring system for predicting cardiac

TABLE 44-2. Clinical Indicators of Heart Disease During Pregnancy

Symptoms
Progressive dyspnea or orthopnea
Nocturnal cough
Hemoptysis
Syncope
Chest pain
Clinical Findings
Cyanosis
Clubbing of fingers
Persistent neck vein distension
Systolic murmur grade 3/6 or greater
Diastolic murmur
Cardiomegaly
Persistent arrhythmia
Persistent split second sound
Criteria for pulmonary hypertension

complications during pregnancy. The system is based on their prospective analysis of 562 consecutive pregnant women with heart disease during 617 pregnancies in 13 Canadian teaching hospitals. Predictors of cardiac complications included the following:

- Prior heart failure, transient ischemic attack, arrhythmia, or stroke.
- Baseline NYHA class III or IV or cyanosis.
- Left-sided obstruction defined as mitral valve area less than 2 cm^2, aortic valve area less than 1.5 cm^2, or peak left ventricular outflow tract gradient above 30 mm Hg by echocardiography.
- Ejection fraction less than 40 percent.

The risk of pulmonary edema, sustained arrhythmia, stroke, cardiac arrest, or cardiac death was substantively increased with one of these factors and even more so with two or more factors.

At lease two studies have been done using these risk criteria. Khairy and colleagues (2006) reviewed 90 pregnancies in

TABLE 44-3. Approximated Risks for Cardiac Complications During 1712 Pregnancies in Women with Preexisting Heart Disease

		Complication No. (%)			
Type of Cardiac Lesion	No.	Heart Failure	Arrhythmia	Thrombosis	Death
Congenital	804	52 (6.5)	26 (3.2)	2 (0.3)	11 (1.4)
Acquired	820	116 (14)	35 (4.3)	18 (2.2)	11 (1.3)
Arrhythmia	88	2 (23)	22 (25)	0	0

Data from Avila (2003), Ford (2008), Madazli (2009), Siu (2001), Stangl (2008), and all their co-workers.

53 women with congenital heart disease at Brigham and Women's Hospital. There were no maternal deaths, and heart failure and symptomatic arrhythmias occurred in 16.7 and 2.8 percent of the women, respectively. Similar to the Canadian study cited above, the most important predictors of complications were prior congestive heart failure, depressed ejection fraction, and smoking. In a German study, Stangl and co-workers (2008) also used the predefined risk predictors and found them to be accurate in assessing outcomes in most of the 93 pregnancies in women with congenital or acquired heart disease.

Preconceptional Counseling

Women with severe heart disease will benefit immensely from counseling before deciding to become pregnant (see Chap. 7, p. 177). Maternal mortality rates generally vary directly with functional classification, however, this relationship may change as pregnancy progresses. In the Canadian study cited earlier, Siu and colleagues (2001) observed significant worsening of NYHA class in 26 of 579 pregnancies—4.4 percent—in which the baseline class was I or II. Their experiences, however, as well as those of McFaul and co-workers (1988), were that there were no maternal deaths in 1041 women with class I or II disease.

In some women, life-threatening cardiac abnormalities can be reversed by corrective surgery, and subsequent pregnancy is less dangerous. In other cases, such as women with mechanical valves taking warfarin, fetal considerations predominate. Shown in Table 44-3 are cardiac complications during pregnancy compiled from five recent reports. In most of these, about 15 percent of all pregnant women with heart disease suffered one or more of these complications.

Congenital Heart Disease in Offspring

Many congenital heart lesions appear to be inherited as polygenic characteristics (see Chap. 12, p. 281). Thus, some women with congenital lesions give birth to similarly affected infants, the risk of which varies widely as shown in Table 44-4.

GENERAL MANAGEMENT

In most instances, management involves a team approach with an obstetrician, cardiologist, anesthesiologist, and other specialists as needed. Cardiovascular changes likely to be poorly tolerated by an individual woman are identified, and a plan is formulated to minimize these. Four changes that affect management are emphasized by the American College of Obstetricians and Gynecologists (1992):

- The 50-percent increase in blood volume and cardiac output by the early third trimester
- Further fluctuations in volume and cardiac output in the peripartum period

TABLE 44-4. Congenital Heart Disease Risks in the Fetus with Affected Family Members

Maternal Heart Disease	Congenital Heart Disease in Fetus (Percent)		
Cardiac Lesion	Previous Sibling Affected	Father Affected	Mother Affected
Marfan syndrome	NS	50	50
Aortic stenosis	2	3	15–18
Pulmonary stenosis	2	2	6–7
Ventricular septal defect	3	2	10–16
Atrial septal defect	2.5	1.5	5–11
Patent ductus arteriosus	3	2.5	4
Coarctation of the aorta	NS	NS	14
Fallot tetralogy	2.5	1.5	2–3

NS = not stated.
From Lupton and colleagues (2002), with permission.

- A decline in systemic vascular resistance, reaching a nadir in the second trimester, and then rising to 20 percent below normal by late pregnancy
- Hypercoagulability, which is of special importance in women requiring anticoagulation before pregnancy with coumarin derivatives.

Within this framework, both prognosis and management are influenced by the nature and severity of the specific lesion in addition to the functional classification.

Management of NYHA Class I and II Disease

With rare exceptions, women in NYHA class I and most in class II proceed through pregnancy without morbidity. Special attention should be directed toward both prevention and early recognition of heart failure. As reviewed by Jessup and Brozena (2003), the onset of congestive heart failure is generally gradual. The first warning sign is likely to be persistent basilar rales, frequently accompanied by a nocturnal cough. A sudden diminution in ability to carry out usual duties, increasing dyspnea on exertion, or attacks of smothering with cough are symptoms of serious heart failure. Clinical findings may include hemoptysis, progressive edema, and tachycardia.

Infection with sepsis syndrome is an important factor in precipitating cardiac failure. Moreover, bacterial endocarditis is a deadly complication of valvular heart disease. Each woman should receive instructions to avoid contact with persons who have respiratory infections, including the common cold, and to report at once any evidence for infection. Pneumococcal and influenza vaccines are recommended.

Cigarette smoking is prohibited, both because of its cardiac effects and its propensity to cause upper respiratory infections. Illicit drug use may be particularly harmful, an example being the cardiovascular effects of cocaine or amphetamines. In addition, intravenous drug use increases the risk of infective endocarditis.

Labor and Delivery

In general, vaginal delivery is preferred unless there are obstetrical indications for cesarean delivery. Induction is generally safe (Oron and colleagues, 2004). In some women, *pulmonary artery catheterization* may be indicated for hemodynamic monitoring (see Chap 42, p. 928). In our experience, however, invasive monitoring is rarely indicated.

During labor, the mother with significant heart disease should be kept in a semirecumbent position with lateral tilt. Vital signs are taken frequently between contractions. Increases in pulse rate much above 100 bpm or respiratory rate above 24 per minute, particularly when associated with dyspnea, may suggest impending ventricular failure. If there is any evidence of cardiac decompensation, intensive medical management must be instituted immediately. It is essential to remember that delivery itself does not necessarily improve the maternal condition. Moreover, emergency operative delivery may be particularly hazardous. Clearly, both maternal and fetal status must be considered in the decision to hasten delivery under these circumstances.

Analgesia and Anesthesia. Relief from pain and apprehension is important. Although intravenous analgesics provide satisfactory pain relief for some women, continuous epidural analgesia is recommended in most cases. The major problem with conduction analgesia is maternal hypotension (see Chap. 19, p. 455). This is especially dangerous in women with intracardiac shunts in whom flow may be reversed. Blood passes from right to left within the heart or aorta and thereby bypasses the lungs. Hypotension can also be life-threatening with pulmonary hypertension or aortic stenosis because ventricular output is dependent on adequate preload. In women with these conditions, narcotic conduction analgesia or general anesthesia may be preferable.

For vaginal delivery in women with only mild cardiovascular compromise, epidural analgesia given with intravenous sedation often suffices. This has been shown to minimize intrapartum cardiac output fluctuations and allows forceps or vacuum-assisted delivery. Subarachnoid blockade is not generally recommended in women with significant heart disease. For cesarean delivery, epidural analgesia is preferred by most clinicians with caveats for its use with pulmonary hypertension (see p. 971). Finally, general endotracheal anesthesia with thiopental, succinylcholine, nitrous oxide, and at least 30-percent oxygen has also proved satisfactory (see Chap. 19, p. 459).

Intrapartum Heart Failure. Cardiovascular decompensation during labor may manifest as pulmonary edema with hypoxia or as hypotension, or both. The proper therapeutic approach depends on the specific hemodynamic status and the underlying cardiac lesion. For example, decompensated mitral stenosis with pulmonary edema due to fluid overload is often best approached with aggressive diuresis. If precipitated by tachycardia, heart rate control with β-blocking agents is preferred. Conversely, the same treatment in a woman suffering decompensation and hypotension due to aortic stenosis could prove fatal. Unless the underlying pathophysiology is understood and the cause of the decompensation clear, empirical therapy may be hazardous.

Puerperium

Women who have shown little or no evidence of cardiac distress during pregnancy, labor, or delivery may still decompensate postpartum. Therefore, it is important that meticulous care be continued into the puerperium (Keizer and colleagues, 2006; Zeeman, 2006). Postpartum hemorrhage, anemia, infection, and thromboembolism are much more serious complications in those with heart disease. Indeed, these factors often act in concert to precipitate postpartum heart failure (Cunningham and associates, 1986). In many of these—for example, sepsis and severe preeclampsia—pulmonary edema is caused by or worsened by permeability edema resulting from endothelial activation and capillary-alveolar leakage (see Chap. 42, p. 929).

Sterilization and Contraception

If tubal sterilization is to be performed after vaginal delivery, it is best to delay the procedure until the mother has become

TABLE 44-5. Outcomes Reported Since 1990 in Pregnancies Complicated by a Heart-Valve Replacement

		Complications[a]	
Type of Valve	Total	Maternal	Perinatal
Mechanical	499[b]	34 thromboses 17 emboli 14 hemorrhages 12 deaths	94 miscarriages/abortions 34 stillbirths
Porcine	265[c]	32 valve failure or deterioration	9 abortions 3 stillbirths

[c]Data from Hanania (1994), Lee (1994), Sadler (2000), Sbarouni (1994), and all their colleagues.

hemodynamically near normal, and when she is afebrile, not anemic, and ambulates normally. Other women are given detailed contraceptive advice. Special considerations for contraception in women with various cardiac disorders are discussed in some of the following sections and throughout Chapter 32.

Management of Class III and IV Disease

These severe cases are uncommon today. In the Canadian study by Siu and associates (2001), only 3 percent of approximately 600 pregnancies were complicated by NYHA class III heart disease, and no women had class IV when first seen. An important question in these women is whether pregnancy should be undertaken. If women make that choice, they must understand the risks and cooperate fully with planned care. If feasible, women with some types of severe cardiac disease should consider pregnancy interruption. If the pregnancy is continued, prolonged hospitalization or bed rest is often necessary.

Epidural analgesia for labor and delivery is usually recommended. Vaginal delivery is preferred in most cases, and labor induction can usually be done safely (Oron and associates, 2004). Cesarean delivery is usually limited to obstetrical indications, and considerations are given for the specific cardiac lesion, overall maternal condition, and availability of experienced anesthesia personnel and general support facilities. These women often tolerate major surgical procedures poorly and are best delivered in a unit facile with management of complicated cardiac disease.

SURGICALLY CORRECTED HEART DISEASE

Most clinically significant lesions are repaired during childhood. Examples of defects not diagnosed until adulthood include atrial septal defects, pulmonic stenosis, bicuspid aortic valve, and aortic coarctation (Brickner and colleagues, 2000). In some cases, the defect is mild and surgery is not required. In others, a significant structural anomaly is amenable to surgical correction. With successful repair, many women attempt pregnancy. In some instances, surgical corrections have been performed during pregnancy.

Valve Replacement before Pregnancy

A number of reproductive-aged women have had a prosthesis implanted to replace a severely damaged mitral or aortic valve. Reports of subsequent pregnancy outcomes are now numerous, and indeed, successful pregnancies have followed prosthetic replacement of even three heart valves (Nagorney and Field, 1981).

Effects on Pregnancy

Pregnancy is undertaken only after serious consideration. Women with a *mechanical valve prosthesis* must be anticoagulated, and when not pregnant, warfarin is recommended. As shown in Table 44-5, a number of serious complications can develop, especially with mechanical valves. Thromboembolism involving the prosthesis and hemorrhage from anticoagulation are of extreme concern (Nassar and co-workers, 2004). There also may be deterioration in cardiac function. **Overall, the maternal mortality rate is 3 to 4 percent with mechanical valves, and fetal loss is common.**

Porcine tissue valves are much safer during pregnancy, primarily because anticoagulation is not required as thrombosis is rare (see Table 44-5). To the contrary, valvular dysfunction, deterioration, or failure are common, and develop in 5 to 25 percent of pregnancies. Another drawback is that bioprostheses are not as durable as mechanical ones, and valve replacement averages every 10 to 15 years. Although some reports suggest that pregnancy may accelerate structural deterioration of bioprosthetic valves, this could simply reflect normal deterioration (Elkayam and Bitar, 2005).

Management

The critical issue for women with mechanical prosthetic valves is anticoagulation, and there is a suggestion that heparin may be less effective than warfarin in preventing thromboembolic events.

Warfarin. Although most effective to prevent mechanical valve thrombosis, warfarin is teratogenic and can cause miscarriage,

TABLE 44-6. American College of Chest Physicians Guidelines for Anticoagulation of Pregnant Women with Mechanical Prosthetic Valves

For pregnant women with mechanical heart valves, any one of the following anticoagulant regimens is recommended:

- Adjusted-dose *LMWH* twice daily throughout pregnancy. The doses should be adjusted to achieve the manufacturer's peak anti-Xa level 4 hours after subcutaneous injection.
- Adjusted-dose *UFH* administered every 12 hours throughout pregnancy. The doses should be adjusted to keep the midinterval aPTT at least twice control or attain an anti-Xa heparin level of 0.35 to 0.70 U/mL.
- LMWH or UFH as above until 13 weeks' gestation with warfarin substitution until close to delivery when LMWH or UFH is resumed.

In women judged to be at very high risk of thromboembolism and in whom concerns exist about the efficacy and safety of LMWH or UFH as dosed above—some examples include older-generation prosthesis in the mitral position or history of thromboembolism. Warfarin is suggested throughout pregnancy with replacement by UFH or LMWH (as above) close to delivery. In addition, low-dose aspirin—75 to 100 mg daily—should be orally administered.

aPTT = activated partial thromboplastin time; LMWH = low-molecular-weight heparin; UFH = unfractionated heparin.
Adapted from Bates and colleagues (2008).

stillbirths, and fetal malformation (see Chap. 14, p. 325). For example, Cotrufo and colleagues (2002) described 71 pregnancies in women given warfarin for a mechanical valve prosthesis throughout pregnancy. Although there were no serious maternal complications, the rates of miscarriage were 32 percent; stillbirth, 7 percent; and embryopathy, 6 percent. The risk was highest when the mean daily dose of warfarin exceeded 5 mg. From their review, Chan and co-workers (2000) concluded that the best maternal outcomes were achieved with warfarin anticoagulation with the tradeoff of a 6.4-percent embryopathy rate. And although heparin substituted before 12 weeks eliminated embryopathy, thromboembolic complications increased significantly.

Low-Dose Heparin. Prophylaxis using low-dose unfractionated heparin is definitely inadequate. Iturbe-Alessio and colleagues (1986) reported that three of 35 women on such therapy suffered massive thrombosis of a mitral prosthesis—two of these died. Similarly, Chan and co-workers (2000) found that two of five women treated solely with low-dose heparin during pregnancy died.

Anticoagulation with Heparin. Full anticoagulation with either unfractionated heparin (UFH) or one of the low-molecular-weight heparins (LMWH) is also problematic because of reports of valvular thrombosis in patients. This has been especially problematic with LMWH given to pregnant women, who were apparently adequately anticoagulated (Leyh and colleagues, 2002, 2003; Rowan and associates, 2001). Following such reports and a warning issued by Aventis Pharmaceuticals, the American College of Obstetricians and Gynecologists (2002) advised against use of low-molecular-weight heparins during pregnancy for those with prosthetic valves. On the other hand, the American College of Chest Physicians has recommended use of any of several regimens that include adjusted-dose UFH or LMWH heparin given throughout pregnancy as subsequently discussed.

Recommendations for Anticoagulation. A number of different treatment options—none of which are completely ideal—have been proposed and are principally based on consensus opinion. For this reason, they differ and allow more than one scheme. For example, and as shown in Table 44-6, the most recent guidelines of the American College of Chest Physicians for the management of pregnant women with mechanical prosthetic valves offer several different treatment options.

Similar to one of the American College of Chest Physicians recommendations, Reimold and Rutherford (2003) suggest unfractionated heparin from 6 to 12 weeks, and again after 36 weeks. Throughout the rest of pregnancy, they recommend warfarin therapy to achieve a target international normalized ratio (INR) of 2.0 to 3.0. The European Society of Cardiology favors warfarin anticoagulation until 36 weeks, at which time heparin is given until delivery (Butchart and associates, 2005).

Heparin is discontinued just before delivery. If delivery supervenes while the anticoagulant is still effective, and extensive bleeding is encountered, then *protamine sulfate* is given intravenously. Anticoagulant therapy with warfarin or heparin may be restarted 6 hours following vaginal delivery, usually with no problems. Following cesarean delivery, full anticoagulation is withheld, but the duration is not exactly known. It is our practice to wait at least 24 hours—and preferably 48 hours—following a major surgical procedure. Clark and colleagues (2000) reviewed the use of warfarin derivatives and concluded they are safe for breast-feeding women because of minimal transfer to milk.

Contraception

Because of their possible thrombogenic action, estrogen-progestin oral contraceptives are relatively contraindicated in women with prosthetic valves (see Chap. 32, p. 680). These women are generally fully anticoagulated, and thus any increased risk is speculative. Sterilization should be considered because of the serious pregnancy risks faced by women with significant heart disease.

Valve Replacement During Pregnancy

Although usually postponed until after delivery, valve replacement during pregnancy may be lifesaving. A number of reviews all confirm that surgery on the heart or great vessels is associated with major maternal and fetal morbidity and mortality. For example, Sutton and associates (2005) found that maternal mortality rates with cardiopulmonary bypass are between 1.5 and 5 percent. Although these are similar to rates for nonpregnant women, the fetal mortality rate approaches 20 percent. In a study from Brazil, Arnoni and associates (2003) described 58 such women in whom the maternal mortality rate was 8 percent. Almost 20 percent of the fetuses died as a direct result of the surgery. To minimize these bad outcomes, Chandrasekhar and co-workers (2009) recommend that surgery is done electively when possible, pump flow rate is maintained >2.5 L/min/m^2, normothermic perfusion pressure is >70 mm Hg, pulsatile flow is used, and hematocrit is >28 percent.

Mitral Valvotomy During Pregnancy

Tight mitral stenosis that requires intervention during pregnancy was previously treated by closed mitral valvotomy (Pavankumar and associates, 1988). In the past two decades, however, percutaneous transcatheter balloon dilatation of the mitral valve has largely replaced surgical valvotomy during pregnancy (Fawzy, 2007). To compare these two, de Souza and colleagues (2001a) studied 24 consecutive pregnant women who underwent open mitral commissurotomy between 1985 and 1990 and compared them with 21 women who underwent percutaneous valvuloplasty between 1990 and 1995. The balloon procedure was more than 90-percent successful, and functional outcomes in the two groups were similar. There was one maternal death in the open-repair group. Importantly, perinatal mortality rate was sixfold higher in the open repair group—33 versus 5 percent.

More recently, Rahimtoola (2006) summarized outcomes of 36 women—25 of whom were NYHA class III or IV—who underwent balloon commissurotomy at an average gestational age of 26 weeks. The procedure was successful in 35. Left atrial and pulmonary artery pressures were reduced and associated with an increased mitral valve area from 0.74 to 1.59 cm^2. Esteves and associates (2006) described similarly good outcomes in 71 pregnant women with tight mitral stenosis and heart failure who underwent percutaneous valvuloplasty. At delivery, 98 percent were in either NYHA Class I or II. At a mean of 44 months, their total event-free maternal survival rate was 54 percent. One woman died from transfusion-acquired hepatitis, and eight required another surgical intervention. The 66 infants who were delivered at term all had normal growth and development.

Pregnancy after Heart Transplantation

The first successful pregnancy in a heart transplant recipient was reported more than 20 years ago by Löwenstein and associates (1988). Since that time, more than 50 pregnancies in heart-transplant recipients have been described. Key (1989) and Kim (1996) and their colleagues provided detailed data to show that the transplanted heart responds normally to pregnancy-induced changes. Despite this, complications are common during pregnancy (Dashe and associates, 1998). Armenti and associates (2002) from the National Transplantation Pregnancy Registry and Miniero and colleagues (2004) described outcomes of 53 pregnancies in 37 heart recipients. Almost half developed hypertension, and 22 percent suffered at least one rejection episode during pregnancy. They were delivered—usually by cesarean—at a mean of 37 to 38 weeks, and three fourths of infants were liveborn. At follow-up, at least five women had died more than 2 years postpartum. A scholarly review of pregnancy in solid-organ transplant recipients is provided by McKay and Josephson (2006). Ethical considerations of counseling and caring for such women regarding pregnancy were summarized by Ross (2006).

VALVULAR HEART DISEASE

Rheumatic fever is uncommon in the United States because of less crowded living conditions, availability of penicillin, and evolution of nonrheumatogenic streptococcal strains. Still, it remains the chief cause of serious mitral valvular disease (O'Shea and Braunwald, 2008).

Mitral Stenosis

Rheumatic endocarditis causes three fourths of mitral stenosis cases. The normal mitral valve surface area is 4.0 cm^2. When stenosis narrows this to less than 2.5 cm^2, symptoms usually develop (Desai and colleagues, 2000). The contracted valve impedes blood flow from the left atrium to the ventricle. The most prominent complaint is dyspnea due to pulmonary venous hypertension and edema. Fatigue, palpitations, cough, and hemoptysis are also common.

With tight stenosis, the left atrium is dilated, left atrial pressure is chronically elevated, and significant passive pulmonary hypertension can develop (**Table 44-7**). The increased preload of normal pregnancy, as well as other factors that increase cardiac output, may cause ventricular failure with pulmonary edema in these women who have a relatively fixed cardiac output. Indeed, a fourth of women with mitral stenosis have cardiac failure for the first time during pregnancy (Caulin-Glaser and Setaro, 1999). Because the murmur may not be heard in some women, this clinical picture may be confused with idiopathic peripartum cardiomyopathy (Cunningham and colleagues, 1986).

With significant stenosis, tachycardia shortens ventricular diastolic filling time and increases the mitral gradient. This increase raises left atrial and pulmonary venous and capillary pressures and may result in pulmonary edema. Thus, sinus tachycardia is often treated prophylactically with β-blocking agents. Atrial tachyarrhythmias, including fibrillation, are common in mitral stenosis and are treated aggressively. Atrial fibrillation also predisposes to mural thrombus formation and cerebrovascular embolization that can cause stroke (see Chap. 55, p. 1168). Hameed and associates (2005) described three pregnant women with tight mitral stenosis—valve area of 0.9 cm^2—who each developed an atrial thrombus despite a sinus rhythm. One suffered an embolic stroke, and another had pulmonary edema and maternal hypoxemia that caused fetal encephalopathy.

TABLE 44-7. Major Cardiac Valve Disorders

Type	Cause	Pathophysiology	Pregnancy
Mitral stenosis	Rheumatic valvulitis	LA dilation and passive pulmonary hypertension Atrial fibrillation	Heart failure from fluid overload, tachycardia
Mitral insufficiency	Rheumatic valvulitis Mitral-valve prolapse LV dilatation	LV dilatation and eccentric hypertrophy	Ventricular function improves with afterload decrease
Aortic stenosis	Congenital Bicuspid valve	LV concentric hypertrophy, decreased cardiac output	Moderate stenosis tolerated; severe is life-threatening with decreased preload, e.g., obstetrical hemorrhage or regional analgesia
Aortic insufficiency	Rheumatic valvulitis Connective-tissue disease Congenital	LV hypertrophy and dilatation	Ventricular function improves with afterload decrease
Pulmonary stenosis	Congenital Rheumatic valvulitis	Severe stenosis associated with RA and RV enlargement	Mild stenosis usually well tolerated; severe stenosis associated with right heart failure and atrial arrhythmias

LA = left atrium, LV = left ventricle, RA = right atrium, RV = right ventricle.

Pregnancy Outcomes

In general, complications are directly associated with the degree of valvular stenosis. Recall that investigators from the large Canadian study found that women with a mitral-valve area <2 cm^2 were at greatest risk for complications. In another study from the University of Southern California Medical Center between 1979 and 1998, Hameed and associates (2001) cared for 46 pregnant women with mitral stenosis. Complications included heart failure in 43 percent and arrhythmias in 20 percent. Fetal-growth restriction was more common in those women with a mitral valve area less than 1.0 cm^2.

The maternal prognosis is also related to functional capacity. Among 486 pregnancies complicated by rheumatic heart disease—predominantly mitral stenosis—Sawhney and associates (2003) reported that eight of 10 maternal deaths were in women in NYHA classes III or IV.

Management

Limited physical activity is generally recommended. If symptoms of pulmonary congestion develop, activity is further reduced, dietary sodium is restricted, and diuretic therapy is started (Siva and Shah, 2005). A β-blocker drug is usually given to blunt the cardiac response to activity and anxiety (Al Kasab and associates, 1990). If new-onset atrial fibrillation develops, intravenous verapamil, 5 to 10 mg, is given, or electrocardioversion is performed. For chronic fibrillation, digoxin, a β-blocker, or a calcium-channel blocker is given to slow ventricular response. Therapeutic anticoagulation with heparin is indicated with persistent fibrillation. Hameed and co-workers (2005) recommend heparinization with severe stenosis even if there is a sinus rhythm.

Labor and delivery are particularly stressful for women with symptomatic mitral stenosis. Pain, exertion, and anxiety cause tachycardia, with possible rate-related heart failure. Epidural analgesia for labor is ideal, but with strict attention to avoid fluid overload. Abrupt increases in preload may increase pulmonary capillary wedge pressure and cause pulmonary edema. The cardiovascular effects of labor in women with mitral stenosis are shown in **Figure 44-2**. Wedge pressures increase even more immediately postpartum. Clark and colleagues (1985) hypothesize that this is likely due to loss of the low-resistance placental circulation along with the venous "autotransfusion" from the lower extremities, pelvis, and the now-empty uterus.

Most consider vaginal delivery to be preferable in women with mitral stenosis. Elective induction is reasonable so that labor and delivery are attended by a scheduled, experienced team. With severe stenosis and chronic heart failure, insertion of a pulmonary artery catheter may help guide management decisions. Consideration for endocarditis prophylaxis is discussed on page 974.

Mitral Insufficiency

When there is improper coaptation of mitral valve leaflets during systole, some degree of mitral regurgitation develops. This is

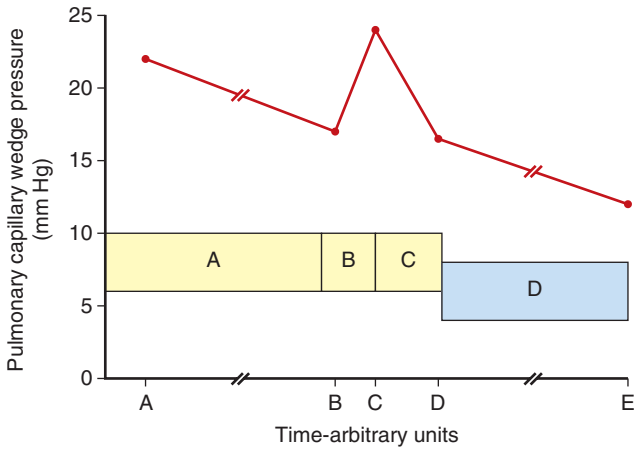

FIGURE 44-2 Mean pulmonary capillary wedge pressure measurements in eight women with mitral valve stenosis (*red graph line*). **A.** First-stage labor. **B.** Second-stage labor 15 to 30 minutes before delivery. **C.** Postpartum 5 to 15 minutes. **D.** Postpartum 4 to 6 hours. **E.** Postpartum 18 to 24 hours. Shaded yellow and blue boxes are mean (±1 SD) pressures in nonlaboring normal women at term. (Data from Clark and colleagues, 1985, 1989.)

eventually followed by left ventricular dilatation and eccentric hypertrophy (see Table 44-7). *Chronic mitral regurgitation* has a number of causes, including rheumatic fever, mitral valve prolapse, or left ventricular dilatation of any etiology—for example, dilated cardiomyopathy. Less common causes include a calcified mitral annulus, possibly some appetite suppressants, and in older women, ischemic heart disease. Mitral valve vegetations—*Libman-Sacks endocarditis*—are relatively common in women with antiphospholipid antibodies (Roldan and colleagues, 1996). These sometimes coexist with systemic lupus erythematosus (see Chap. 54, p. 1152). *Acute mitral insufficiency* is caused by rupture of a chorda tendineae, infarction of papillary muscle, or leaflet perforation from infective endocarditis.

In nonpregnant patients, symptoms from mitral valve incompetence are rare, and valve replacement is seldom indicated unless infective endocarditis develops. Likewise, mitral regurgitation is well tolerated during pregnancy, probably because decreased systemic vascular resistance results in less regurgitation. Heart failure only rarely develops during pregnancy, and occasionally tachyarrhythmias need to be treated. Intrapartum prophylaxis against bacterial endocarditis may be indicated (see p. 974).

Aortic Stenosis

This is a disease of aging, and in women younger than 30 years, it is most likely due to a congenital lesion. Aortic stenosis itself is less common since the decline in incidences of rheumatic diseases. In the United States, the most common lesion is a bicuspid valve (Friedman and co-workers, 2008). Stenosis reduces the normal 2- to 3-cm^2 aortic orifice and creates resistance to ejection. Reduction in the valve area to a fourth its normal size produces severe obstruction to flow and a progressive pressure overload on the left ventricle (Carabello, 2002). Concentric left ventricular hypertrophy follows, and if severe, end-diastolic pressures become elevated, ejection fraction declines, and cardiac output is reduced (see Table 44-7). Characteristic clinical manifestations develop late and include chest pain, syncope, heart failure, and sudden death from arrhythmias. Life expectancy averages only 5 years after exertional chest pain develops, and valve replacement is indicated for symptomatic patients.

Clinically significant aortic stenosis is uncommonly encountered during pregnancy. Although mild to moderate degrees of stenosis are well tolerated, severe disease is life threatening. The principal underlying hemodynamic problem is the fixed cardiac output associated with severe stenosis. During pregnancy, a number of factors commonly decrease preload further and thus aggravate the fixed cardiac output. These include regional analgesia, vena caval occlusion, and hemorrhage. Importantly, these also decrease cardiac, cerebral, and uterine perfusion. It follows that severe aortic stenosis may be extremely dangerous during pregnancy. From the large Canadian multicenter study by Siu and co-workers (2001) cited above, there were increased complications when aortic valve area was < 1.5 cm^2. And in the report described earlier by Hameed and associates (2001), the maternal mortality rate with aortic stenosis was 8 percent. Women with valve gradients exceeding 100 mm Hg appear to be at greatest risk.

Management

For the asymptomatic woman with aortic stenosis, no treatment except close observation is required. Management of the symptomatic woman includes strict limitation of activity and prompt treatment of infections. If symptoms persist despite bed rest, valve replacement or valvotomy using cardiopulmonary bypass must be considered. In general, balloon valvotomy for aortic valve disease is avoided because of serious complications, which exceed 10 percent. These include stroke, aortic rupture, aortic valve insufficiency, and death (Carabello and Crawford, 1997; Reich and co-workers, 2004). In rare cases, it may be preferable to perform valve replacement during pregnancy (Angel and colleagues, 1988; Lao and associates, 1993).

For women with critical aortic stenosis, intensive monitoring during labor is important. Pulmonary artery catheterization may be helpful because of the narrow margin separating fluid overload from hypovolemia. Women with aortic stenosis are dependent on adequate end-diastolic ventricular filling pressures to maintain cardiac output and systemic perfusion. Abrupt decreases in end-diastolic volume may result in hypotension, syncope, myocardial infarction, and sudden death. Thus, the key to management is the avoidance of decreased ventricular preload and the maintenance of cardiac output. During labor and delivery, such women should be managed on the "wet" side, maintaining a margin of safety in intravascular volume in anticipation of possible hemorrhage. In women with a competent mitral valve, pulmonary edema is rare, even with moderate volume overload.

During labor, narcotic epidural analgesia seems ideal, thus avoiding potentially hazardous hypotension, which may be encountered with standard conduction analgesia techniques. Easterling and colleagues (1988) studied the effects of epidural analgesia in five women with severe stenosis and demonstrated immediate and profound effects of decreased filling pressures. Camann and Thornhill (1999) and Xia and associates (2006)

emphasize slow administration of dilute local anesthetics into the epidural space. Forceps or vacuum delivery are used for standard obstetrical indications in hemodynamically stable women. Tzemos and co-workers (2009) reported that late cardiac events that included pulmonary edema, arrhythmias, cardiac interventions, and death were identified within 1 year of delivery in 70 pregnancies.

Aortic Insufficiency

Aortic regurgitation is the diastolic flow of blood from the aorta into the left ventricle. Common causes of aortic valvular incompetence are rheumatic fever, connective-tissue abnormalities, and congenital lesions. With Marfan syndrome, the aortic root may dilate, resulting in regurgitation (see p. 976). Acute insufficiency may develop with bacterial endocarditis or aortic dissection. Aortic and mitral valve insufficiency have been linked to the appetite suppressants fenfluramine and dexfenfluramine and to ergot-derived dopamine agonists (Gardin, 2000; Khan, 1998; Schade, 2007; Zanettini, 2007, and all their associates). With chronic disease, left ventricular hypertrophy and dilatation develop (see Table 44-7). This is followed by slow-onset fatigue, dyspnea, and edema, although rapid deterioration usually follows.

Aortic insufficiency is generally well tolerated during pregnancy. Like mitral valve incompetence, diminished vascular resistance is thought to improve the lesion. If symptoms of heart failure develop, diuretics are given and bed rest is encouraged. Epidural analgesia is used for labor and delivery, and bacterial endocarditis prophylaxis may be required (see p. 974).

Pulmonic Stenosis

The pulmonary artery valve is affected by rheumatic fever far less often than the other valves. Instead, pulmonic stenosis is usually congenital and also may be associated with Fallot tetralogy or Noonan syndrome. The clinical diagnosis is typically identified by auscultating a systolic ejection murmur over the pulmonary area that is louder during inspiration.

Increased hemodynamic burdens of pregnancy can precipitate right-sided heart failure or atrial arrhythmias in women with severe stenosis (see Table 44-7). Siu and Colman (2001) recommend consideration for surgical correction before or during pregnancy if symptoms progress. Drenthen and co-workers (2006a) studied outcomes of 81 pregnancies in 51 Dutch women with pulmonary stenosis. Cardiac complications were infrequent. However, NYHA classification worsened in two women, and nine experienced palpitations or arrhythmias. No changes in pulmonary valvular function or other adverse cardiac events were reported. Noncardiac complications were increased—17 percent had preterm delivery; 15 percent, hypertension; and 3.7 percent, thromboembolism. Interestingly, two of the offspring were diagnosed with pulmonary stenosis, and another had complete transposition and anencephaly.

CONGENITAL HEART DISEASE

The incidence of congenital heart disease in the United States is approximately 8 per 1000 liveborn infants. About a third of these have critical disease that requires cardiac catheterization or surgery during the first year of life. Others require surgery in childhood, and it is currently estimated that there are nearly 1 million adults in this country with congenital heart disease (Bashore, 2007). With the decline in rheumatic heart disease, congenital lesions are now responsible for most heart disease during pregnancy (Iserin, 2001). Morbidity depends largely on the individual lesion. Khairy and colleagues (2006) reported 90 pregnancies complicated by maternal congenital heart disease. Almost 20 percent of mothers and 30 percent of neonates experienced complications. Ford and co-workers (2008) reported similar findings in 74 pregnancies in 69 women with a congenital heart lesion. Almost half suffered at least one adverse obstetrical event. Those with abnormal shunts had the most serious complications.

Septal Defects

Atrial Septal Defects

After bicuspid aortic valve, these are the most commonly encountered adult congenital cardiac lesions. Indeed, a fourth of all adults have a patent foremen ovale (Kizer and Devereux, 2005). Most are asymptomatic until the third or fourth decade. The secundum-type defect accounts for 70 percent, and associated mitral valve myxomatous abnormalities with prolapse are common. Most recommend repair if discovered in adulthood. Pregnancy is well tolerated unless pulmonary hypertension has developed, but this is rare because pulmonary artery pressures are usually low (Zuber and associates, 1999). If congestive heart failure or an arrhythmia develops, treatment is given. Bacterial endocarditis prophylaxis has been recommended in certain circumstances with unrepaired defects (see p. 974). Based on their review, Aliaga and associates (2003) concluded that the risk of endocarditis with an atrial septal defect is negligible.

The potential to shunt blood right to left makes possible a *paradoxical embolism*—entry of a venous thrombus through the septal defect and into the systemic circulation. This may result in an embolic stroke (see Chap. 55, p. 1169). Erkut and associates (2006) described a postpartum woman who developed an entrapped thrombus in a patent foramen ovale. In an asymptomatic woman, prophylaxis against thromboembolism is problematic, and recommendations for a septal defect alone are either observation or antiplatelet therapy (Kizer and Devereux, 2005). Compression stockings and prophylactic heparin in the pregnant woman with a septal defect in the presence of immobility or other risk factors for thromboembolism has been recommended (Head and Thorne, 2005).

Ventricular Septal Defects

These defects close spontaneously during childhood in 90 percent of cases. Most defects are paramembranous, and physiological derangements are related to the size of the defect. In general, if the defect is less than 1.25 cm^2, pulmonary hypertension and heart failure do not develop. When the effective size of the defect exceeds that of the aortic valve orifice, symptoms rapidly develop. For these reasons, most children undergo surgical

repair before pulmonary hypertension develops. Adults with unrepaired large defects develop left ventricular failure and pulmonary hypertension, as well as a high incidence of bacterial endocarditis (Brickner and colleagues, 2000).

Pregnancy is well tolerated with small to moderate left-to-right shunts. When pulmonary arterial pressures reach systemic levels, however, there is reversal or bidirectional flow—*Eisenmenger syndrome* (see p. 970). When this develops, the maternal mortality rate is 30 to 50 percent. Thus, pregnancy is not generally advisable. Bacterial endocarditis is more common with unrepaired defects, and antimicrobial prophylaxis is often required (see p. 974). About 10 to 15 percent of offspring born to these women also have a ventricular septal defect (see Table 44-4).

Atrioventricular Septal Defect

These account for approximately 3 percent of all congenital cardiac malformations and are distinct from isolated atrial or ventricular septal defects. An atrioventricular (AV) septal defect is characterized by a common, ovoid-shaped AV junction. Although this defect is associated with aneuploidy, Eisenmenger syndrome, and other malformations, some of these women become pregnant. Compared with simple septal defects, complications are more frequent during pregnancy. Drenthen and associates (2005b) reviewed outcomes in 48 pregnancies of 29 such women. Complications included persistent deterioration of NYHA class in 23 percent, significant arrhythmias in 19 percent, and heart failure in 2 percent. Congenital heart disease was identified in 15 percent of the offspring.

Persistent Ductus Arteriosus

Physiological consequences of this lesion are related to its size, as is the case for other shunts. Most significant lesions are repaired in childhood, but for individuals who do not undergo repair, the mortality rate is high after the fifth decade (Brickner and colleagues, 2000). With an unrepaired persistent ductus, some women develop pulmonary hypertension, heart failure, or cyanosis if systemic blood pressure falls with reversal of blood flow from the pulmonary artery into the aorta. A sudden blood pressure decrease at delivery—such as with conduction analgesia or hemorrhage—may lead to fatal collapse. Therefore, hypotension should be avoided whenever possible and treated vigorously if it develops. Prophylaxis for bacterial endocarditis may be indicated at delivery for unrepaired defects (see p. 974). The incidence of inheritance is approximately 4 percent (see Table 44-4).

Cyanotic Heart Disease

When congenital heart lesions are associated with right-to-left shunting of blood past the pulmonary capillary bed, cyanosis develops. The classical and most commonly encountered lesion in pregnancy is the *Fallot tetralogy*. This is characterized by a large ventricular septal defect, pulmonary stenosis, right ventricular hypertrophy, and an overriding aorta that receives blood from both the right and left ventricles. The magnitude of the shunt varies inversely with systemic vascular resistance. Hence, during pregnancy, when peripheral resistance decreases, the shunt increases and cyanosis worsens. Women who have undergone repair, and in whom cyanosis did not reappear, do well in pregnancy.

Some women with *Ebstein anomaly* of the tricuspid valve may reach reproductive age. Right ventricular failure from volume overload and appearance or worsening of cyanosis are common during pregnancy. In the absence of cyanosis, these women usually tolerate pregnancy well.

Effects on Pregnancy

Women with cyanotic heart disease generally do poorly during pregnancy. With uncorrected Fallot tetralogy, for example, maternal mortality rates approach 10 percent. Moreover, any disease complicated by severe maternal hypoxemia is likely to lead to miscarriage, preterm delivery, or fetal death. There is a relationship between chronic hypoxemia, polycythemia, and pregnancy outcome. When hypoxemia is intense enough to stimulate a rise in hematocrit above 65 percent, pregnancy wastage is virtually 100 percent.

Pregnancy after Surgical Repair

With satisfactory surgical correction before pregnancy, maternal and fetal outcomes are much improved. Gelson (2008) and Singh (1982) and their associates described 66 pregnancies in 43 women with surgically corrected tetralogy. Pregnancy was usually well tolerated in those with no major residual defects. Similarly, Meijer and co-workers (2005) reported generally good perinatal outcomes, however, six of 50 pregnancies were complicated by symptomatic right-sided heart failure or arrhythmias, or both. Two women with heart failure had severe pulmonary regurgitation. For those with a pulmonary valve replacement, Oosterhof and co-workers (2006) reported that pregnancy did not adversely affect graft function.

Pregnancy following surgical correction of *transposition of the great vessels* also has risks. Canobbio and colleagues (2006) and Drenthen and co-workers (2005a) described the outcomes of 119 pregnancies in 68 women—90 percent had a *Mustard procedure* and 10 percent a *Senning procedure*. A fourth had arrhythmias, and 12 percent developed heart failure—one of these subsequently required cardiac transplantation. One woman died suddenly a month after delivery, and another died 4 years later. A third of the newborns were delivered preterm, but no infant had heart disease.

Successful—although eventful—pregnancies in women with previously repaired *truncus arteriosus* and *double-outlet right ventricle* have been described by Hoendermis and colleagues (2008) and Drenthen and associates (2008), respectfully. Hoare and Radford (2001) described four pregnancies in three women who had previously undergone a *Fontan repair* for a congenital *single functional ventricle*. There were no maternal deaths, but complications were frequent. All were delivered preterm, two had supraventricular arrhythmias, and two developed ventricular failure. In a comprehensive review, Drenthen and co-workers (2006b) also found no reports of maternal mortality, but they described similarly high complication rates.

Labor and Delivery

Vaginal delivery is preferred. Pulmonary artery catheter monitoring has limitations because of the sometimes bizarre anatomical abnormalities. Care must be taken to avoid sudden hypotension. For labor pain, epidural opiates may suffice. There is controversy regarding epidural analgesia versus general anesthesia for cesarean delivery in these women (Camann and Thornhill, 1999).

Eisenmenger Syndrome

This is secondary pulmonary hypertension that develops from any cardiac lesion. The syndrome develops when pulmonary vascular resistance exceeds systemic resistance, with concomitant right-to-left shunting. The most common underlying defects are atrial or ventricular septal defects and persistent ductus arteriosus. Patients are asymptomatic for years, but eventually pulmonary hypertension becomes severe enough to cause right-to-left shunting. After it develops, survival is 20 to 30 years (Makaryus and associates, 2006).

The prognosis for pregnancy depends on the severity of pulmonary hypertension. In a review of 44 cases through 1978, Gleicher and associates (1979) reported maternal and perinatal mortality rates to approximate 50 percent. In a later review of 73 pregnancies, Weiss and co-workers (1998) cited a 36-percent maternal death rate. Only three of the 26 deaths were antepartum, and the remainder died intrapartum or within a month of delivery. Women with Eisenmenger syndrome tolerate hypotension poorly, and the cause of death usually is right ventricular failure with cardiogenic shock. Management is discussed subsequently.

PULMONARY HYPERTENSION

Normal resting mean pulmonary artery pressure is 12 to 16 mm Hg. In the study by Clark and colleagues (1989), pulmonary vascular resistance was approximately 80 dyne/sec/cm^{-5} in late pregnancy—a 34-percent decrease compared with the nonpregnant value of 120 dyne/sec/cm^{-5}. Pulmonary hypertension—*a hemodynamic observation and not a diagnosis*—is defined in nonpregnant individuals as a mean pulmonary pressure >25 mm Hg. Some causes of pulmonary hypertension are shown in Table 44-8. Currently, classification of the World Health Organization is used, and this has been adopted by the American College of Cardiology and the American Heart Association (McLaughlin and co-workers, 2009).

There are important prognostic and therapeutic distinctions between class I pulmonary hypertension and all the other conditions. Class I indicates a *specific disease that affects pulmonary arterioles.* It includes idiopathic or "primary" pulmonary hypertension as well as those cases secondary to a known cause such as connective-tissue disease. Approximately one third of women with scleroderma and 10 percent with systemic lupus erythematosus have pulmonary hypertension (Rich and McLaughlin, 2005). Other causes in young women are sickle-cell disease and thyrotoxicosis (Sheffield and Cunningham, 2004). Moreover, Sigel and colleagues (2007) described a maternal death from plexogenic pulmonary arteriopathy associated with cirrhosis and portal hypertension.

TABLE 44-8. Clinical Classification of Some Causes of Pulmonary Hypertension in Pregnancy

I	Pulmonary arterial hypertension
	Idiopathic—previously "primary" pulmonary hypertension
	Familial—e.g., chromosome 2 gene in TGF superfamily
	Associated with: collagen-vascular disorders, congenital left-to-right cardiac shunts, HIV infection, thyrotoxicosis, sickle hemoglobinopathies, antiphospholipid antibody syndrome, diet drugs, portal hypertension
	Persistent pulmonary hypertension of the newborn
	Other
II	Pulmonary hypertension with left-sided heart disease
	Left-sided atrial or ventricular disease
	Left-sided valvular disease
III	Pulmonary hypertension associated with lung disease
	Chronic obstructive pulmonary disease
	Interstitial lung disease
	Other
IV	Pulmonary hypertension due to chronic thromboembolic disease
V	Miscellaneous

HIV = Human immunodeficiency virus; TGF = transforming growth factor.
Adapted from the World Health Organization classification of pulmonary hypertension reported by Simmoneau and co-workers (2004).

Class II disorders are more commonly encountered in pregnant women. These are secondary to pulmonary *venous* hypertension caused by left-sided atrial, ventricular, or valvular disorders. A typical example is mitral stenosis discussed on page 965. Although cardiac catheterization remains the standard criterion for the measurement of pulmonary artery pressures, noninvasive echocardiography is often used to provide an estimate.

Diagnosis

Symptoms may be vague, and dyspnea with exertion is the most common. With class II disorders, orthopnea and nocturnal dyspnea are usually also present. Angina and syncope occur when right ventricular output is fixed, and they suggest advanced disease. Chest radiography commonly shows enlarged pulmonary hilar arteries and attenuated peripheral markings. It also may disclose parenchymal causes of hypertension. Diagnosis is by echocardiography and is confirmed by right-sided catheterization, which usually may be deferred during pregnancy. In their review of 33 pregnant women who underwent both echocardiography and cardiac catheterization, Penning and colleagues

(2001) cautioned that pulmonary artery pressures were significantly overestimated by echocardiography in a third of cases.

Prognosis

Longevity depends on the cause and severity at discovery. For example, although invariably fatal, idiopathic pulmonary hypertension has a 3-year survival rate of 60 percent, whereas for collagen-vascular diseases, this rate is only 35 percent (McLaughlin and colleagues, 2004). Some disorders respond to pulmonary vasodilators, calcium-channel blockers, prostacyclin analogs, or endothelin-receptor blockers, all which may improve quality of life. The prostacyclin analogs, epoprostenol and trepostinil, significantly lower pulmonary vascular resistance but must be given parenterally (Humbert and colleagues, 2004; Roeleveld and co-workers, 2004). Preconceptional counseling is imperative as emphasized by Easterling and associates (1999).

Pulmonary Hypertension and Pregnancy

Maternal mortality is appreciable, especially with idiopathic pulmonary hypertension. In the past, there were usually poor distinctions between causes and severity of hypertension. The most severe cases—usually idiopathic—had the worst prognosis, and it was erroneously assumed that all types of pulmonary hypertension were equally dangerous. With widespread use of echocardiography, the less-severe better-prognosis lesions were identified. Kiss and colleagues (1995) reported maternal mortality in seven of 11 women—65 percent—with primary disease. Weiss and associates (1998) reviewed 27 cases of assorted causes reported from 1978 through 1996 and found a 30-percent mortality rate. After their recent review, Bedard and co-workers (2009) reported that mortality statistics improved during the decade ending in 2007 compared with those for the decade ending 1996—it was 25 vs 38 percent, respectively. Importantly, almost 80 percent of the deaths were during the first month postpartum.

Pregnancy is contraindicated with severe disease, especially those with pulmonary arterial changes—most class I. With milder degrees of other causes—class II being common—the prognosis is much better. For example, with the more common use of echocardiography and pulmonary artery catheterization in young women with heart disease, we have identified women with mild to moderate pulmonary hypertension who tolerate pregnancy, labor, and delivery well. Sheffield and Cunningham (2004) described pulmonary hypertension that develops with thyrotoxicosis but is reversible with its treatment (see Chap. 53, p. 1128). Boggess and colleagues (1995) described nine women with interstitial and restrictive lung disease with varying degrees of pulmonary hypertension, and all tolerated pregnancy reasonably well.

Treatment of symptomatic pregnant women includes limitation of activity and avoidance of the supine position in late pregnancy. Diuretics, supplemental oxygen, and vasodilator drugs are standard therapy for symptoms. In addition, there are several reports describing the successful use of direct pulmonary artery vasodilators such as epoprostenol (prostacyclin) in both singleton and twin gestations (Badalian, 2000; Easterling, 1999; Nahapetian, 2008, and all their associates).

Management of labor and delivery is particularly problematic. These women are at greatest risk when there is diminished venous return and right ventricular filling, which is associated with most maternal deaths. To avoid hypotension, careful attention is given to epidural analgesia induction and to preventing blood loss at delivery. Pollack and colleagues (1990), as well as others, have reported successful labor analgesia without significant cardiovascular effects from morphine administered intrathecally. Parneix and co-workers (2009) describe low-dose spinal-epidural analgesia for cesarean delivery. Lam and colleagues (2001) have described intubation and inhaled nitric oxide during labor and forceps delivery of a nullipara with severe primary pulmonary hypertension. Weiss and co-workers (2000) described a woman with severe primary pulmonary hypertension who had a successful cesarean delivery with epidural analgesia and inhalation of 20 mg of aerosolized iloprost, a prostacyclin analog. Successful intrapartum use of inhaled epoprostenol has also been described (Bildirici and Shumway, 2004).

OTHER CARDIOVASCULAR CONDITIONS

Mitral Valve Prolapse

This diagnosis implies the presence of a pathological connective tissue disorder—often termed *myxomatous degeneration*—which may involve the valve leaflets themselves, the annulus, or the chordae tendineae. Mitral insufficiency may develop. Most women with mitral valve prolapse are asymptomatic and are diagnosed by routine examination or while undergoing echocardiography. The small percentage of women with symptoms have anxiety, palpitations, atypical chest pain, and syncope. Those with redundant or thickened mitral valve leaflets are at increased risk for sudden death, infective endocarditis, or cerebral embolism (Braunwald, 2005). Looking at this another way, of 213 young women with documented ischemic strokes, only 1.9 percent had mitral valve prolapse compared with 2.7 percent of controls (Gilon and co-workers, 1999).

Effects on Pregnancy

Pregnant women with mitral valve prolapse rarely have cardiac complications. In fact, pregnancy-induced hypervolemia may improve alignment of the mitral valve (Rayburn and colleagues, 1987). Women without evidence of pathological myxomatous change may in general expect excellent pregnancy outcome (Chia and associates, 1994; Leśniak-Sobelga and co-workers, 2004). For women who are symptomatic, β-blocking drugs are given to decrease sympathetic tone, relieve chest pain and palpitations, and reduce the risk of life-threatening arrhythmias. Mitral valve prolapse with regurgitation or valvular damage is considered to be a moderate risk for bacterial endocarditis (see p. 974).

Peripartum Cardiomyopathy

Currently, this disorder is a diagnosis of exclusion following a contemporaneous cardiac evaluation of peripartum heart failure. In most aspects, it is similar to idiopathic dilated cardiomyopathy encountered in nonpregnant adults. Although the term peripartum cardiomyopathy has been used widely, there is very little evidence to support a unique pregnancy-induced

cardiomyopathy. In 1997, the National Heart, Lung, and Blood Institute and the Office of Rare Diseases convened a workshop that established the following diagnostic criteria (Pearson and associates, 2000):

1. Development of cardiac failure in the last month of pregnancy or within 5 months after delivery,
2. Absence of an identifiable cause for the cardiac failure,
3. Absence of recognizable heart disease prior to the last month of pregnancy, and
4. Left ventricular systolic dysfunction demonstrated by classic echocardiographic criteria such as depressed shortening fraction or ejection fraction.

Although the workshop panel concluded that the disease is acute, rather than a preexisting one preceding pregnancy, at least three reports do not support idiopathic pregnancy-induced cardiomyopathy. Cunningham and associates (1986) carefully evaluated 28 women at Parkland Hospital with peripartum heart failure of obscure etiology who were initially thought to have idiopathic peripartum cardiomyopathy. In 21 of these, heart failure was found to be caused by hypertensive heart disease, clinically silent mitral stenosis, obesity, or viral myocarditis. Particularly important were the silent cardiomyopathic effects that even intermediate-duration chronic hypertension may have on ventricular function.

Felker and colleagues (2000) performed endomyocardial biopsies in 1230 nonpregnant patients who had unexplained cardiomyopathy. In half of these, a cause for cardiomyopathy was found—the most common was myocarditis. And in the subset of 51 women with peripartum cardiomyopathy, 26 had histological evidence for myocarditis. Bültmann and co-workers (2005) studied endomyocardial biopsy specimens from 26 women with peripartum cardiomyopathy and reported that 16—over half—had histological evidence of "borderline myocarditis." Half of these 16 also had viral genomic material for parvovirus B19, human herpesvirus 6, Epstein-Barr virus, and human cytomegalovirus. The researchers attributed these findings to reactivation of latent viral infection that triggered an autoimmune response.

Chronic hypertension with superimposed preeclampsia is likely the most common cause of heart failure during pregnancy (see Chap. 45, p. 987). In some cases, mild antecedent hypertension is undiagnosed, and when superimposed preeclampsia develops, it may cause otherwise inexplicable peripartum heart failure. As discussed throughout Chapter 43, obesity is a common cofactor with chronic hypertension, and it can cause or contribute to underlying ventricular hypertrophy. In the Framingham Heart Study, obesity alone was associated with a doubling of the risk of heart failure in nonpregnant individuals (Kenchaiah and colleagues, 2002). Dilated cardiomyopathy is also found in human immunodeficiency virus (HIV) infection (Barbaro and associates, 1998).

Regardless of the underlying condition that causes cardiac dysfunction, women who develop peripartum heart failure often have obstetrical complications that either contribute to or precipitate heart failure. For example, preeclampsia is common and may precipitate afterload failure. Acute anemia from blood loss magnifies the physiological effects of compromised ventricular function. Similarly, infection and accompanying fever increase cardiac output and oxygen utilization.

It seems probable that specific human pregnancy-related cardiomyopathies are yet undiscovered. For example, Hilfiker-Kleiner and associates (2007) recently described mice that developed peripartum cardiomyopathy associated with a cardiomyocyte-specific deletion of the *stat 3* gene. Ultimately, a biologically active prolactin derivative serves to mediate development of the cardiomyopathy.

Idiopathic Cardiomyopathy in Pregnancy

After exclusion of an underlying cause for heart failure, the default diagnosis is idiopathic or peripartum cardiomyopathy. Thus, its incidence is highly dependent upon the diligence of the search for a cause. Because of this, the cited incidence varies from 1 in 1500 to 1 in 15,000 pregnancies. In a review of the National Hospital Discharge Survey database, Mielniczuk and co-workers (2006) screened 3.6 million discharges of all patients from 1990 to 2002. Those coded with diagnoses consistent with peripartum cardiomyopathy had an incidence of 1 in 3200. Unfortunately, this figure ignores overdiagnosis, which is common in our experiences. Specifically, after careful evaluation of women with peripartum heart failure at Parkland Hospital, we identified idiopathic cardiomyopathy in approximately 1 in 15,000 deliveries—an incidence similar to that of idiopathic cardiomyopathy in young nonpregnant women (Cunningham and colleagues, 1986).

Women with cardiomyopathy present with signs and symptoms of congestive heart failure. Dyspnea is universal, and other symptoms include orthopnea, cough, palpitations, and chest pain (Sheffield and Cunningham, 1999). The hallmark finding usually is impressive cardiomegaly (**Fig. 44-3**). Echocardiographic findings include an ejection fraction less than 45 percent or a fractional shortening less than 30 percent, or both, and an end-diastolic dimension greater than 2.7 cm/m^2 (Hibbard and colleagues, 1999).

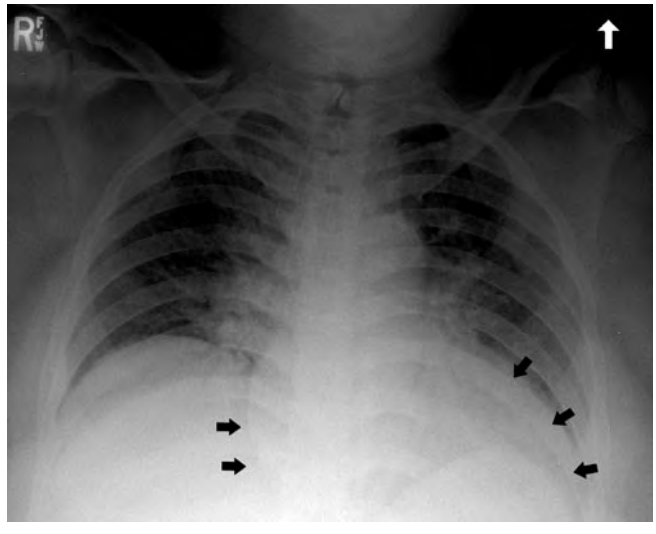

FIGURE 44-3 Cardiomyopathy with mild pulmonary edema. Anterior-posterior projection chest radiograph of a woman with an abnormally enlarged heart (*black arrows*) and mild perihilar opacification consistent with dilated cardiomyopathy.

Management. Therapy consists of treatment for heart failure (Ro and Frishman, 2006). Diuretics are given to reduce preload, and afterload reduction is accomplished with hydralazine or another vasodilator. Because of marked fetal effects, angiotensin-converting enzyme inhibitors are withheld until the woman is delivered (see Chap. 14, p. 319). Digoxin is given for its inotropic effects unless complex arrhythmias are identified. Because there is a high incidence of associated thromboembolism, prophylactic heparin is often recommended. Smith and Gillham (2009) reported that extracorporeal membranous oxygenation was lifesaving in a woman with fulminating cardiomyopathy.

Acute mortality rate varies, depending again on the accuracy of the diagnosis. In the database survey by Mielniczuk and associates (2006), the immediate mortality rate was approximately 2 percent.

Long-Term Prognosis

The distinction between peripartum heart failure from an identifiable cause versus idiopathic cardiomyopathy is of primary importance. In a follow-up study from the Albert Schweitzer Hospital in Haiti, Fett and co-workers (2009) performed echocardiography every 6 months in 116 women with peripartum cardiomyopathy. Using a left ventricular ejection fraction >.50 as recovery, only 28 percent of these women recovered, and three fourths took more than 12 months to attain this level of function. These data indicate that long-term mortality rates are significant. As shown in **Figure 44-4**, the 5- and 10-year survival rates are substantially lower in nonpregnant patients with idiopathic cardiomyopathy. That said, these mortality statistics are optimistic compared with other reports. There seems to be no doubt that women with peripartum cardiomyopathy who regain ventricular function within 6 months have a good prognosis (Lampert and associates, 1997). But those who do not, however, have high morbidity and mortality rates. With a mean follow-up of 39 months, de Souza and colleagues (2001b) reported that eight of 44 such women—18 percent—had died from end-stage heart failure. Of the others, two women had a nonfatal pulmonary embolism, one had a cerebral ischemic stroke, and another underwent heart transplantation at 14 months. Of eight women with NYHA class IV heart failure, only five improved to class I or II, and two to class III.

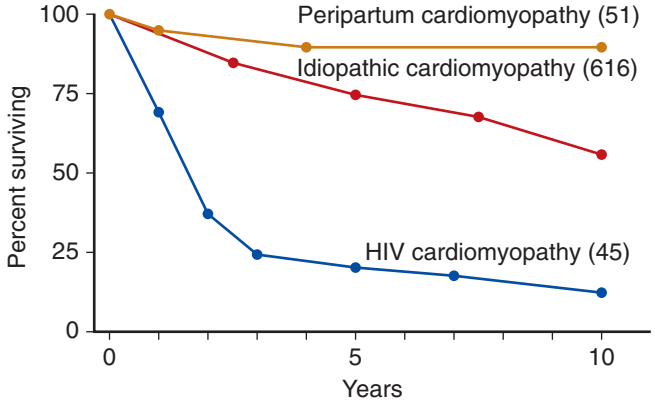

FIGURE 44-4 Survival according to underlying cause of cardiomyopathy. (HIV = human immunodeficiency virus.)(Data from Felker and colleagues, 2000.)

Elkayam and co-workers (2001) reported similar long-term outcomes obtained by a survey of members of the American College of Cardiology. There were 60 subsequent pregnancies in 44 women who had peripartum cardiomyopathy. In 28 of 44 women—63 percent—in whom left ventricular function had returned to normal, 20 percent developed heart failure during pregnancy, but none died. In the remaining 16 with persistent left ventricular dysfunction, 44 percent developed heart failure, and three women died between 2 and 24 months postpartum. Thus, although a return to normal ventricular function does not guarantee a problem-free pregnancy, these studies certainly indicate that another pregnancy is undertaken with reservations in women with an ejection fraction persistently less than 50 percent.

Hypertrophic Cardiomyopathy

Concentric left ventricular hypertrophy may be familial, and there also is a sporadic form not related to hypertension, termed *idiopathic hypertrophic subaortic stenosis.* Epidemiological studies suggest that the disorder is common, affecting approximately 1 in 500 adults (Maron, 2004). The condition—characterized by cardiac hypertrophy, myocyte disarray, and interstitial fibrosis—is caused by mutations in any one of more than a dozen genes that encode proteins of the cardiac sarcomere. Inheritance is autosomal dominant, and genetic screening is complex and not currently clinically available (Osio and associates, 2007; Spirito and Autore, 2006). The abnormality is in the myocardial muscle, and it is characterized by left ventricular myocardial hypertrophy with a pressure gradient to left ventricular outflow (Wynne and Braunwald, 2008). Diagnosis is established by echocardiographic identification of a hypertrophied and nondilated left ventricle in the absence of other cardiovascular conditions.

Most affected women are asymptomatic, but dyspnea, anginal or atypical chest pain, syncope, and arrhythmias may develop. Complex arrhythmias may progress to sudden death, which is the most common form of death. Asymptomatic patients with runs of ventricular tachycardia are especially prone to sudden death. Symptoms are usually worsened by exercise. Nishimura and Holmes (2004) have provided an excellent review.

Pregnancy

Although limited reports suggest that pregnancy is well tolerated, congestive heart failure is common (Benitez, 1996). Thaman and co-workers (2003) reviewed 271 pregnancies in 127 affected women. Although there were no maternal deaths, more than 25 percent experienced at least one adverse cardiac symptom, including dyspnea, chest pain, or palpitations.

Management is similar to that for aortic stenosis. Strenuous exercise is prohibited during pregnancy. Abrupt positional changes are avoided to prevent reflex vasodilation and decreased preload. Likewise, drugs that evoke diuresis or diminish vascular resistance are generally not used. If symptoms develop, especially angina, β-adrenergic or calcium-channel blocking drugs are given. The route of delivery is determined by obstetrical indications. Spinal analgesia is contraindicated, and even carefully administered epidural analgesia is controversial (Camann and

Thornhill, 1999). Endocarditis prophylaxis is given if bacteremia is suspected. Infants rarely demonstrate inherited lesions at birth.

Infective Endocarditis

This infection involves cardiac endothelium and produces vegetations that usually deposit on a valve. Infective endocarditis can involve a native or a prosthetic valve, and it may be associated with intravenous drug abuse. Children and adults who have had corrective surgery for congenital heart disease are at greatest risk (Morris and co-workers, 1998). Approximately half of affected adults have a known preexisting heart lesion (Hoen and colleagues, 2002).

Subacute bacterial endocarditis usually is due to a low-virulence bacterial infection superimposed on an underlying structural lesion. These are usually native valve infections. Organisms that cause indolent endocarditis are most commonly viridans-group streptococci or *Enterococcus* species. Historically, *acute endocarditis* was usually caused by coagulase-positive staphylococci. Two large and more recent epidemiological studies, however, indicate that the most common causative organisms are streptococci—especially viridans—followed by *Staphylococcus aureus* and *Enterococcus* species (Hasbun and associates, 2003; Hoen and colleagues, 2002). Among intravenous drug abusers, *S. aureus* is the predominant organism. *Staphylococcus epidermidis* commonly causes prosthetic valve infections. *Streptococcus pneumoniae* and *Neisseria gonorrhoeae* may occasionally cause acute, fulminating disease (Bataskov and colleagues, 1991). Antepartum endocarditis has been described with *Neisseria sicca* and *Neisseria mucosa*, the latter causing maternal death (Cox and associates, 1988; Deger and Ludmir, 1992). Only a few cases of group B streptococcal endocarditis have been described (Kangavari and co-workers, 2000). Kulaš and Habek (2006) reported a case of endocarditis due to *Escherichia coli* following cesarean delivery in an otherwise healthy young woman.

Diagnosis

Symptoms of endocarditis are variable and often develop insidiously. Fever is virtually universal, and a murmur ultimately is heard in 80 to 85 percent of cases (Karchmer, 2005). Anorexia, fatigue, and other constitutional symptoms are common, and the illness is frequently described as "flulike." Other findings are anemia, proteinuria, and manifestations of embolic lesions, including petechiae, focal neurological manifestations, chest or abdominal pain, and ischemia in an extremity. In some cases, heart failure develops. Symptoms may persist for several weeks before the diagnosis is found, and a high index of suspicion is necessary. Diagnosis is made using the *Duke criteria,* which include positive blood cultures for typical organisms and evidence of endocardial involvement (Karchmer, 2005). Echocardiography is useful, but lesions less than 2 mm in diameter or those on the tricuspid valve may be missed. A negative echocardiographic study does not exclude endocarditis.

Management

Treatment is primarily medical with appropriate timing of surgical intervention if necessary. Knowledge of the infecting organism is imperative for sensible antimicrobial selection. Most viridans streptococci are sensitive to penicillin G given intravenously with gentamicin for 2 weeks (Karchmer, 2005). Complicated infections are treated longer, and women allergic to penicillin are either desensitized or given intravenous ceftriaxone or vancomycin for 4 weeks. Staphylococci, enterococci, and other organisms are treated according to microbial sensitivity for 4 to 6 weeks (Darouiche, 2004). Prosthetic valve infections are treated for 6 to 8 weeks. Persistent native valve infection may require replacement, and this is even more commonly indicated with an infected prosthetic valve. Right-sided infections caused by *methicillin-resistant S. aureus (MRSA)* are treated with vancomycin (see Chap. 58, p. 1223). Fowler and colleagues (2006) have presented promising findings for treatment of MRSA endocarditis with *daptomycin*—a cyclic lipopeptide.

Endocarditis in Pregnancy

Infective endocarditis is uncommon during pregnancy and the puerperium. During a 7-year period, the incidence of endocarditis at Parkland Hospital was approximately 1 in 16,000 deliveries (Cox and associates, 1988). Two of seven women died. Treatment is the same as that described earlier. From their reviews, Seaworth and Durack (1986) and Cox and Leveno (1989) cited a maternal mortality rate of 25 to 35 percent.

Antimicrobial Prophylaxis

The efficacy of antimicrobial prophylaxis to prevent bacterial endocarditis is questionable. Only 13 percent of cases arising in patients with high-risk cardiac lesions do so after a procedure (Van der Meer and associates, 1992). The American Heart Association recommends prophylaxis based on risk stratification (**Table 44-9**). These recommendations have

TABLE 44-9. American Heart Association Guidelines for Endocarditis Prophylaxis with Dental Procedures

Prophylaxis is recommended for all dental procedures that involve manipulation of gingival tissue or the periapical tooth region or perforation of oral mucosa in patients with any of the following cardiac conditions:

(1) Prosthetic heart valve or prosthetic material used for valve repair
(2) Previous infective endocarditis
(3) Certain forms of congenital heart lesions:
- Unrepaired cardiac lesions causing cyanotic heart disease, including palliative shunts and conduits
- Repaired defect with prosthetic material or device—placed surgically or by catheter—for 6 months following repair procedure and before endothelialization
- Repaired defect with residual defects at or adjacent to the site of a prosthetic part or device that inhibit endothelialization

From Wilson and colleagues, 2007.

been endorsed by the American College of Obstetricians and Gynecologists (2003).

Obstetrical Procedures. The current recommendations of the American College of Cardiology and the American Heart Association are shown in Table 44-9. These guidelines suggest that prophylaxis for bacterial endocarditis be administered intrapartum to women at risk only in the presence of suspected bacteremia or active infection. They estimate that the incidence of transient bacteremia at delivery is 1 to 5 percent. Antimicrobial prophylaxis is considered optional for women undergoing an uncomplicated delivery who are at high risk for endocarditis (American College of Obstetricians and Gynecologists, 2003). Prophylaxis is overused, likely because of previously liberal recommendations. In a study from one busy institution, Pocock and Chen (2006) reported that only six of 50 women who received antibiotics for endocarditis prophylaxis had an appropriate indication.

Only a few regimens are recommended by the American College of Obstetricians and Gynecologists (2008) for prophylaxis, which is given preferably 30 to 60 minutes before the procedure. Either ampicillin, 2 g, or cefazolin or ceftriaxone, 1 g, is given intravenously. For penicillin-sensitive patients, one of the latter regimens is given, or if there is a history of anaphylaxis, then clindamycin, 600 mg is given intravenously. The recommended oral regimen is 2 g of amoxicillin. If enterococcus infection is of concern, vancomycin is also given.

Arrhythmias

Both new and preexisting cardiac arrhythmias are commonly encountered during pregnancy, labor, delivery, and the puerperium (Gowda and associates, 2003). In a study of 73 women with a history of prepregnant supraventricular tachycardia, paroxysmal atrial flutter or fibrillation, or ventricular tachycardia, Silversides and associates (2006) observed recurrence rates of 50, 52, and 27 percent, respectively. The mechanism(s) responsible for the increased incidence of arrhythmias during pregnancy is not well elucidated. According to Eghbali and associates (2006), adaptive electric cardiac remodeling of K^+-channel genes may be key. Perhaps the normal but mild hypokalemia of pregnancy and/or the physiological increase in heart rate serve to induce arrhythmias (see Chap. 5, p. 118). Alternatively, their detection may be increased because of more frequent visits during prenatal care.

Bradyarrhythmias, including complete heart block, are compatible with a successful pregnancy outcome. Some women with complete heart block have syncope during labor and delivery, and occasionally temporary cardiac pacing is necessary (Hidaka and colleagues, 2006). In our experiences, as well as those of Jaffe and associates (1987), women with permanent artificial pacemakers usually tolerate pregnancy well. With fixed-rate devices, cardiac output apparently is increased by augmented stroke volume.

Tachyarrhythmias are relatively common and should prompt consideration of underlying cardiac disease. *Paroxysmal supraventricular tachycardia* is encountered most frequently. Siu and associates (1997) followed 25 women who had supraventricular tachycardia diagnosed before pregnancy. Half of these women had *Wolff-Parkinson-White (WPW) syndrome.* Three of 12 women with WPW syndrome and six of 13 without the condition had supraventricular tachycardia during pregnancy. If vagal maneuvers do not stimulate conversion, treatment consists of adenosine followed by calcium-channel or β-blocking drugs (Delacrétez, 2006). Our experiences are similar to those of others that adenosine is safe and effective for cardioversion in hemodynamically stable pregnant women (Chakhtoura and coworkers, 1998; Robins and Lyons, 2004). Although these drugs do not appear to harm the fetus, fetal bradycardia with adenosine has been described (Dunn and Brost, 2000).

Electrical cardioversion is not contraindicated in pregnancy, but vigilance is important. Barnes and associates (2002) described a case in which direct current cardioversion led directly to a sustained uterine contraction and fetal bradycardia. In some patients, accessory pathway ablation may be indicated (Pappone and colleagues, 2003). The typical fluoroscopic procedure-related fetal radiation dose is less than 1 cGy (Damilakis and associates, 2001).

Atrial flutter or fibrillation are more likely associated with underlying disease, such as thyrotoxicosis or mitral stenosis. Major complications include stroke (Ezekowitz and Levine, 1999). Thus, heparin is recommended by some if fibrillation is chronic and persists during pregnancy, especially if there is mitral stenosis (O'Gara and Braunwald, 2008). If atrial fibrillation is associated with mitral stenosis, pulmonary edema may develop in late pregnancy if the ventricular rate is increased.

Ventricular tachycardia is uncommon in healthy young women without underlying heart disease. Brodsky and associates (1992) described seven pregnant women with new-onset ventricular tachycardia and reviewed 23 reports. Most of these women were not found to have structural heart disease—in 14 tachycardia was precipitated by physical exercise or psychological stress. Abnormalities found included two cases of myocardial infarction, two of prolonged QT interval, and anesthesia-provoked tachycardia in another. They concluded that pregnancy events precipitated tachycardia and recommended β-blocker therapy for control. Occasionally *arrhythmogenic right ventricular dysplasia* will result in ventricular tachyarrhythmias (Lee and co-workers, 2006). For pregnant women requiring defibrillation for ventricular arrhythmias, Nanson and associates (2001) found that standard adult energy settings were adequate.

QT-interval prolongation may predispose individuals to a potentially fatal ventricular arrhythmia known as *torsades de pointes* (Roden, 2008). Two studies involving a combined total of 502 pregnant women with *long QT syndrome* both reported a significant increase in cardiac events postpartum but not during pregnancy (Rashba and colleagues, 1998; Seth and associates, 2007). They hypothesized that the normal increase in heart rate during pregnancy may be partially protective. Paradoxically, β-blocker therapy has been shown to decrease the risk of torsades de pointes in patients with long QT syndrome and should be continued during pregnancy and postpartum (Gowda and colleagues, 2003; Seth and associates, 2007). Importantly, many medications, including some used during pregnancy such as erythromycin and clarithromycin, may predispose to QT prolongation (Al-Khatib and associates, 2003; Roden, 2004).

DISEASES OF THE AORTA

Aortic Dissection

Marfan syndrome and coarctation are two aortic diseases that place the pregnant woman at increased risk for *aortic dissection.* Half of cases of dissection in young women are related to pregnancy (O'Gara and associates, 2004). Other risk factors are bicuspid aortic valve and Turner or Noonan syndrome. Pepin and colleagues (2000) reported a high rate of aortic dissection or rupture in patients with *Ehlers-Danlos syndrome* (see Chap. 54, p. 1159). Although the mechanism(s) involved is unclear, the initiating event is an aortic intimal tear, and rupture may follow medial hemorrhage.

In most cases, aortic dissection presents with severe chest pain described as ripping, tearing, or stabbing in nature. Diminution or loss of peripheral pulses in conjunction with a recently acquired murmur of aortic insufficiency are important physical findings. The differential diagnosis of aortic dissection includes myocardial infarction, pulmonary embolism, pneumothorax, and aortic valve rupture. Lang and Borow (1991) rightfully add obstetrical catastrophes to the list, especially placental abruption and uterine rupture.

More than 90 percent of affected patients have an abnormal chest radiograph. Aortic angiography is the most definitive method for confirming the diagnosis, however, noninvasive imaging—sonography, computed tomography, and magnetic resonance (MR) imaging—is used more frequently. The urgency of the clinical situation frequently dictates which procedure is best.

Initial medical treatment is given to lower blood pressure. Proximal dissections most often need to be resected, and the aortic valve replaced if necessary. Distal dissections are more complex, and many may be treated medically. Lederle and colleagues (2002) have shown that survival in nonpregnant patients is not improved by elective repair of abdominal aortic aneurysms smaller than 5.5 cm. Lee and associates (2001) described a successful vaginal delivery in a woman with a 4.5-cm thoracic aortic aneurysm.

Marfan Syndrome

This syndrome is usually inherited as an autosomal dominant trait with a high degree of penetrance. The incidence is 2 to 3 per 10,000 individuals and is without racial or ethnic predilection (Ammash and associates, 2008). Prenatal diagnosis is usually possible using linkage analysis (see Chap. 12, p. 283). The syndrome is caused by abnormal *fibrillin*—a constituent of elastin—caused by any of dozens of mutations in the *FBN1* gene located on chromosome 15q21 (Biggin and co-workers, 2004). Thus, Marfan syndrome is a connective-tissue disorder characterized by generalized weakness that can result in dangerous cardiovascular complications. Because all tissues are involved, other defects are frequent and include joint laxity and scoliosis. Progressive aortic dilatation causes aortic valve insufficiency, and there may be infective endocarditis and mitral valve prolapse with insufficiency. Aortic dilatation and dissecting aneurysm are the most serious abnormalities. Early death is due either to valvular insufficiency and heart failure or to a dissecting aneurysm. Long-term benefits from β-blocker therapy have been described for nonpregnant adults (Shores and colleagues, 1994).

Effect of Pregnancy

In the past, case reports reflected biased outcomes, and the maternal mortality rate was magnified (Elkayam and associates, 1995). In a prospective evaluation of 21 women during 45 pregnancies cared for at the Johns Hopkins Hospital, only two had dissection, and one died postpartum from graft infection (Rossiter and colleagues, 1995). Although there were no maternal deaths among 14 women followed by Rahman and co-workers (2003), two required surgical correction of an aortic aneurysm.

Both latter groups of investigators concluded that aortic dilatation of more than 40 mm or mitral valve dysfunction are high-risk factors for life-threatening cardiovascular complications during pregnancy. Conversely, women with minimal or no dilatation and those with normal cardiac function by echocardiography are counseled regarding the small but serious potential risk of aortic dissection. Elkayam and colleagues (1995) also concluded that pregnancy was safer in women with Marfan syndrome who had no cardiovascular manifestations or aortic arch dilatation. They recommended prophylactic β-blocker therapy during pregnancy.

The aortic root usually measures about 20 mm, and during normal pregnancy it increases slightly (Easterling and colleagues, 1991). If dilatation reaches 40 mm, then dissection is more likely (Simpson and D'Alton, 1997). If it reaches 50 to 60 mm, then elective surgery should be considered before pregnancy (Gott and associates, 1999; Williams and co-workers, 2002). Successful cases of aortic root replacement during pregnancy have been described, but it has also been associated with fetal hypoxic-ischemic cerebral damage (Mul and co-workers, 1998; Seeburger and associates, 2007). And Papatsonis and co-workers (2009) described emergency cesarean delivery at term in a woman with an acute type A dissection that was repaired successfully during the same operation. Although Marfan syndrome itself is not an indication, some recommend cesarean delivery if there is aortic involvement. Otherwise, obstetrical indications for delivery are followed.

Perinatal Outcomes

Obstetrical outcomes of 63 women with Marfan syndrome with a total of 142 pregnancies were reviewed by Meijboom and colleagues (2006). There were 111 delivered after 20 weeks; 15 percent had preterm delivery; and 5 percent, preterm prematurely ruptured membranes. Two infants were stillborn, and there were six neonatal deaths. As expected, half of the survivors were subsequently diagnosed with Marfan syndrome.

Aortic Coarctation

This is a relatively rare lesion often accompanied by abnormalities of other large arteries. A fourth of affected patients have a bicuspid aortic valve, and another 10 percent have cerebral artery aneurysms. Other associated lesions are persistent ductus arteriosus, septal defects, and Turner syndrome. The collateral circulation arising above the coarctation expands, often to a

striking extent, to cause localized erosion of rib margins by hypertrophied intercostal arteries. Typical findings include hypertension in the upper extremities but normal or reduced pressures in the lower extremities. Sherer (2002), Dizon-Townson (1995), Zwiers (2006), and their colleagues have described diagnoses during pregnancy using MR imaging.

Effects on Pregnancy

Major complications are congestive heart failure after long-standing severe hypertension, bacterial endocarditis of the bicuspid aortic valve, and aortic rupture. Maternal mortality rates average 3 percent (McAnulty and co-workers, 1990). Because hypertension may worsen in pregnancy, antihypertensive therapy using β-blocking drugs is usually required. Aortic rupture is more likely late in pregnancy or early postpartum. Cerebral hemorrhage from *circle of Willis aneurysms* may also develop. Beauchesne and associates (2001) described the outcomes of 188 pregnancies from the Mayo Clinic in 50 such women. A third had hypertension that was related to significant coarctation gradients, and one woman died from dissection at 36 weeks.

Congestive heart failure demands vigorous efforts to improve cardiac function and may warrant pregnancy interruption. Some authors have recommended that resection of the coarctation be undertaken during pregnancy to protect against the possibility of a dissecting aneurysm and aortic rupture. This poses significant risk, especially for the fetus, because all the collaterals must be clamped for variable periods of time.

Some authors recommend cesarean delivery to prevent transient blood pressure elevations that might lead to rupture of the aorta or coexisting cerebral aneurysms. Available evidence, however, suggests that cesarean delivery should be limited to obstetrical indications. Intrapartum endocarditis prophylaxis is given if bacteremia is suspected.

ISCHEMIC HEART DISEASE

Mortality from coronary artery disease and *myocardial infarction* is a rare complication of pregnancy. In fact, the overall incidence appears to be declining due to reductions in major risk factors and better medical therapies (Ford and co-workers, 2007). That said, evidence suggests that the incidence in pregnancy may be increasing. In a review of California hospital discharge records between 1991 and 2000, Ladner and co-workers (2005) reported myocardial infarction to complicate 1 in 37,500 deliveries. In a similar review of Canadian hospitals between 1970 and 1998, MacArthur and co-workers (2006) reported the incidence of peripartum myocardial ischemia to be 1.1 per 100,000 deliveries. James and co-workers (2006) used the Nationwide Inpatient Sample database for 2000 to 2002 and reported acute myocardial infarction in 6.2 per 100,000 deliveries. Collectively, these epidemiological studies are consistent with mortality statistics from the United States that indicate that the mortality rate from coronary heart disease among all women aged 35 to 44 years has been increasing by an average of 1.3 percent per year since 1997 (Ford and Capewell, 2007).

Pregnant women with coronary artery disease commonly have classic risk factors such as diabetes, smoking, hypertension, hyperlipidemia, and obesity (James and co-workers, 2006). Bagg and colleagues (1999) reviewed the course of 22 diabetic pregnant women with ischemic heart disease—class H diabetes (see Chap. 52, p. 1105). These authors, as well as Pombar (1995) and Reece (1986) and their colleagues, documented unusually high mortality rates in those who suffered myocardial infarction. Mousa (2000) and Sutaria (2000) and their associates each described coronary artery occlusion in two pregnant smokers with hypercholesterolemia following a routine intramuscular injection of 0.5-mg ergometrine. Schulte-Sasse (2000) described myocardial ischemia associated with prostaglandin E_1 vaginal suppositories for labor induction. Karpati and co-workers (2004) reported that half of 55 otherwise healthy normal women with shock from postpartum hemorrhage developed myocardial ischemia.

Diagnosis during pregnancy is not different from the nonpregnant patient. Measurement of serum levels of the cardiac-specific contractile protein, *troponin I*, is accurate for diagnosis (Shade and associates, 2002). Troponin I was reported by Shivvers and colleagues (1999) to be undetectable across normal pregnancy. Moreover, Koscica and colleagues (2002) found that levels do not increase following either vaginal or cesarean delivery. Finally, Atalay (2005) and Yang (2006) and their associates found that levels of troponin I are higher in preeclamptic women than in normotensive controls.

Pregnancy with Prior Ischemic Heart Disease

The advisability of pregnancy after a myocardial infarction is unclear. Ischemic heart disease is characteristically progressive, and because it is usually associated with hypertension or diabetes, pregnancy in most of these women seems inadvisable. Vinatier and associates (1994) reviewed 30 pregnancies in women who had sustained an *infarction remote from pregnancy.* Although none of these women died, four had congestive heart failure and four had worsening angina during pregnancy. Pombar and coworkers (1995) reviewed outcomes of women with diabetes-associated ischemic heart disease and infarction. Three had undergone coronary artery bypass grafting before pregnancy. Of 17 women, eight died during pregnancy. Certainly, pregnancy increases cardiac workload, and all of these investigators concluded that ventricular performance should be assessed using ventriculography, radionuclide studies, echocardiography, or coronary angiography prior to conception. If there is no significant ventricular dysfunction, pregnancy will likely be tolerated.

For the woman who becomes pregnant before these studies are performed, echocardiography should be done. Exercise tolerance testing may be indicated, and radionuclide ventriculography results in minimal radiation exposure for the fetus (see Chap. 41, p. 920). Zaidi and co-workers (2008) have described the use of serial T2-weighted cardiovascular MR imaging in a woman with suffered a myocardial infarction during the first trimester to better define the extent and severity of infarction.

Myocardial Infarction During Pregnancy

In this setting, most agree that the mortality rate in pregnancy is increased compared with age-matched nonpregnant women.

Hankins and co-workers (1985) reviewed 68 cases and reported an overall maternal mortality rate of approximately 35 percent. Hands and colleagues (1990) found an overall mortality rate of 30 percent. The mortality rate was 40 percent in the third trimester compared with 20 percent before then. Recent studies are more reassuring. In the Nationwide Inpatient Sample study totaling 859 pregnancies complicated by acute infarction during 2000 to 2002, James and associates (2006) cited a 5.1-percent death rate. Women who sustain an infarction less than 2 weeks prior to labor are at especially high risk of death (Esplin and Clark, 1999).

Treatment is similar to that for nonpregnant patients (Roth and Elkayam, 2009). Acute management includes administration of nitroglycerin and morphine with close blood pressure monitoring (Esplin and Clark, 1999). Lidocaine is used to suppress malignant arrhythmias. Calcium-channel blockers or β-blockers are given if indicated. *Tissue plasminogen activator* has been used in pregnant women remote from delivery (Schumacher and associates, 1997). In some women, invasive or surgical procedures may be indicated because of acute or unrelenting disease. Balmain (2007) and Dwyer (2005) and their associates recently reported successful percutaneous transluminal coronary angioplasty and stent placement during pregnancy.

If the infarct has healed sufficiently, cesarean delivery is reserved for obstetrical indications, and epidural analgesia is ideal for labor (Esplin and Clark, 1999). Epidural analgesia or general anesthesia may be used for cesarean delivery (Smith and associates, 2008). Camann and Thornhill (1999) recommend pulmonary artery catheter monitoring if an infarction occurs within 6 months of delivery or if there is ventricular dysfunction. Others, including us, recommend such monitoring only if there is cardiac dysfunction.

CHAPTER 45

Chronic Hypertension

DEFINITIONS 983
DIAGNOSIS 984
TREATMENT FOR NONPREGNANT ADULTS 985
PRECONCEPTIONAL AND EARLY PREGNANCY EVALUATION 985
EFFECTS OF CHRONIC HYPERTENSION ON PREGNANCY 986
MANAGEMENT DURING PREGNANCY 988

Worldwide, it is estimated that hypertension affected 972 million adults in 2000, and it was further predicted this would increase to 1.56 billion by 2025 (Kearney and colleagues, 2005). The prevalence of chronic hypertension in American women has been chronicled since 1960 by the National Center for Health Statistics (1964). The ongoing study—the National Health and Nutrition Examination Survey (NHANES)—still provides periodic information. The average prevalence of hypertension in women 18 to 39 years of age was 7.2 percent for the 1999–2000 biennium (Hajjar and Kotchen, 2003). This is a substantive increase when compared with 6 percent for the previous decade. Importantly, a third of these patients are unaware of their hypertension, and its importance in relation to women's healthcare was highlighted in the Clinical Update by the American College of Obstetricians and Gynecologists (2005).

Chronic hypertension is also one of the most common medical complications encountered during pregnancy. For example, Podymow and August (2007) cite a 3-percent incidence from their review. Its variable incidence and severity, along with the well-known proclivity for pregnancy to induce or aggravate hypertension, has caused confusion concerning its management. Most women with antecedent hypertension demonstrate improved blood-pressure control during pregnancy. In others, however, there is worsening of hypertension that may be accompanied by proteinuria, symptoms, and convulsions. These latter women in whom hypertension antedates pregnancy are indistinguishable from an otherwise normotensive woman who develops preeclampsia in her first pregnancy.

DEFINITIONS

There is a wide range of blood pressures in normal adults as well as in those with chronic hypertension. Categorization therefore relates to acute or long-term adverse effects associated with sustained levels of those blood pressures. These associations with normal or abnormal blood pressures are primarily based on morbidity and mortality in men. A useful categorization is that provided by the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. In its seventh report—JNC-7—the Joint National Committee (2003) used the classification and management scheme summarized in **Table 45-1**. A newly added significant change is the category termed *prehypertension*, which was intended to convey that cardiovascular risk begins to increase at levels of 115 mm Hg systolic and 75 mm Hg diastolic. Within each of these categories shown in Table 45-1, morbidity or mortality rates are further influenced by age, gender, race, and personal behaviors that include smoking, excessive alcohol, obesity, and physical activity.

Proven benefits accrue with treatment of chronic hypertension at sustained diastolic pressures of 90 mm Hg or greater using Korotkoff phase, systolic pressures of 160 mm Hg or more, or both. Benefits are apparent even in otherwise healthy adults. Treatment at even lower levels may benefit patients with evidence of renal or cardiac dysfunction, those who have had a cerebrovascular thrombosis or hemorrhage, elderly patients, or patients with appreciable underlying atherosclerotic disease or

TABLE 45-1. Classification and Management of Blood Pressure for Adults

Blood Pressure			Management[a]		
				Initial Drug Therapy	
Classification	Systolic mm Hg	Diastolic mm Hg	Lifestyle Modification	Without Compelling Indication	With Compelling Indications[b]
Normal	<120	and <80	Encourage	Treatment not indicated	Chronic renal disease or diabetes
Prehypertension	120–139	or 80–90	Yes		
Stage 1 Hypertension	140–159	or 90–99	Yes	Thiazide-type diuretics for most. May consider ACE inhibitor, ARB, β-blocker, CCB, or combination	Chronic renal disease or diabetes Other drugs as needed: diuretics, ACE inhibitors, ARB, β-blocker, CCB
Stage 2 Hypertension	≥160	or ≥100	Yes	Two-drug combination for most[c]: usually thiazide-type diuretic and ACEI, or ARB, or β-blocker, or CCB[c]	

[a]Treatment determined by highest blood pressure category.
[b]Treat patients with chronic kidney disease or diabetes to a goal of blood pressure < 130/80 mm Hg.
[c]Initial combined therapy should be used cautiously in those at risk for orthostatic hypotension.
ACEI = angiotensin-converting enzyme inhibitor; ARB = angiotensin-receptor blocker; CCB = calcium-channel blocker.
From the Joint National Committee (2003).

postmyocardial infarction. The Seventh Joint National Committee report (2003) recommends:

1. In persons older than 50 years, systolic pressures >140 mm Hg are a more important cardiovascular disease risk factor than diastolic pressure
2. Individuals with a systolic blood pressure of 120 to 139 mm Hg, or a diastolic blood pressure of 80 to 89 mm Hg, should be considered as *prehypertensive* and require health-promoting lifestyle modifications to prevent cardiovascular disease
3. Thiazide-type diuretics should be used in drug treatment for most patients with uncomplicated hypertension, either alone or combined with drugs from other classes
4. Most adults with hypertension require two or more medications to achieve a blood pressure less than 140/90 mm Hg or less than 130/80 mm Hg in patients with diabetes or renal disease.

Throughout middle and old age, blood pressure is strongly and directly related to vascular as well as overall mortality rates and with values down to at least 115/75 mm Hg (Prospective Studies Collaboration, 2002; Qureshi and colleagues, 2002).

DIAGNOSIS

Chronic hypertension precedes pregnancy or may be apparent prior to 20 weeks (see Chap. 34, p. 709). Some women without overt chronic hypertension have repeated pregnancies in which *transient hypertension* appears only late in pregnancy and regresses postpartum. It is considered evidence of latent chronic hypertension, and thus it is analogous to gestational diabetes. Long-term follow-up studies of Chesley and co-workers (1976) and Sibai and colleagues (1986b, 1992) support this view.

In most women with hypertension antedating pregnancy, elevated blood pressure is the only demonstrable finding. Some, however, have complications that increase the risks during pregnancy and may shorten life expectancy. These include hypertensive or ischemic cardiac disease, renal insufficiency, or a prior cerebrovascular event. These are encountered more frequently in older women.

Obesity is an important factor predisposing to chronic hypertension (see Chap. 43). Specifically, the prevalence of hypertension may be increased as much as tenfold in obese women, and these women also are more likely to develop superimposed preeclampsia. Diabetes mellitus is also prevalent in chronically

hypertensive women, and its interplay with obesity is overwhelming. Heredity has an important role, and according to the review by Cowley (2006), there are hundreds of blood pressure–related phenotypes and genomic regions that have been identified. In some cases, candidate genes for preeclampsia and chronic hypertension have been described (Levesque and associates, 2004). Hypertension is common in African- and Latino-Americans, and frequently many members of the same family are hypertensive. Wang and colleagues (2006) observed significant ethnic and gender differences in a 15-year longitudinal study of blood pressures in African- and European-American young adults. They reported that the nocturnal blood-pressure decline was blunted and also exacerbated with age in African-American patients.

Chronic hypertension all too frequently remains undetected. Even if detected, therapy is not universal, not always adequate, and not always monitored appropriately. For example, Roumie and colleagues (2006) reported poor blood-pressure control in 65 percent of hypertensive patients. This is worsened by the alarming frequency reported with medication noncompliance (Simpson, 2006).

Pregnancy

In most women with chronic hypertension, blood pressure falls in early pregnancy and then rises during the third trimester to levels somewhat above those in early pregnancy (**Fig. 45-1**). According to studies by Tihtonen and associates (2007), women with chronic hypertension have persistently elevated vascular resistance and possibly reduced intravascular volume increase. There is no doubt that adverse outcomes in these women are dependent largely on whether superimposed preeclampsia develops. This may be related to observations reported by Hibbard and colleagues (2005) that arterial mechanical properties are most marked in women with superimposed preeclampsia.

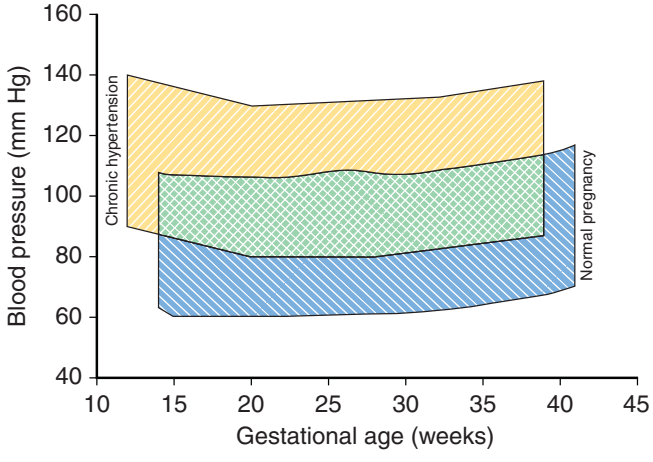

FIGURE 45-1 Mean systolic and diastolic blood pressures across pregnancy in 90 untreated chronically hypertensive women (*yellow*). Compared with mean blood pressures across pregnancy in 4589 healthy nulliparous women (*blue*). (Data from Levine and associates, 1997; Sibai and colleagues, 1990a.)

TREATMENT FOR NONPREGNANT ADULTS

Even with mildly elevated blood pressures shown in Table 45-1, interventions to reduce pressure are beneficial. Almost 30 trials involving nearly 162,000 participants have established that antihypertensive treatment of adults with mild to moderate hypertension will decrease mortality rates, stroke, and major cardiac events (Blood Pressure Lowering Treatment Trialists' Collaboration, 2003; Psaty and colleagues, 2003). Reductions in stroke average approximately 35 percent, myocardial infarction about 25 percent, and heart failure more than 50 percent (Neal and colleagues, 2000). In patients with stage 1 hypertension who have additional cardiovascular risk factors, a sustained 12-mm Hg reduction in systolic pressure will decrease 10-year mortality rates by 10 percent (Ogden and colleagues, 2000).

Most women with stage 1 hypertension would ideally have been prescribed lifestyle modifications and antihypertensive medications (**Table 45-2**). Low-dose diuretics are very effective for first-line treatment. In the ALLHAT Trial (2002) of 33,357 adults 55 years or older, thiazide-type diuretics were superior to and less expensive than angiotensin-converting enzyme (ACE) inhibitors or calcium-channel blockers to prevent cardiovascular disease. These results were similar for women treated in the Second Australian National Blood Pressure Study Group (Wing and associates, 2003). In the CONVINCE Trial reported by Black and colleagues (2003), 16,602 hypertensive adults with one or more risk factors for cardiovascular disease were randomized to verapamil, atenolol, or hydrochlorothiazide. Over a 3-year period, verapamil was the least effective to reduce cardiovascular disease.

In older adults, daily *low-dose aspirin* is recommended for the prevention of myocardial infarction. Hermida and colleagues (2005) reported significant lowering of blood pressure in 328 untreated hypertensive patients given 100 mg of aspirin at bedtime—but not on awakening. Further data are obviously needed. Abbott and Bakris (2004) have provided a useful summary of treatment trials done to study essential hypertension.

From the foregoing, it is clear that antihypertensive therapy in nonpregnant reproductive-aged women with sustained diastolic pressures of 90 mm Hg or greater would be considered standard. In women identified to have chronic hypertension prior to midpregnancy, the benefits and safety of instituting antihypertensive therapy are less clear, as subsequently discussed.

PRECONCEPTIONAL AND EARLY PREGNANCY EVALUATION

Women with chronic hypertension should ideally be counseled prior to pregnancy (see Chap. 7, p. 177). The duration of hypertension, degree of blood-pressure control, and current therapy are ascertained. Women with average pressures greater than 135/85 mm Hg measured at home are considered to be hypertensive. Home measurement devices should be checked for accuracy (American Heart Association, 2004). General health, daily activities, diet, and adverse behaviors are also assessed.

TABLE 45-2. Lifestyle Modifications to Manage Hypertension

Modification[a]	Recommendation	Systolic Blood Pressure Reduction (Range)
Weight reduction	Maintain normal body weight: BMI 18.5–24.9 kg/m^2	5–20 mm Hg/10 kg weight loss
DASH eating plan	Diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat	8–14 mm Hg
Dietary sodium reduction	Reduce dietary sodium intake to no more than 100 mmol per day: 2.4 g sodium or 6 g sodium chloride	2–8 mm Hg
Physical activity	Engage in regular aerobic physical activity such as brisk walking, at least 30 min per day, most days of the week	4–9 mm Hg
Alcohol consumption moderation	Limit consumption to no more than 2 drinks—1-oz or 30-mL ethanol, e.g., 24-oz beer, 10-oz wine, or 3-oz 80-proof whiskey—per day in most men and to no more than 1 drink per day in women and lighter weight persons	2–4 mm Hg

[a]The effects of implementing these modifications are dose and time dependent, and could be greater for some individuals.
BMI = body mass index; DASH = dietary approaches to stop hypertension.
From the Joint National Committee (2003).

Women with prior adverse events such as a cerebrovascular accident or myocardial infarction, as well as cardiac or renal dysfunction, are at markedly increased risk for a recurrence or worsening during pregnancy. Those who require multiple medications for control, or those who are poorly controlled, are also at increased risk for adverse pregnancy outcomes.

Renal and cardiovascular function should be assessed. Ophthalmological evaluation and echocardiography are indicated in women with any prior adverse outcome or in those with long-term hypertension. Gainer and co-workers (2005) found that pregnant women with treated chronic hypertension commonly have underlying heart lesions such as left ventricular hypertrophy determined by echocardiography. Cardiac dysrhythmias or evidence of left ventricular hypertrophy indicate long-standing or poorly controlled hypertension, or both. Women with these conditions are at increased risk for heart failure during pregnancy (see Chap. 42, p. 929).

Renal function is assessed by serum creatinine measurement and quantification of proteinuria. If either is abnormal, there is further increased risk for adverse pregnancy outcomes. The Working Group Report on High Blood Pressure in Pregnancy (2000) of the National Heart, Lung, and Blood Institute concluded that the risks of fetal loss and accelerated deterioration of renal disease are increased if serum creatinine is above 1.4 mg/dL around the time of conception. It can be difficult to separate the effects of the pregnancy from progression of renal disease (Cunningham, 1990; Lindheimer, 2007; Ramin, 2006, and all their associates). Severity of renal insufficiency is proportional to the risk of hypertensive complications during pregnancy, although the relationship is not linear (see Chap. 48, p. 1040). Most clinicians believe that pregnancy is relatively contraindicated in women who maintain persistent diastolic pressures of ≥110 mm Hg despite therapy, require multiple antihypertensives, or have a serum creatinine level of >2 mg/dL. Stronger contraindications are prior cerebrovascular thrombosis or hemorrhage, myocardial infarction, or cardiac failure. Symptoms at rest and with activity should be determined.

Of interest, Poyares and colleagues (2007) recommend use of nasal continuous positive airway pressure (CPAP) at night in women with chronic hypertension and who chronically snore**.** They reported better blood-pressure control and improved pregnancy outcomes with CPAP use.

EFFECTS OF CHRONIC HYPERTENSION ON PREGNANCY

Maternal Morbidity/Mortality

Most women taking monotherapy whose hypertension is well controlled prior to pregnancy do well. That said, even these women are at increased risk for superimposed preeclampsia and placental abruption. Jain (1997) reported a maternal mortality rate of 230 per 100,000 live births in women with chronic hypertension. Complications were more likely with severe baseline maternal disease, especially with documented end-organ damage. More recently, Gilbert and colleagues (2007) reported pregnancy outcomes in 29,842 chronically hypertensive California women from 1991 to 2001. In addition to markedly increased fetal, neonatal, and in-hospital maternal mortality rates, there was also markedly increased maternal morbidity including stroke and renal failure.

Pregnancy-aggravated hypertension manifests as an increase in blood pressure. Systolic pressures >200 mm Hg or diastolic

pressures >130 mm Hg may rapidly result in renal or cardiopulmonary dysfunction. When there is superimposed severe preeclampsia or eclampsia, the maternal prognosis is poor unless the pregnancy is terminated. Placental abruption is a common and serious complication (see Chap. 35, p. 761). Aortic dissection at term has been described by Weissman-Brenner and associates (2004) and is discussed in Chapter 44 (p. 976).

Hypertensive disorders contribute appreciably to maternal mortality rates. This is especially of concern in less developed countries. The World Health Organization (2004) reported the maternal mortality rate in 2000 to be 440 per 100,000 in developing countries compared with 20 per 100,000 in developed countries. Moodley (2007) reported that 18 percent of 3406 maternal deaths from 2002 to 2004 in South Africa were associated with hypertensive disorders. Of these 628 deaths, cerebrovascular complications were responsible for half.

Superimposed Preeclampsia

There is no precise definition of superimposed preeclampsia in women with chronic hypertension. In their review, August and Lindheimer (1999) reported that superimposed preeclampsia developed in 4 to 40 percent of women. The risk of superimposed preeclampsia is directly related to the severity of baseline hypertension, especially early in pregnancy, as well as the need for treatment to achieve control. In a Maternal-Fetal Medicine Units Network trial, Caritis and co-workers (1998) used predefined criteria to diagnose preeclampsia in 774 women with chronic hypertension. They identified superimposed preeclampsia in 25 percent. The incidence of superimposed preeclampsia was similar whether or not the women had baseline proteinuria (Sibai and co-workers, 1998). It was, however, significantly increased in those who had hypertension for at least 4 years or who had preeclampsia during a prior pregnancy.

There is evidence that women destined to develop superimposed preeclampsia may be identified early. Zeeman and colleagues (2003) found that uterine artery Doppler velocimetry findings of increased impedance at 16 to 20 weeks were predictive of superimposed preeclampsia at 28 to 32 weeks. Riskin-Mashiah and Belfort (2004, 2005) reported that pregnant women with mild chronic hypertension had normal cerebral vasomotor reactivity to carbon dioxide (CO_2) breathing and isometric handgrip testing. They then studied 17 such women during midpregnancy. The seven women who subsequently developed superimposed preeclampsia demonstrated increased Doppler-determined perfusion pressure when they inhaled 5 percent CO_2 or when exposed to a 2-minute isometric handgrip test.

More recently, there has been interest in the use of circulating angiogenic factor levels to discriminate among chronic hypertension, gestational hypertension, and preeclampsia (Moore Simas, 2007; Sibai, 2008; Woolcock, 2008, and all their associates). This is discussed further in Chapter 34 (p. 714).

Prevention of Superimposed Preeclampsia. Trials of low-dose aspirin to prevent preeclampsia in women with chronic hypertension have shown little tangible benefits. In the Network study by Caritis and associates (1998) cited above, the incidence of superimposed preeclampsia, fetal-growth restriction, or both was similar in women given low-dose aspirin or placebo. Reduced maternal serum levels of thromboxane B_2 were also not predictive of improved pregnancy outcomes in women given low-dose aspirin (Hauth and colleagues, 1998).

The efficacy of low-dose aspirin is not entirely settled. Both Duley (2007) and Meads (2008) and their colleagues performed Cochrane reviews and reported that low-dose aspirin was beneficial in high-risk women. Askie and associates (2007) also reported minimal benefits from their meta-analysis. To the contrary, the PARIS Collaborative Group (2007) reviewed individual data from 33,897 pregnant women enrolled in 33 randomized trials of low-dose aspirin. They found a 10-percent significant reduction in women randomized to aspirin for the incidence of preeclampsia, delivery before 34 weeks, and serious adverse outcomes, however, women with chronic hypertension had no derived benefits.

Spinnato and colleagues (2007) randomized 311 women with chronic hypertension to antioxidant treatment with vitamins C and E or to a placebo. A similar number in both groups developed preeclampsia—17 versus 20 percent, respectively.

Placental Abruption

In all women, premature placental separation complicates about 1 in 200 to 300 pregnancies (see Chap. 35, p. 761). This incidence is substantively increased to 1 in 60 to 120 pregnancies in women with chronic hypertension (Hogberg, 2007; Ananth, 2007; Sibai, 1998, and all their colleagues). This risk is increased further if the woman smokes or if she develops superimposed preeclampsia. The likelihood of abruption is also increased with severe hypertension. Vigil-De Gracia and colleagues (2004) reported that 8.4 percent of 154 women with severe chronic hypertension suffered a placental abruption. Data from the Norwegian Birth Registry showed a slightly decreased incidence when adjusted for chronic hypertension of abruption if women took supplemental folic acid (Nilsen and co-workers, 2008).

Perinatal Outcomes

Almost all adverse perinatal outcomes are increased in pregnancies complicated by chronic hypertension. Shown in **Table 45-3** are three comparisons that exemplify this. From the University of Alabama at Birmingham, all pregnant women with chronic hypertension were included. Perinatal outcomes were similar to those from the Network study that included all women. In the latter study, however, development of superimposed preeclampsia doubled the rates of preterm delivery and NICU admission. The Parkland study shows the affects of more severe chronic hypertension on fetal growth.

Fetal-Growth Restriction

In a population-based study from Sweden, Zetterström and associates (2006) reported a 2.4-fold risk for fetal-growth restriction in 2754 chronically hypertensive women. The incidence and severity of restricted fetal growth are directly related to the severity of hypertension. Chappell and associates (2007) recently reported that almost half of women with superimposed preeclampsia had fetal-growth restriction compared with 21 percent in women without

TABLE 45-3. Selected Pregnancy Outcomes in Women with Chronic Hypertension, Superimposed Preeclampsia, or Who Required Antihypertensive Treatment Early in Pregnancy

			Pregnancy Outcomes in Percent			
Data	Category of Chronic Hypertension	N	Delivery <35 weeks[a]	Birthweight <10th Percentile	NICU Admission	Perinatal Mortality Rate
University of Alabama at Birmingham (1991–1995)[b]	All patients	568	20	—	21	9
Maternal-Fetal Medicine Units Network (1991–1995)[c]	All patients	763	18	11	24	5
	No Preeclampsia	570	12	11	19	4
	Preeclampsia	193	36	13	40	8
Parkland Hospital (1997–2002)[d]	R_x BP >150/100 mm Hg before 20 weeks	117	—	20	17	5

BP = blood pressure; NICU = neonatal intensive care unit.

preeclampsia. Growth restriction is also dependent on other maternal factors such as age and hypertension control to include the need for additional antihypertensive medications. Moreover, fetal-growth restriction is more prevalent and severe in women who develop superimposed preeclampsia (Table 45-3). If there is end-organ damage such as renal or cardiac dysfunction, the risk is also increased. In the Network trial, the 81 women who also had proteinuria early in pregnancy had a 23-percent incidence of fetal-growth restriction (Sibai and colleagues, 1998).

Preterm Delivery and Perinatal Mortality

Preterm delivery is often indicated in women with chronic hypertension. As seen in Table 45-3, in all women with chronic hypertension, almost a fifth were delivered prior to 35 weeks and there was a correspondingly high NICU admission rate. These numbers were almost doubled if superimposed preeclampsia developed. Importantly, perinatal mortality rate is increased three- to fourfold in women with chronic hypertension when compared with either normotensive controls or the general obstetrical population (Ferrer and colleagues, 2000). Finally, if diabetes coexists with chronic hypertension, then preterm delivery, fetal-growth restriction, and perinatal mortality rates are increased even more (Gonzalez-Gonzalez and co-workers, 2008).

MANAGEMENT DURING PREGNANCY

Diagnosis of chronic hypertension in pregnancy should be confirmed. For example, Brown and associates (2005) reported "white-coat" hypertension in a third of 241 women diagnosed in early pregnancy. Within this third, pregnancy outcomes were good, and only 8 percent developed preeclampsia. Confirmation of abnormal blood pressures with home self-measurements may be beneficial as well as to optimize blood-pressure control (Staessen and co-workers, 2004).

The goal is to reduce adverse maternal or perinatal outcomes discussed in the preceding section. Management is targeted toward prevention of moderate or severe hypertension and delay or amelioration of pregnancy-aggravated hypertension. To some extent, these goals can be achieved pharmacologically. Blood-pressure self-monitoring is encouraged with caveats for the accuracy of automated devices (Brown and colleagues, 2004). Personal health behavioral modifications include dietary counseling and reduction of behaviors such as smoking, alcohol, cocaine, or other substance abuse (see Table 45-2).

Blood Pressure Control

Pregnant women with *severe hypertension* must be treated for maternal indications regardless of pregnancy status (American College of Obstetricians and Gynecologists, 2001). These are women with prior adverse outcomes to include cerebrovascular events, myocardial infarction, and cardiac or renal dysfunction. We agree with the philosophy of beginning antihypertensive treatment in otherwise healthy pregnant women with persistent diastolic pressures of 100 mm Hg or greater (August and Lindheimer, 1999; Working Group Report, 2000). With end-organ dysfunction, treatment of pregnant women with diastolic pressures of 90 mm Hg or higher is reasonable.

There are no data indicating salutary effects on pregnancy outcomes with simply lowering blood pressure. For example, it seems certain that the incidence of superimposed preeclampsia is not appreciably affected. And although there is minimal evidence that outcomes are improved by such treatment, the same evidence attests to the apparent safety of antihypertensive therapy. Exclusions are angiotensin-converting enzyme (ACE)

inhibitors, angiotensin-receptor blockers, and possibly atenolol. Despite lack of scientific data that treatment improves maternal or perinatal outcomes, some clinicians recommend empirical antihypertensive therapy. As emphasized by the Working Group Report (2000), there is a need for further trials in these women.

"Tight Control"

Recently the concept has been espoused that "tight control" of blood pressure—similar to that of glycemic control of pregnant diabetic women—will improve pregnancy outcome. El Guindy and Nabhan (2008) randomized 125 women with mild chronic essential hypertension or gestational hypertension to tight or to less strict blood pressure control during pregnancy. More women in the less tightly controlled group had severe hypertension during follow-up, and antenatal hospitalization was also significantly higher in this group. The gestational age at delivery was significant better in the tightly controlled group. At this time, there are no data to support this theory.

Antihypertensive Drugs

The following summary of antihypertensive drugs is abstracted from several sources, including the *2007 Physicians' Desk Reference*. In nonpregnant adults with chronic hypertension, results of large trials of single-drug therapy cited earlier support conclusions of Frohlich (2003) and August (2003) that antihypertensive use should be based on proven efficacy in persons with equivalent degrees of hypertension.

Diuretics. Thiazide and loop-acting diuretics such as furosemide are commonly used in nonpregnant hypertensives. In the short term, they provide sodium and water diuresis with volume depletion, but with time, there is *sodium escape,* and volume depletion is corrected. Some aspect of lowered peripheral vascular resistance likely contributes to their effectiveness in reducing long-term morbidity and mortality rates (Williams, 2001).

Volume reexpansion may not occur in pregnant women. Sibai and colleagues (1984) assessed plasma volume during pregnancy in 20 chronically hypertensive women. Plasma volume expanded only about 20 percent in the half who continued diuretic therapy throughout pregnancy compared with 50 percent in the other half who discontinued treatment early in pregnancy. Despite this, perinatal outcomes were similar in both groups. Largely due to concerns regarding their effect on maternal plasma volume expansion, diuretics are usually not given as first-line therapy during pregnancy, particularly after 20 weeks (Working Group Report, 2000). Even so, in their recent Cochrane review, Churchill and colleagues (2007) reported no differences in perinatal outcomes in 1836 nonhypertensive women randomized to a thiazide diuretic or placebo for primary preeclampsia prevention.

Adrenergic-Blocking Agents. Some of these drugs act *centrally* by reducing sympathetic outflow to effect a generalized decreased vascular tone. Central-acting agents include clonidine and α-methyldopa. *Peripherally* acting β-adrenergic receptor blockers also cause a generalized decrease in sympathetic tone. Examples are propranolol, metoprolol, and atenolol. Labetalol is a commonly used α/β-adrenergic blocker. Peripheral blockers are thought to have more potential for postural hypotension than centrally acting agents. The most commonly used drugs in pregnancy to treat hypertension are methyldopa or a β- or α/β-receptor blocker.

Vasodilators. Hydralazine relaxes arterial smooth muscle and has been used parenterally for decades to safely treat severe peripartum hypertension (see Chap. 34, p. 740). Oral hydralazine monotherapy for chronic hypertension is not recommended because of its weak antihypertensive effects and resultant tachycardia. It may be an effective adjunct for long-term use with other antihypertensives, especially if there is chronic renal insufficiency.

Calcium-Channel Blockers. These agents are divided into three subclasses based on their modification of calcium entry into cells and interference with binding sites on voltage-dependent calcium channels. Common agents include nifedipine—a dihydropyridine, and verapamil—a phenylalkyl amine derivative. These agents have negative inotropic effects and thus can worsen ventricular dysfunction and congestive heart failure. Pahor and associates (2000) concluded that they are inferior to other first-line drugs in nonpregnant hypertensives. There is minimal published experience with these agents during pregnancy (Smith and colleagues, 2000).

The safety of acute peripartum nifedipine treatment has been questioned by various authors. In obstetrics, the drug is used by some for rapid control of severe hypertension, and it is becoming widely used for tocolysis in preterm labor (see Chap. 36, p. 825). Oei (2006) reviewed the use of nifedipine for tocolysis and concluded that calcium-channel blockers should not be combined with intravenous β-agonists. He also recommended that intravenous nicardipine or high doses of oral nifedipine not be given to women with cardiovascular compromise or those with multifetal gestation. Finally, he recommended that blood pressure be monitored and cardiotocography recorded during the administration of immediate release tablets which should not be chewed. Van Geijn and colleagues (2005) expressed similar concerns.

Myocardial infarction during nifedipine therapy for preterm labor has been reported (Oei and colleagues, 1999; Verhaert and Van Acker, 2004). Its use has also been associated with pulmonary edema (Abbas, 2006; Bal, 2004; Vaast, 2004, and all their colleagues). Severe maternal hypotension with resultant fetal compromise necessitating cesarean delivery and fetal death have also been reported (Johnson and Mason, 2005; Kandysamy and Thomson, 2005; van Veen and colleagues, 2005).

Angiotensin-Converting Enzyme Inhibitors. These drugs inhibit the conversion of angiotensin-I to the potent vasoconstrictor angiotensin-II. They can cause severe fetal malformations that include hypocalvaria when given in the second and third trimesters (Chap. 14, p. 319). Because of this, they are not recommended during pregnancy (Briggs and colleagues, 2005).

Angiotensin-receptor blockers act in a similar manner, but instead of blocking the production of angiotensin-II, they inhibit binding to its receptor. They are presumed to have the same fetal effects as ACE inhibitors and are also contraindicated.

Drug Treatment During Pregnancy

As discussed, continuation of prepregnancy antihypertensive treatment when women become pregnant is debated. Although blood-pressure reduction is certainly beneficial to the mother in the long term, it at least theoretically can decrease uteroplacental perfusion. Older observational reports in general described that most pregnancy outcomes were good without treatment (Chesley, 1978). In general, perinatal mortality rates were acceptable unless superimposed preeclampsia developed.

Some randomized trials of drug therapy in pregnant women with mild chronic hypertension reported after 1975 are shown in Table 45-4. Only two of three trials reported during the 1990s were of appreciable size. Thus, data are not sufficient to provide a definitive answer regarding whether to treat women with mild or even moderate hypertension in pregnancy. An important observation of the two largest recent studies was that no adverse outcomes were found in women given treatment. Thus, it is not unreasonable to treat women with uncomplicated mild or moderate sustained chronic hypertension who would be prescribed antihypertensive therapy when not pregnant.

The concern over fetal-growth restriction from reduced placental perfusion from lowering maternal blood pressure is confounded because worsening blood pressure itself is associated with abnormal fetal growth. Breart and colleagues (1982) found that women with chronic hypertension whose diastolic pressure was less than 90 mm Hg had a 3-percent risk of fetal-growth restriction, those with 90 mm Hg had a 6-percent risk, and those with 110 mm Hg or more had a 16-percent risk. Again, in the two most recent large randomized trials shown in Table 45-4, the incidence of growth restriction did not change when women were randomized to treatment.

Other findings of these two trials are worthy of mention. In the Memphis trial reported by Sibai and colleagues (1990a), the goal of therapy was to maintain pressures less than 140/90 mm Hg. Although women treated throughout pregnancy had significantly lower blood pressures than those randomized to no treatment, adverse outcomes were not altered by treatment. The important clinical difference was that more women who initially were not treated eventually required antihypertensive therapy for pressures >160/110 mm Hg—11 versus 6 percent compared with women treated with either labetalol or methyldopa.

In the study by the Gruppo di Studio Ipertensione in Raviana (1998), 283 women were randomized to treatment with slow-release nifedipine, 10 mg twice daily, or to no treatment. After this, all women were treated with nifedipine if diastolic pressure exceeded 110 mm Hg. The investigators found neither benefits nor harm in either group. The 45-percent preterm delivery rate in treated women was not significant from that of 37 percent in those not treated. Birthweight and the incidence of fetal-growth restriction were similar in each group.

Severe Chronic Hypertension

All available data suggest that the prognosis for pregnancy outcome with chronic hypertension is dependent on the severity of disease before pregnancy. This may be related to findings that many women with severe hypertension have underlying renal disease (Cunningham and colleagues, 1990). In the study by Sibai and co-workers (1986a), there were 44 pregnancies in women whose blood pressure at 6 to 11 weeks was 170/110 mm Hg or higher. They all were given treatment with α-methyldopa and oral hydralazine to maintain pressures less than 160/110 mm Hg. Afterward, they were hospitalized and

TABLE 45-4. Randomized Trials of Antihypertensive Drug Therapy in Pregnancies Complicated by Mild Chronic Hypertension

Study	No.	Mean Gestation at Entry (weeks)	Mean DBP at Entry (mm Hg)	Treatment	Principal Findings
Redman (1976)	208	21–22	88–90	Methyldopa ± hydralazine vs no drug	Fewer midpregnancy losses in treated women
Arias and Zamora (1979)	58	15–16	90–99	Methyldopa, diuretics, or hydralazine vs no drug	Compromised infants born to mothers in whom severe hypertension developed despite treatment
Butters et al. (1990)	29	16	86	Atenolol vs placebo	Poor fetal growth in treated women
Sibai et al. (1990a)	263	<11	91–92	Methyldopa vs labetalol vs no drug	No differences in outcomes
Gruppo di Studio Ipertensione in Gravidanza (1998)	283	24	95–96	Slow-release nifedipine vs no drug	No differences in outcomes

DBP = diastolic blood pressure.
Adapted from Haddad B, Sibai BM: Chronic hypertension in pregnancy, *Ann Med* 31(4):246, 1999, with permission.

treated with parenteral hydralazine if pressures exceeded 180/120 mm Hg. Half developed superimposed preeclampsia, and all adverse perinatal outcomes were in this group. Specifically, all infants born to women with superimposed preeclampsia were preterm, and nearly 80 percent were growth restricted. The perinatal mortality rate was 48 percent. Women with severe chronic hypertension who did not develop superimposed preeclampsia, however, had much better outcomes—only 5 percent of fetuses were growth restricted, and there were no perinatal deaths.

Antihypertensive Therapy Selection

Mulrow and colleagues (2000) performed an extensive review for the Agency for Healthcare Research and Quality and summarized the risks and benefits of antihypertensive agents given during pregnancy. They found no evidence of major adverse fetal or maternal events.

Because of its long-standing record of safety, α-methyldopa is frequently used to control chronic hypertension during pregnancy. The drug has been extensively studied during pregnancy (Cockburn and associates, 1982; Montan and colleagues, 1992, 1993). In their review, Ferrer and colleagues (2000) concluded that its use in the first trimester has not been associated with any pattern of fetal anomalies. Various adrenergic-blocking drugs have been used extensively in England, Scotland, and Australia (Redman, 1982; Rubin and colleagues, 1983; Walker and associates, 1983). The results of treatment with labetalol are consistent with the view that the drug offers no advantages over α-methyldopa (Sibai and colleagues, 1990a). Khalil and colleagues (2009) found that vascular stiffness was significantly improved by treatment with alpha methyldopa in women with preeclampsia but remained higher than in normotensive controls.

The β-blocker atenolol has especial considerations. Butters and colleagues (1990) reported that atenolol treatment resulted in a higher incidence of growth-restricted neonates compared with those born to untreated mothers. In another study of 223 women, Lydakis and colleagues (1999) observed that atenolol treatment was associated with lower birthweight and ponderal indices—birthweight/length^3. There was also a trend toward more preterm births compared with the effects of other antihypertensives or of no treatment. Easterling and associates (1999) also concluded that atenolol therapy was associated with reduced infant birthweight. Montan and Ingemarsson (1989) reported ominous intrapartum fetal heart rate patterns in 20 percent of women receiving β-blocker therapy for hypertension. Ominous patterns were increased even more in growth-restricted fetuses as well as in half of women given epidural analgesia. Because of these findings, the American College of Obstetricians and Gynecologists (2001) recommends that atenolol not be given during pregnancy.

Experiences and newer safety concerns are not sufficient to permit recommendations to be made about routine use of nifedipine for pregnant women with chronic hypertension. Bartolus and associates (2000) reported the effects of maternal nifedipine on child development at 18 months. Outcomes were similar in 94 infants whose hypertensive mothers were treated compared with those of 161 similar women who were not exposed. Malformations were identified in 5.3 percent of nifedipine-exposed women compared with 1.2 percent of controls, however, the study was underpowered to determine significance.

Therapy Recommendations

The Working Group on High Blood Pressure in Pregnancy (2000) concluded that there were limited data from which to draw conclusions concerning any decision to treat mild chronic hypertension in pregnancy. The Group did recommend empirical therapy in women whose blood pressures exceed threshold levels of 150 to 160 mm Hg systolic or 100 to 110 mm Hg diastolic or when there is target-organ damage such as left ventricular hypertrophy or renal insufficiency. They also concluded that early treatment of hypertension would probably reduce subsequent hospitalization during pregnancy. Recall the study by Sibai and associates (1990a) in which subsequent treatment was needed for dangerous hypertension in 11 percent of women not given treatment beginning early in pregnancy. This compared with only 6 percent in women initially randomized to either α-methyldopa or labetalol earlier in pregnancy.

Resistant Hypertension

In some women, worrisome hypertension persists despite usual therapy. For nonpregnant patients, Moser and Setaro (2006) provided a comprehensive review of resistant hypertension. Considerations include inaccurate blood-pressure measurements, suboptimal treatment, and antagonizing substances. In pregnant women, consideration is always given for possible pregnancy-aggravated hypertension, with or without superimposed preeclampsia. Again in nonpregnant patients, Garg and colleagues (2005) confirmed that a suboptimal medication regimen was the most common reason for resistant hypertension. Sowers and colleagues (2005) reported destabilization of hypertension control from simultaneous administration of nonsteroidal anti-inflammatory drugs including cyclooxygenase-2 inhibitors. And ideally not often seen in pregnant women is worsening blood-pressure control from alcohol consumption (Xin and associates, 2001).

Pregnancy-Aggravated Hypertension or Superimposed Preeclampsia

As discussed, the incidence of superimposed preeclampsia for women with chronic hypertension varies depending on severity. A reasonable average is about 25 percent as determined in the Network study reported by Caritis and co-workers (1998). The incidence of superimposed preeclampsia may be underreported in some studies because diagnosis is based solely on urine protein dipstick testing. Lai and colleagues (2006) and Gangaram and associates (2005) found appreciable false-negative rates—39 and 25 percent—when dipstick testing of a single voided urine sample was compared with a 24-hour collection.

The diagnosis may be difficult to make, especially in women with hypertension who have underlying renal disease with chronic proteinuria (Cunningham and associates, 1990). Conditions that support the diagnosis of superimposed

preeclampsia include new-onset proteinuria; neurological symptoms such as severe headaches and visual disturbances; generalized edema; oliguria; and certainly, convulsions or pulmonary edema. Laboratory abnormalities that support the diagnosis include increasing serum creatinine, thrombocytopenia, appreciable serum hepatic transaminase elevations, or combinations of the three.

Some women with chronic hypertension have worsening during pregnancy with no other findings of superimposed preeclampsia. This is most commonly encountered near the end of the second trimester. In the absence of other supporting criteria for superimposed preeclampsia, including fetal-growth restriction or decreased amnionic fluid volume, this likely represents the higher end of the normal blood-pressure curve shown in Figure 45-1. In such women, it is reasonable to begin or to increase the dose of antihypertensive therapy.

Fetal Assessment

Women with well-controlled chronic hypertension and who have no complicating factors can generally be expected to have a good pregnancy outcome. Because even those with mild hypertension have an increased risk of superimposed preeclampsia and fetal-growth restriction, serial antepartum assessment of fetal well-being as detailed in Chapter 15 (p. 337) is recommended by some. According to the American College of Obstetricians and Gynecologists (2001), there are no conclusive data to address either benefit or harm associated with various monitoring strategies.

Delivery

In women with uncomplicated and well-controlled chronic hypertension who have documented normal fetal growth and amnionic fluid volume, it is our practice to await labor at term. Special consideration for delivery prior to term for women with a multifetal gestation may be advisable. In women with complications or in those in whom fetal testing becomes abnormal, delivery is considered. Superimposed severe preeclampsia prompts delivery even with markedly preterm pregnancy. These women are at increased risk for placental abruption and cerebral hemorrhage (Cunningham, 2005; Martin and colleagues, 2005). And, as discussed in Chapter 42 (p. 926), pulmonary edema from peripartum heart failure is common at this time.

In general, management of these women is the same as for preeclampsia described in Chapter 34 (p. 728). Tenets of this management are summarized:

1. Magnesium sulfate prophylaxis is recommended for prevention of eclampsia in women with chronic hypertension who develop severe gestational hypertension with or without other evidence for preeclampsia (Alexander and colleagues, 2006). The optimal duration to continue prophylaxis postpartum is not known. That said, the safety and efficacy of its empirical use for 24 hours is well documented. For women with mild preeclampsia, Ehrenberg and Mercer (2006) provided preliminary evidence that 12 hours may be sufficient. We are of the view that further data are needed before changing current management guidelines.
2. Severe hypertension—diastolic blood pressure 110 mm Hg or higher or systolic pressure 160 mm Hg or higher—is treated with either intravenous hydralazine or labetalol. Some prefer to treat women with a diastolic pressure of 100 to 105 mm Hg as detailed in Chapter 34 (p. 740). Vigil-De Gracia and colleagues (2006) randomized 200 women to intravenous hydralazine or labetalol to acutely lower severe blood pressure in pregnancy. Outcomes were similar except for significantly more maternal palpitations and tachycardia with hydralazine and significantly more neonatal hypotension and bradycardia with labetalol.
3. Vaginal delivery is usually preferable, and cesarean delivery performed for usual obstetrical indications. Most women can be induced successfully and delivered vaginally (Alexander and colleagues, 1999; Atkinson and associates, 1995). Conduction analgesia for labor and delivery, including cesarean delivery, is appropriate in these women and as described in Chapter 19 (p. 454). Importantly, labor epidural analgesia does not serve to treat hypertension (Lucas and colleagues, 2001).

Some recommend glucocorticoid therapy ostensibly to improve the clinical response of women with chronic hypertension and superimposed hemolysis, elevated liver enzymes, low platelet count (HELLP) syndrome (see Chap. 34, p. 734). In a randomized trial, however, Fonseca and colleagues (2005) reported no benefit from dexamethasone treatment. Thus, we agree with Sibai and Barton (2005) that high-dose dexamethasone for women with HELLP syndrome after 34 weeks or postpartum should be considered experimental.

Postpartum Considerations

In many respects, postpartum observation and prevention and management of adverse complications are similar in women with severe chronic hypertension and in those with severe preeclampsia–eclampsia. The development of cerebral or pulmonary edema, heart failure, renal dysfunction, or cerebral hemorrhage is especially high within the first 48 hours after delivery (Benedetti, 1980, 1985; Cunningham, 1986, 2005; Martin, 2005; Sibai, 1990b, and all their co-workers). Following delivery, as maternal peripheral resistance increases, left ventricular workload also increases. This increase is further aggravated by appreciable amounts of interstitial fluid that are mobilized for excretion as endothelial damage is repaired. In these women, sudden hypertension—either moderate or severe—exacerbates diastolic dysfunction and may cause pulmonary edema (Cunningham and colleagues, 1986; Gandhi and associates, 2001). Prompt hypertension control, along with diuretic therapy, usually quickly resolves pulmonary edema. In some cases, this clinical situation can be forestalled by the administration of intravenous furosemide to augment the normal diuresis that develops postpartum. Ascarelli and colleagues (2005) reported that 20-mg oral furosemide given daily to postpartum women with severe preeclampsia aided in blood-pressure control.

Contraception

Women with chronic hypertension have especial consideration for contraceptive choices. These are discussed in detail throughout Chapter 32. In addition, these women are at ultimate high risk for lifetime cardiovascular complications which are increased if preeclampsia and diabetes coexist (Berends and colleagues, 2008).

CHAPTER 46

Pulmonary Disorders

PULMONARY PHYSIOLOGY 996
ASTHMA 996
ACUTE BRONCHITIS 1001
PNEUMONIA 1001
TUBERCULOSIS 1005
SARCOIDOSIS 1007
CYSTIC FIBROSIS 1007
CARBON MONOXIDE POISONING 1009

A number of acute and chronic pulmonary disorders are encountered during pregnancy. The most common is asthma, which affects up to 4 percent of women. Together with community-acquired pneumonia, it accounted for almost 10 percent of nonobstetrical antepartum hospitalizations in one managed care plan (Gazmararian and colleagues, 2002). Acute and chronic lung disorders are superimposed upon several important adaptive changes of pulmonary physiology and function during pregnancy. And although there is no evidence that pulmonary function is impaired because of pregnancy, advanced pregnancy may intensify the pathophysiological effects of some lung diseases. One example is the disparate number of maternal deaths during the influenza pandemics of 1918 and 1957. Another is the poor tolerance for pregnancy of women with severe chronic lung disease.

PULMONARY PHYSIOLOGY

The important and sometimes marked changes in the respiratory system induced by pregnancy are found in Chapter 5 (p. 121) and the Appendix. Lung volumes and capacities that are measured directly to describe pulmonary pathophysiology may be significantly altered. In turn, these change the results of gas concentrations and acid-base values in blood. Some of the physiological changes induced by pregnancy were recently summarized by Wise and associates (2006):

1. *Vital capacity* and *inspiratory capacity* increase by approximately 20 percent by late pregnancy
2. *Expiratory reserve volume* decreases from 1300 mL to approximately 1100 mL
3. *Tidal volume* increases approximately 40 percent as a result of the respiratory stimulant properties of progesterone
4. *Minute ventilation* increases about 30 to 40 percent due to increased tidal volume. Arterial pO_2 also increases from 100 to 105 mm Hg
5. Carbon dioxide production increases approximately 30 percent, but diffusion capacity also increases, and with alveolar hyperventilation, the pCO_2 decreases from 40 to 32 mm Hg
6. *Residual volume* decreases approximately 20 percent from 1500 mL to approximately 1200 mL
7. The expanding uterus and increased abdominal pressure cause chest wall compliance to be reduced by a third. Thus, the *functional residual capacity*—the sum of expiratory reserve and residual volumes—decreases by 10 to 25 percent.

The sum of these changes is substantively increased ventilation due to deeper but not more frequent breathing. These changes presumably are induced by basal oxygen consumption, which increases incrementally by 20 to 40 mL/min in the second half of pregnancy. The kidney increases bicarbonate excretion and serum levels decrease to approximately 15 to 20 meq/L, while pH is slightly alkalotic at 7.45.

ASTHMA

Asthma is common in young women and therefore is seen frequently during pregnancy. Asthma prevalence increased steadily

in many countries beginning in the mid-1970s but may have plateaued in the United States during the past decade (Eder and colleagues, 2006). According to Fanta (2009) and the National Center for Health Statistics (2007), almost 8 percent of the general population has asthma. Kwon and associates (2006) estimated asthma prevalence during pregnancy to range between 4 and 8 percent. Moreover, Namazy and Schatz (2005) reported that the prevalence in pregnant women appears to be increasing.

Pathophysiology

Asthma is a chronic inflammatory airway disorder with a *major hereditary component*. Increased airway responsiveness and persistent subacute inflammation have been associated with genes on chromosomes 5, 11, and 12 that include cytokine gene clusters, β-adrenergic and glucocorticoid receptor genes, and the T-cell antigen receptor gene (McFadden, 2005). There inevitably is an *environmental allergic stimulant* such as influenza or cigarette smoke in susceptible individuals (Hartert and colleagues, 2003).

The hallmarks of asthma are reversible airway obstruction from bronchial smooth muscle contraction, vascular congestion, tenacious mucus, and mucosal edema. There is airway inflammation and increased responsiveness to a number of stimuli including irritants, viral infections, aspirin, cold air, and exercise. Inflammation is caused by response of mast cells, eosinophils, lymphocytes, and bronchial epithelium. A number of inflammatory mediators by these and other cells include histamine, leukotrienes, prostaglandins, cytokines, and many others. IgE also plays a central role in pathophysiology (Strunk and Bloomberg, 2006). **Because F-series prostaglandins and ergonovine exacerbate asthma, these commonly used obstetrical drugs should be avoided if possible.**

Clinical Course

Asthma represents a broad spectrum of clinical illness ranging from mild wheezing to severe bronchoconstriction. The functional result of acute bronchospasm is airway obstruction and decreased airflow. The work of breathing progressively increases, and patients present with chest tightness, wheezing, or breathlessness. Subsequent alterations in oxygenation primarily reflect ventilation–perfusion mismatching, because the distribution of airway narrowing is uneven.

The variations of asthma manifestations have led to a simple classification that considers severity as well as onset and duration of symptoms (Table 46-1). With persistent or worsening bronchial obstruction, stages progress as shown in Figure 46-1. Hypoxia initially is well compensated by hyperventilation, normal arterial pO_2, decreased pCO_2, and resultant respiratory alkalosis. As airway narrowing worsens, ventilation–perfusion defects increase, and arterial hypoxemia ensues. With severe obstruction, ventilation becomes impaired because fatigue causes early CO_2 retention. Because of hyperventilation, this may only be seen initially as an arterial pCO_2 returning to the normal range. With continuing obstruction, respiratory failure follows from fatigue.

Although these changes are generally reversible and well tolerated by the healthy nonpregnant individual, even early stages of asthma may be dangerous for the pregnant woman and her fetus. This is because smaller functional residual capacity and

TABLE 46-1. Classification of Asthma Severity

	Severity			
	Intermittent	Persistent		
Component		Mild	Moderate	Severe
Symptoms	≤2 day/wk	>2 day/wk, not daily	Daily	Throughout day
Nocturnal awakenings	≤2×/mo	3–4×/mo	>1/wk, not nightly	Often 7×/wk
Short-acting β-agonist for symptoms	≤2 day/wk	≥2 day/wk, but not >1×/day	Daily	Several times daily
Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Lung function	Normal between exacerbations			
• FEV_1	>80% predicted	≥80% predicted	60–80% predicted	<60% predicted
• FEV_1/FVC	Normal	Normal	Reduced 5%	Reduced >5%

FEV = forced expiratory volume, FVC = forced vital capacity.

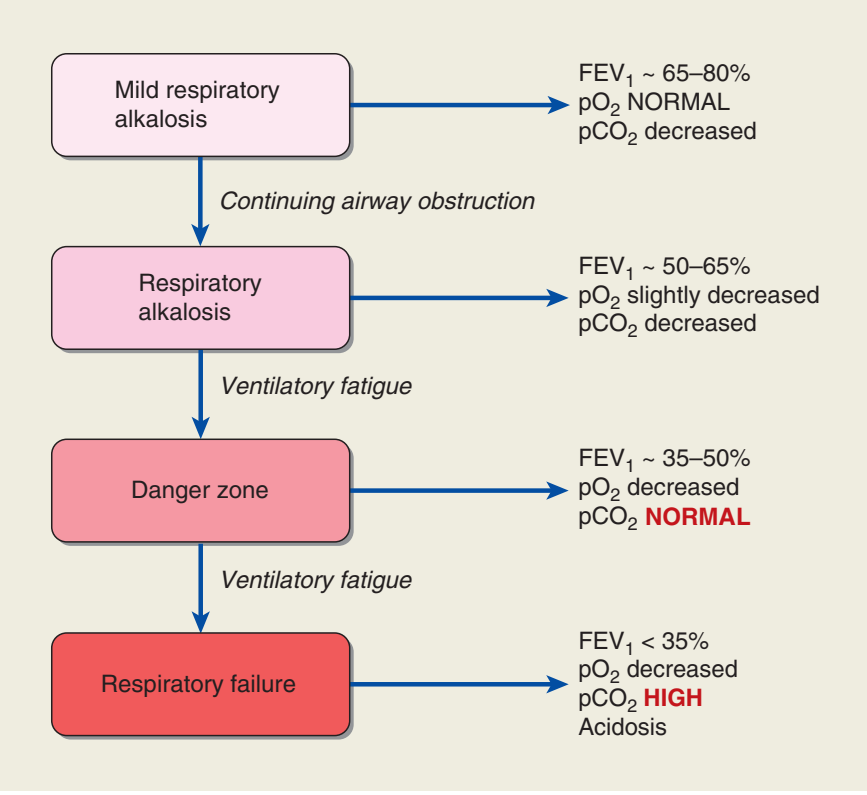

FIGURE 46-1 Clinical stages of asthma.

increased effective shunt render the woman more susceptible to hypoxia and hypoxemia.

Effects of Pregnancy on Asthma

There is no evidence that pregnancy has a predictable effect on underlying asthma. In their review of six prospective studies of more than 2000 pregnant women, Gluck and Gluck (2006) reported that approximately one third each improved, remained unchanged, or clearly worsened. In a study by Schatz and associates (2003), baseline severity correlated with asthma morbidity during pregnancy. With mild disease, 13 percent of women had an exacerbation and 2.3 percent required admission; with moderate disease, these numbers were 26 and 7 percent; and for severe asthma, 52 and 27 percent. Murphy and colleagues (2005) reported similar observations. Hendler and co-workers (2006) reported that women with severe disease were more likely to have an exacerbation during pregnancy. And Carroll and associates (2005) reported disparate morbidity in black compared with white women.

Approximately 20 percent of women with mild or moderate asthma have been reported to have an intrapartum exacerbation (Schatz and associates, 2003). Conversely, Wendel and associates (1996) reported exacerbations at the time of delivery in only 1 percent of women. Mabie and co-workers (1992) reported an 18-fold increased risk of exacerbation following cesarean versus vaginal delivery.

Pregnancy Outcome

Pregnancy outcomes in asthmatics have improved during the past 20 years. From his scholarly review of some recent studies, Dombrowski (2006) concluded that, unless there is severe disease, pregnancy outcomes are generally excellent. Maternal and perinatal outcomes for more than 9000 pregnancies in asthmatic women are shown in Table 46-2. However, findings are not consistent between the studies. In some studies, there is a slightly increased incidence of preeclampsia, preterm labor,

TABLE 46-2. Maternal and Perinatal Outcomes in Pregnancies Complicated by Asthma

		Perinatal Outcomes (Percent)		
Study	No.	Gestational Hypertension	Growth Restriction	Preterm Delivery
Demissie et al (1998)	2289	8	15	18
Liu et al (2001)	2193	13	12	10
Bracken et al (2003)	872	NS[a]	8.5	8.5
Ramsey et al (2003)	1381	NS	1.7	Not ↑[b]
Dombrowski et al (2004a)	1739	12.2[b]	7.1[b]	16[b]
Mihrshahi et al (2003)	340	7[c]	—	3.2[b]
Schatz et al (2006)	384	8.1	7	18
Approximate average	9291	11	12	12

[a]NS = not stated.
[b]Incidence not significantly different compared with control group or general obstetrical population.
[c]Incidence significantly greater than control group.

low-birthweight infants, or perinatal mortality. In another report, Getahun and associates (2006) found a small increase in the incidence of placental abruption and an increase in preterm rupture of membranes (Getahun and co-workers, 2007). But, in a recent European report, 37,585 pregnancies of women with asthma were compared with pregnant nonasthmatics. Risks of most obstetrical complications were not higher in asthmatic women, except depression, miscarriages, and cesarean delivery (Tata and co-workers, 2007).

It appears that significantly increased morbidity is linked to progressively more severe disease, poor control, or both (Källén and Otterblad Olausson, 2007). For example, in the study by the Maternal-Fetal Medicine Units (MFMU) Network, delivery before 37 weeks was not increased among the 1687 pregnancies of asthmatics compared with 881 controls (Dombrowski and colleagues, 2004a). But for women with severe asthma, the rate was increased about twofold. In a prospective evaluation of 656 asthmatic pregnant women and 1052 pregnant controls, Triche and co-workers (2004) found that women with moderate to severe asthma, regardless of treatment, are at increased risk of preeclampsia. Finally, the MFMU Network study suggests a direct relationship of baseline pregnancy *forced expiratory volume at 1 second (FEV_1)* with birthweight and an inverse relationship with rates of gestational hypertension and preterm delivery (Schatz and associates, 2006).

Life-threatening complications from *status asthmaticus* include muscle fatigue with respiratory arrest, pneumothorax, pneumomediastinum, acute cor pulmonale, and cardiac arrhythmias. Maternal and perinatal mortality rates are substantively increased when mechanical ventilation is required.

Fetal Effects. With reasonable control of asthma, perinatal outcomes are generally good. For example, in the MFMU Network study cited above, there were no significant adverse neonatal sequelae from asthma (Dombrowski and co-workers, 2004a). The caveat is that severe asthma was uncommon in this closely monitored group. But when respiratory alkalosis develops, both animal and human studies suggest that fetal hypoxemia develops well before the alkalosis compromises maternal oxygenation (Rolston and associates, 1974). It is hypothesized that the fetus is jeopardized from decreased uterine blood flow, decreased maternal venous return, and an alkaline-induced leftward shift of the oxyhemoglobin dissociation curve.

The fetal response to maternal hypoxemia is decreased umbilical blood flow, increased systemic and pulmonary vascular resistance, and decreased cardiac output. Observations by Bracken and colleagues (2003) confirm that the incidence of fetal-growth restriction increases with asthma severity. The realization that the fetus may be seriously compromised as asthma severity increases underscores the need for aggressive management. Monitoring the fetal response is, in effect, an indicator of maternal status.

Possible teratogenic or adverse fetal effects of drugs given to control asthma have been a concern. Fortunately, and as discussed in Chapter 14 (p. 315), considerable data have accrued with no evidence that commonly used anti-asthmatic drugs are harmful (Blais and colleagues, 2007; Källén, 2007; Namazy and Schatz, 2006). Despite this, Enriquez and co-workers (2006) reported a 13- to 54-percent patient-generated decrease in β-agonist and corticosteroid use between 5 to 13 weeks of pregnancy.

Clinical Evaluation

The subjective severity of asthma frequently does not correlate with objective measures of airway function or ventilation. Clinical examination also is inaccurate as a predictor of severity. Useful clinical signs include labored breathing, tachycardia, pulsus paradoxus, prolonged expiration, and use of accessory muscles. Signs of a potentially fatal attack include central cyanosis and altered consciousness.

Arterial blood gas analysis provides objective assessment of maternal oxygenation, ventilation, and acid–base status. With this information, the severity of an acute attack can be assessed (see Fig. 46-1). That said, in a prospective evaluation, Wendel and associates (1996) found that *routine* arterial blood gas analysis did not help to manage most pregnant women who required admission for asthma control. If used, the results must be interpreted in relation to normal values for pregnancy. For example, a $pCO_2 > 35$ mm Hg with a $pH < 7.35$ is consistent with hyperventilation and CO_2 retention in a pregnant woman.

Pulmonary function testing should be routine in the management of chronic and acute asthma. Sequential measurement of the FEV_1 or the *peak expiratory flow rate—PEFR*—are the best measures of severity. An FEV_1 less than 1 L, or less than 20 percent of predicted value, correlates with severe disease defined by hypoxia, poor response to therapy, and a high relapse rate (Noble and colleagues, 1988). The PEFR correlates well with the FEV_1, and it can be measured reliably with inexpensive portable meters. Each woman determines her own baseline when asymptomatic—*personal best*—to compare with values when symptomatic. Brancazio and associates (1997) showed that the PEFR did not change during the course of pregnancy in normal women.

Management of Chronic Asthma

The most recent management guidelines of the Working Group on Asthma and Pregnancy include:

1. Patient education—general asthma management and its effect on pregnancy.
2. Environmental precipitating factors—avoidance or control.
3. Objective assessment of pulmonary function and fetal well-being—monitor with PEFR or FEV_1.
4. Pharmacological therapy—in appropriate combinations and doses to provide baseline control and treat exacerbations (National Heart, Lung and Blood Institute, 2004).

In general, women with moderate to severe asthma should measure and record either their FEV_1 or PEFR twice daily. The FEV_1 ideally is >80 percent of predicted. For PEFR, predicted values range from 380 to 550 L/min. Each woman has her own baseline value, and therapeutic adjustments can be made using this (American College of Obstetricians and Gynecologists, 2008; Rey and Boulet, 2007).

TABLE 46-3. Stepwise Therapy of Chronic Asthma During Pregnancy

Severity	Stepwise Therapy
Mild intermittent	Inhaled β-agonists as needed[a]
Mild persistent	Low-dose inhaled corticosteroids[b] Alternative—cromolyn, leukotriene antagonists, or theophylline
Moderate persistent	Low-dose inhaled corticosteroids and long-acting β-agonists[c] *or* medium-dose inhaled steroids and long-acting β-agonist if needed Alternative—low-dose (or medium if needed) inhaled steroids *and* either theophylline or leukotriene antagonists
Severe persistent	High-dose inhaled corticosteroids and long-acting β-agonist and oral steroids if needed Alternative—high-dose inhaled corticosteroids and theophylline and oral steroids

[a]Albuterol preferred because of more human data on safety in pregnancy.
[b]Budesonide preferred because of more experience in pregnancy.
[c]Salmeterol preferred because of its long availability in this country.
From Dombroski (2006); Fanta (2009); Namazy and Schatz (2006); National Heart, Lung and Blood Institute, National Asthma Education and Prevention Program Working Group Report (2004).

Treatment depends on the severity of disease. Although β-agonists help to abate bronchospasm, corticosteroids treat the inflammatory component. Regimens recommended for outpatient management are listed in **Table 46-3.** For mild asthma, inhaled *β-agonists* as needed are usually sufficient. For persistent asthma, *inhaled corticosteroids* are administered every 3 to 4 hours. The goal is to reduce the use of β-agonists for symptomatic relief. A case-control study from Canada with a cohort of more than 15,600 nonpregnant women with asthma showed that inhaled corticosteroids reduced hospitalizations by 80 percent (Blais and associates, 1998). And Wendel and colleagues (1996) achieved a 55-percent reduction in readmissions for severe exacerbations in pregnant asthmatics given maintenance inhaled corticosteroids along with β-agonist therapy.

Theophylline is a methylxanthine, and its various salts are bronchodilators and possibly anti-inflammatory agents. They have been used less frequently since inhaled corticosteroids became available. Some theophylline derivatives are considered useful for oral maintenance therapy if the initial response is not optimal to inhaled corticosteroids and β-agonists (see Table 46-3). Dombrowski and colleagues (2004b) conducted a randomized trial with nearly 400 pregnant women with moderate asthma. Oral theophylline was compared with inhaled beclomethasone for maintenance. In both groups, about 20 percent had exacerbations. Women taking theophylline had a significantly higher discontinuation rate because of side effects. Pregnancy outcomes were similar in the two groups.

Leukotriene modifiers inhibit their synthesis and include *zileuton, zafirinkast,* and *montelukast.* These drugs are given orally or by inhalation for prevention, but they are not effective for acute disease. For maintenance, they are used in conjunction with inhaled corticosteroids to allow minimal dosing. About half of asthmatics will improve with these drugs (McFadden, 2005). They are not as effective as inhaled corticosteroids (Fanta, 2009). Finally, there is little experience with their use in pregnancy (Bakhireva and colleagues, 2007).

Cromolyn and *nedocromil* inhibit mast cell degranulation. They are ineffective for acute asthma and are taken chronically for prevention. They likely are not as effective as inhaled corticosteroids and have generally been replaced by leukotriene modifiers (Fanta, 2009).

There is no experience in pregnant women with *omalizumab,* a recombinant humanized monoclonal anti-IgE antibody. It binds circulating IgE to deactivate it.

Management of Acute Asthma

Treatment of acute asthma during pregnancy is similar to that for the nonpregnant asthmatic. An exception is a significantly lowered threshold for hospitalization. Intravenous hydration may help clear pulmonary secretions, and supplemental oxygen is given by mask. The therapeutic aim is to maintain the pO_2 greater than 60 mm Hg, and preferably normal, along with 95-percent oxygen saturation. Baseline pulmonary function testing includes FEV_1 or PEFR. Continuous pulse oximetry and electronic fetal monitoring may provide useful information.

First-line therapy for acute asthma includes a *β-adrenergic agonist,* such as terbutaline, albuterol, isoetharine, epinephrine, isoproterenol, or metaproterenol, which is given subcutaneously, taken orally, or inhaled. These drugs bind to specific cell-surface receptors and activate adenylyl cyclase to increase intracellular cyclic AMP and modulate bronchial smooth muscle relaxation. Long-acting preparations are used for outpatient therapy.

If not previously given for maintenance, inhaled corticosteroids are commenced along with intensive β-agonist therapy. For severe exacerbations, inhaled ipratropium bromide is given. *Corticosteroids* should be given early to all patients with severe acute asthma. Unless there is a timely response to treatment, oral or parenteral preparations are given. Intravenous methylprednisolone, 40 to 60 mg, every 6 hours is commonly used. Equipotent doses of hydrocortisone by infusion or prednisone orally can be given instead. **Because their onset of action is several hours, corticosteroids are given initially along with β-agonists for acute asthma.**

Further management depends on the response to therapy. If initial therapy with β-agonists is associated with improvement of FEV_1 or PEFR to above 70 percent of baseline, then discharge can be considered. Some women may benefit from observation. Alternatively, for the woman with obvious respiratory distress, or if the FEV_1 or PEFR is less than 70 percent of predicted after three doses of β-agonist, admission is advisable. Intensive therapy includes inhaled β-agonists, intravenous corticosteroids, and close observation for worsening respiratory distress or fatigue in breathing (Wendel and colleagues, 1996). The woman is cared for in the delivery unit or an intermediate or intensive care unit (Dombrowski, 2006).

Status Asthmaticus and Respiratory Failure

Severe asthma of any type not responding after 30 to 60 minutes of intensive therapy is termed *status asthmaticus*. Braman and Kaemmerlen (1990) have shown that management of nonpregnant patients with status asthmaticus in an intensive care setting results in a good outcome in most cases. Consideration should be given to early intubation when maternal respiratory status worsens despite aggressive treatment (see Fig. 46-1). Fatigue, carbon dioxide retention, and hypoxemia are indications for mechanical ventilation.

Labor and Delivery

Maintenance medications are continued through delivery. Stress-dose corticosteroids are administered to any woman given systemic steroid therapy within the preceding 4 weeks. The usual dose is 100 mg of hydrocortisone given intravenously every 8 hours during labor and for 24 hours after delivery. The PEFR or FEV_1 should be determined on admission, and serial measurements are taken if symptoms develop.

Oxytocin or prostaglandins E_1 or E_2 are used for cervical ripening and induction. A nonhistamine-releasing narcotic such as fentanyl may be preferable to meperidine for labor, and epidural analgesia is ideal. For surgical delivery, conduction analgesia is preferred because tracheal intubation can trigger severe bronchospasm. Postpartum hemorrhage is treated with oxytocin or prostaglandin E_2. **Prostaglandin $F_{2\alpha}$ or ergotamine derivatives are contraindicated because they may cause significant bronchospasm.**

ACUTE BRONCHITIS

Infection of the large airways is manifest by cough without pneumonitis. It is common in adults, especially in winter months. Infections are usually caused by viruses, and of these, influenza A and B, parainfluenza, respiratory syncytial, coronavirus, adenovirus, and rhinovirus are common isolates (Wenzel and Fowler, 2006). Bacterial agents causing community-acquired pneumonia are rarely implicated. The cough of acute bronchitis persists for 10 to 20 days (mean 18 days) and occasionally lasts for a month or longer. According to the 2006 guidelines of the American College of Chest Physicians, routine antibiotic treatment is not justified (Braman, 2006). Influenza bronchitis is managed as discussed below.

PNEUMONIA

According to Anand and Kollef (2009), current classification includes several types of pneumonia. *Community-acquired pneumonia (CAP)* is typically encountered in otherwise healthy young women, including during pregnancy. *Healthcare-associated pneumonia (HCAP)* develops in patients in outpatient care facilities and more closely resembles *hospital-acquired pneumonia (HAP)*. Other types are *nursing home-acquired pneumonia (NHAO)* and *ventilator-associated pneumonia (VAP)*. Community-acquired pneumonia in pregnant women is relatively common and is caused by a number of bacterial or viral pathogens (Sheffield and Cunningham, 2009). Gazmararian and colleagues (2002) reported that pneumonia accounts for 4.2 percent of antepartum admissions for nonobstetrical complications. During influenza season, admissions for respiratory illnesses double compared with the remaining months (Cox and colleagues, 2006). Mortality from pneumonia is infrequent in young women, but during pregnancy severe pneumonitis with appreciable loss of ventilatory capacity is not as well tolerated (Laibl and Sheffield, 2006). This generalization seems to hold true regardless of the etiology of the pneumonia. Hypoxemia and acidosis are also poorly tolerated by the fetus and frequently stimulate preterm labor after midpregnancy. Because many cases of pneumonia follow viral upper respiratory illnesses, worsening or persistence of symptoms may represent developing pneumonia. **Any pregnant woman suspected of having pneumonia should undergo chest radiography.**

Bacterial Pneumonia

Many bacteria that cause community-acquired pneumonia, such as *Streptococcus pneumoniae,* are part of the normal resident flora (Bogaert and co-workers, 2004). Some factors that perturb the symbiotic relationship between colonizing bacteria and mucosal phagocytic defenses include acquisition of a virulent strain or bacterial infections following a viral infection. Cigarette smoking and chronic bronchitis favor colonization with *S. pneumoniae, Haemophilus influenzae,* and *Legionella* species. Other risk factors include asthma, binge drinking, and human immunodeficiency virus (HIV) infection (Goodnight and Soper, 2005; Sheffield and Cunningham, 2009).

Incidence and Causes

Pregnancy itself does not predispose to pneumonia. From Alberta, Jin and colleagues (2003) reported the rate of antepartum hospitalization for pneumonia to be 1.5 per 1000 deliveries—almost identical to the rate of 1.47 per 1000 for nonpregnant women. Likewise, Yost and associates (2000) reported an incidence of 1.5 per 1000 for pneumonia complicating 75,000 pregnancies cared for at Parkland Hospital.

More than half of adult pneumonias are bacterial, and *S. pneumoniae* is the most common cause. Lim and colleagues (2001) studied 267 nonpregnant inpatients with pneumonia and identified a causative agent in 75 percent—*S. pneumoniae* in 37 percent; influenza A, 14 percent; *Chlamydophila pneumoniae,* 10 percent; *H. influenzae,* 5 percent; and *Mycoplasma pneumoniae* and *Legionella pneumophila,* 2 percent each.

Community-acquired methicillin-resistant *Staphylococcus aureus* has recently been reported as causing a necrotizing pneumonia (Rotas and colleagues, 2007).

Diagnosis

Typical symptoms include cough, dyspnea, sputum production, and pleuritic chest pain. Mild upper respiratory symptoms and malaise usually precede these symptoms, and mild leukocytosis is usually present. Chest radiography is essential for diagnosis but does not accurately predict the etiology (Fig. 46-2). The responsible pathogen is identified in less than half of cases. According to the Infectious Diseases Society of America (IDSA) and the American Thoracic Society (ATS), tests to identify a specific agent are optional. Thus, sputum cultures, serological testing, cold agglutinin identification, and tests for bacterial antigens are not recommended. At Parkland Hospital, the one exception to this is rapid serological testing for influenza A and B (Sheffield and Cunningham, 2009).

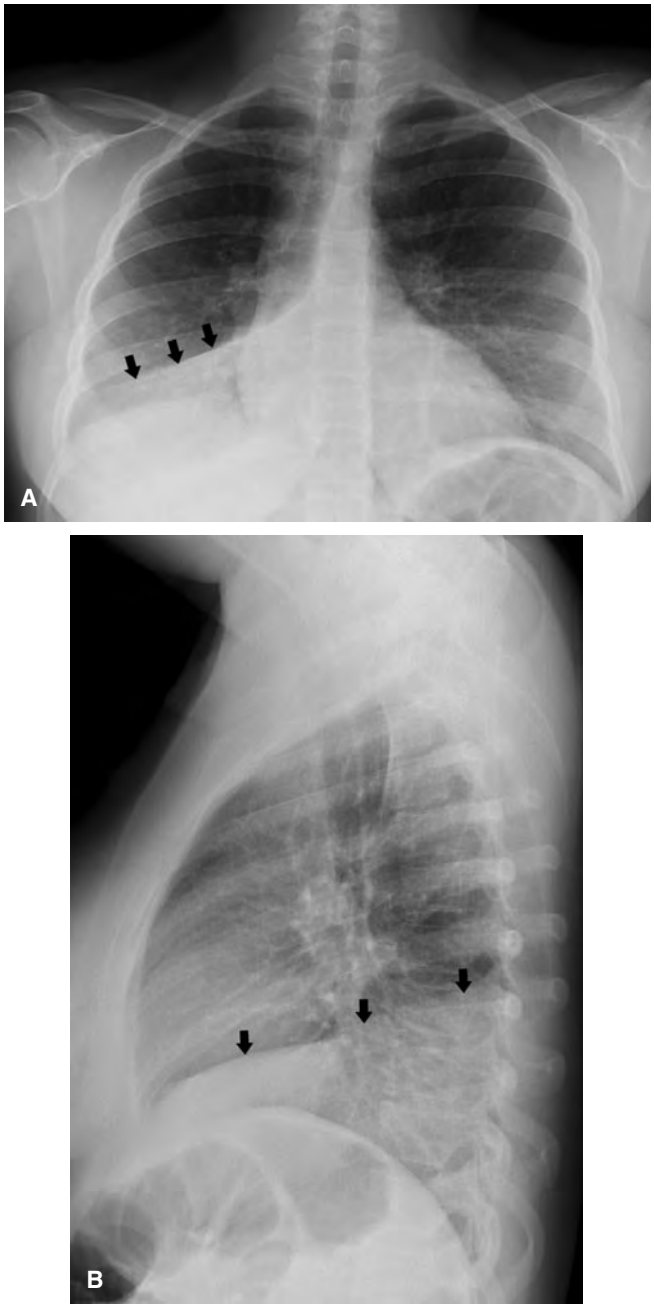

FIGURE 46-2 Chest radiographs in a pregnant woman with right lower lobe pneumonia. **A.** Complete opacification of the right lower lobe (*arrows*) is consistent with the clinical suspicion of pneumonia. **B.** Opacification (*arrows*) is also seen on the lateral projection.

TABLE 46-4. Criteria for Severe Community-Acquired Pneumonia

Respiratory rate ≥30/min
PaO_2/FiO_2 ratio ≤250
Multilobular infiltrates
Confusion/disorientation
Uremia
Leukopenia—WBC <4000/μL
Thrombocytopenia—platelets <100,000/μL
Hypothermia—core temperature <36°C
Hypotension requiring aggressive fluid resuscitation

The Infectious Diseases Society of America/American Thoracic Society (Adapted from Mandell and colleagues, 2007).

Management

Although many otherwise healthy young adults can be safely treated as outpatients, at Parkland Hospital we hospitalize all pregnant women with radiographically proven pneumonia. Outpatient therapy or 23-hour observation is reasonable with optimal follow-up. Risk factors shown in Table 46-4 should prompt hospitalization.

With severe disease, admission to an intensive care or intermediate care unit is advisable. Approximately 20 percent of pregnant women admitted to Parkland Hospital for pneumonia require this level of care (Zeeman and associates, 2003). Severe pneumonia is a relatively common cause of acute respiratory distress syndrome during pregnancy, and mechanical ventilation may become necessary. Indeed, of the 51 pregnant women who required mechanical ventilation in the review by Jenkins and co-workers (2003), 12 percent had pneumonia.

Antimicrobial treatment is empirical. Because most adult pneumonias are caused by pneumococci, mycoplasma, or chlamydophilia, monotherapy initially is with a macrolide—azithromycin, clarithromycin, or erythromycin. Yost and colleagues (2000) reported that erythromycin monotherapy, given intravenously and then orally, was effective in all but one of 99 pregnant women with uncomplicated pneumonia.

For women with severe disease according to criteria in Table 46-4, the IDSA/ATS guidelines call for either: (1) a respiratory fluoroquinolone—levofloxacin, moxifloxacin, or gemifloxacin; or (2) a β-lactam *plus* a macrolide—high-dose amoxicillin or amoxicillin-clavulanate are preferred β-lactams, and alternatives include ceftriaxone, cefpodoxime, or cefuroxime. Levofloxacin is also acceptable. In areas in which 25 percent or more of pneumococcal isolates are resistant to macrolides, these latter regimens are preferred. The teratogenicity risk of fluoroquinolones is low, and these should be given if indicated (Briggs and colleagues, 2005). If

community-acquired methicillin-resistant *S. aureus* is suspected, then vancomycin is added (Sheffield and Cunningham, 2009).

Clinical improvement is usually evident in 48 to 72 hours with resolution of fever in 2 to 4 days. Radiographic abnormalities may take up to 6 weeks to completely resolve (Torres and Menéndez, 2008). Worsening disease is a poor prognostic feature, and follow-up radiography is recommended if fever persists. Even with improvement, however, about 20 percent of women develop a pleural effusion. Therapy is recommended for a minimum of 5 days. Treatment failure may occur in up to 15 percent of cases, and a wider microbial antibiotic regimen is warranted in these cases (Menedez and Torres, 2008).

Pregnancy Outcome with Pneumonia

During the pre-antimicrobial era, as many as a third of pregnant women with pneumonia died (Finland and Dublin, 1939). Although much improved, maternal and perinatal mortality rates both remain formidable. In five studies published after 1990, the maternal mortality rate was 0.8 percent of 632 women. Importantly, almost 7 percent of the women required intubation and mechanical ventilation.

Prematurely ruptured membranes and preterm delivery are common complications and are reported in up to a third of cases (Getahun and associates, 2007; Shariatzadeh and Marrie, 2006). Likely related are older studies reporting a twofold increase in low-birthweight infants (Sheffield and Cunningham, 2009).

Prevention

Pneumococcal vaccine is 60- to 70-percent protective against its 23 included serotypes. Its use has been shown to decrease emergence of drug-resistant pneumococci (Kyaw and associates, 2006). The vaccine is not recommended for otherwise healthy pregnant women (American College of Obstetricians and Gynecologists, 2003). It is recommended for those who are immunocompromised, including those with HIV infection; significant smoking history; diabetes or cardiac, pulmonary, or renal disease; and asplenia, such as with sickle-cell disease.

Influenza Pneumonia

Respiratory infection, including pneumonitis, is caused by RNA viruses of which influenza A and B form one genus (see Chap. 58, p. 1212). Influenza infection can be serious, and it is epidemic in the winter months. The virus is spread by aerosolized droplets and quickly infects ciliated columnar epithelium, alveolar cells, mucus gland cells, and macrophages. Disease onset is 1 to 4 days following exposure (Longman and Johnson, 2007). In most healthy adults, infection is self-limited. Pneumonia is the most common complication, and it is difficult to distinguish from bacterial pneumonia. At Parkland Hospital during the 2003–2004 influenza season, pneumonia developed in 12 percent of pregnant women with influenza (Laibl and Sheffield, 2006).

Primary influenza pneumonitis is the most severe and is characterized by sparse sputum production and radiographic interstitial infiltrates (**Fig. 46-3**). More commonly, secondary pneumonia develops from bacterial superinfection by streptococci or staphylococci after 2 to 3 days of initial clinical improvement. The Centers for Disease Control and Prevention (2007a) reported a number of cases in which community-acquired methicillin-resistant staphylococci caused influenza-associated pneumonitis with a case-fatality rate of 25 percent.

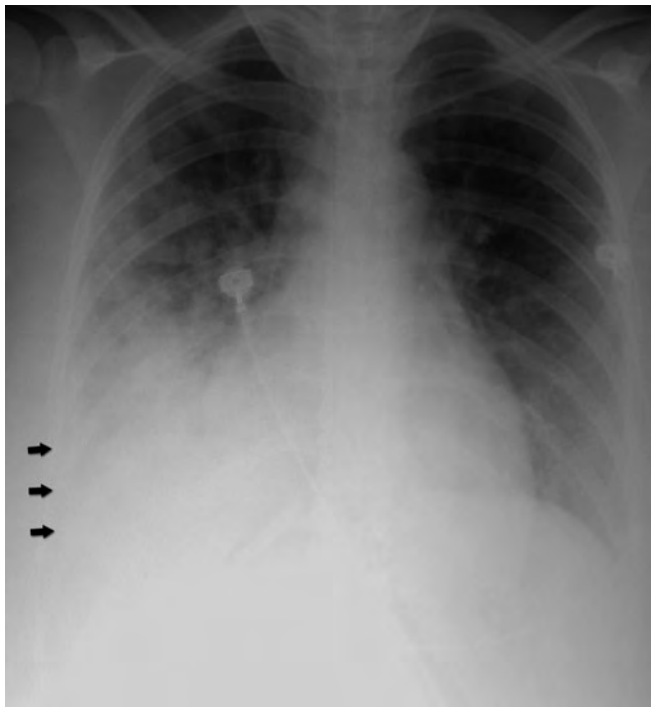

FIGURE 46-3 Chest radiograph of a 30-week pregnant woman with confirmed influenza A pneumonia. Extensive right lower lung field opacification (*arrows*), which represents parenchymal infiltrate and pleural effusion, obscures the right hemidiaphragm. (Used with permission from Dr. Vanessa Laibl Rogers.)

Management

Hospitalizations for influenza during late pregnancy are increased compared with nonpregnant women (Dodds and colleagues, 2007; Schanzer and associates, 2007). Supportive treatment with antipyretics and bed rest is recommended for uncomplicated influenza. Rapid resistance of influenza A (H3N2) strains to *amantadine* or *rimantadine* in 2005 prompted the Centers for Disease Control and Prevention (2006) to recommend against their use. Instead, *neuraminidase inhibitors* were given within 2 days of symptoms onset for chemoprophylaxis and treatment of influenza A and B (see Chap. 58, p. 1212). The drugs interfere with the release of progeny virus from infected host cells and thus prevent infection of new host cells (Moscona, 2005). *Oseltamivir* is given orally, 75 mg twice daily, or *zanamivir* is given by inhalation, 10 mg twice daily. The drugs shorten the course of illness by 1 to 2 days, and they may reduce the risk for pneumonitis. Our practice is to treat all pregnant women who are admitted for severe influenza whether or not pneumonitis is identified. There are few data on the use of these agents in pregnant women, but the drugs were not teratogenic in animal studies and are considered low risk (Briggs and colleagues, 2005).

The concerns that resistance to oseltamivir would develop proved correct, and there was sudden and rapid resistance by influenza A (H1N1) strains during the 2007–2008 flu season

(Gooskens and colleagues, 2009). In December 2008, a CDC Health Advisory was issued with recommendations for treatment of influenza A with oseltamivir *and* amantadine or rimantadine. If the predominate strain in the community is known do be H1N1, then an adamantane is used. However, with the H3N2 strain, oseltamivir is given instead. Local isolates can be determined by visiting the website for the Centers for Disease Control and Prevention.

Other concerns for viral resistance are for avian H5N1 strain isolated in Southeast Asia, which is a candidate virus for an influenza pandemic with a projected mortality rate that exceeds 50 percent (Beigi, 2007; World Health Organization, 2008). Currently, international efforts are being made to produce a vaccine effective against this strain (World Health Organization, 2007).

Prevention

Vaccination for influenza A is recommended and is discussed in detail in Chapter 58 (p. 1213). Prenatal vaccination also affords protection for a third of infants for at least 6 months (Zaman and colleagues, 2008).

Effects on Pregnancy

Severe viral pneumonitis is life-threatening during pregnancy. Other possible adverse effects of influenza A and B on pregnancy outcome are discussed in Chapter 58 (p. 1212).

Varicella Pneumonia

Infection with varicella-zoster virus—chicken pox—results in pneumonitis in 5 percent of pregnant women (Harger and colleagues, 2002). Diagnosis and management are considered in Chapter 58 (p. 1211).

Fungal and Parasitic Pneumonia

Fungal and parasitic pulmonary infections are usually of greatest consequence in immunocompromised hosts, especially in women with acquired immunodeficiency syndrome (AIDS).

Pneumocystis Pneumonia

Lung infection with *Pneumocystis jiroveci*, formerly called *Pneumocystis carinii*, is a common complication in women with AIDS. The opportunistic fungus causes interstitial pneumonia characterized by dry cough, tachypnea, dyspnea, and diffuse radiographic infiltrates. Although this organism can be identified by sputum culture, bronchoscopy with lavage or biopsy may be necessary.

In a report from the AIDS Clinical Trials Centers, Stratton and colleagues (1992) described pneumocystis pneumonia as the most common HIV-related disorder in pregnant women. Ahmad and co-workers (2001) reviewed 22 cases during pregnancy and cited a 50-percent mortality rate. Treatment is with trimethoprim-sulfamethoxazole or the more toxic pentamidine (Walzer, 2005). Experience with dapsone or atovaquone is limited. In some cases, tracheal intubation and mechanical ventilation may be required.

Prophylaxis. A number of international health agencies recommend prophylaxis with one double-strength trimethoprim-sulfamethoxazole tablet daily for some HIV-infected pregnant women. These include women with $CD4^+$ T-lymphocyte counts less than 200/μL, those whose $CD4^+$ T lymphocytes constitute less than 14 percent, or if there is an AIDS-defining illness, particularly oropharyngeal candidiasis (Centers for Disease Control and Prevention, 2008a). After their systematic review, Forna and colleagues (2006) concluded that the benefits of prophylaxis outweighed any risks.

Fungal Pneumonia

Any of a number of fungi can cause pneumonia, and in pregnancy, these are usually seen in women with HIV infection or who are otherwise immunocompromised. Infection is usually mild and self-limited. It is characterized initially by cough and fever, and dissemination is infrequent.

Histoplasmosis and *blastomycosis* do not appear to be more common or more severe during pregnancy. Data concerning *coccidioidomycosis* are conflicting. In a case-control study from an endemic area, Rosenstein and co-workers (2001) reported that pregnancy was a significant risk factor for disseminated disease. In another study, however, Caldwell and colleagues (2000) identified 32 serologically confirmed cases during pregnancy and documented dissemination in only three cases. Arsura (1998) and Caldwell (2000) and their associates reported that pregnant women with symptomatic infection had a better overall prognosis if there was associated *erythema nodosum.* Crum and Ballon-Landa (2006) recently reviewed 80 cases of coccidioidomycosis complicating pregnancy. Almost all women diagnosed in the third trimester had disseminated disease. Although the overall maternal mortality rate was 40 percent, it was only 20 percent for 29 cases reported since 1973. Spinello and colleagues (2007) have recently reviewed coccidioidomycosis in pregnancy.

Most cases of *cryptococcosis* reported during pregnancy were manifest as meningitis. Ely and co-workers (1998) described four otherwise healthy pregnant women with cryptococcal pneumonia. Diagnosis is difficult, because clinical presentation is similar to that of other community-acquired pneumonias.

The 2007 IDSA/ATS guidelines recommend itraconazole as preferred therapy for disseminated fungal infections (Mandell and colleagues, 2007). Pregnant women with disseminated fungal infections have also been given intravenous *amphotericin B* or *ketoconazole* (Hooper and associates, 2007; Paranyuk and colleagues, 2006). Amphotericin B has been used extensively in pregnancy with no embryofetal effects. Because of evidence that fluconazole, itraconazole, and ketoconazole may be embryotoxic in large doses in early pregnancy, Briggs and colleagues (2005) recommend that use at this time should be avoided if possible. Later in pregnancy, however, use of itraconazole seems reasonable.

There are three echinocandin derivatives—*caspofungin*, *micafungin*, and *anidulafungin*—that are effective for invasive candidiasis (Medical Letter, 2006; Reboli and colleagues, 2007). They are embryotoxic and teratogenic in laboratory animals, but use in human pregnancies has not been reported (Briggs and associates, 2005).

Severe Acute Respiratory Syndrome (SARS)

This coronaviral respiratory infection was first identified in China in 2002. It causes atypical pneumonitis with a case-fatality rate of approximately 5 percent (Centers for Disease Control

and Prevention, 2003b). Most cases were reported from Asia with an outbreak in Canada (Yudin and associates, 2005). Experience with SARS in pregnancy comes mostly from Wong (2004) and Lam (2004) and their colleagues from Hong Kong. From their review, Longman and Johnson (2007) reported a case-fatality rate in pregnancy of up to 25 percent. Ng and associates (2006) reported that the placentas from seven of 19 cases showed abnormal intervillous or subchorionic fibrin deposition in three, and extensive fetal thrombotic vasculopathy in two. One recent report noted improvement in maternal respiratory function when a pregnant woman with SARS underwent cesarean delivery (Oram and colleagues, 2007).

TUBERCULOSIS

Although tuberculosis is still a major worldwide concern, it is uncommon in the United States. As shown in **Figure 46-4,** the incidence of *active tuberculosis* decreased by almost half in the decade ending in 2003. Because the incidence in foreign-born persons did not change, over half of active cases in this country are in immigrants (Centers for Disease Control and Prevention, 2009a). Importantly, from 10 to 15 million persons in the United States have *latent tuberculosis* manifest by a positive tuberculin skin test. U.S.-born persons have newly acquired infection, whereas foreign-born persons usually have reactivation of latent infection (Geng and co-workers, 2002). In this country, tuberculosis is a disease of the elderly, the urban poor, minority groups, and patients with AIDS.

Infection is via inhalation of *Mycobacterium tuberculosis*, which incites a granulomatous pulmonary reaction. In more than 90 percent of patients, infection is contained and is dormant for long periods. In some patients, especially those who are immunocompromised or who have other diseases, tuberculosis becomes reactivated to cause clinical disease. Manifestations usually include cough with minimal sputum production, low-grade fever, hemoptysis, and weight loss. A variety of infiltrative patterns are seen on chest radiograph, and there may be associated cavitation or mediastinal lymphadenopathy. Acid-fast bacilli are seen on stained smears of sputum in about two thirds of culture-positive patients. Extrapulmonary tuberculosis may occur in any organ, and almost 40 percent of affected HIV-positive patients have disseminated disease (Weinberger and Weiss, 1999).

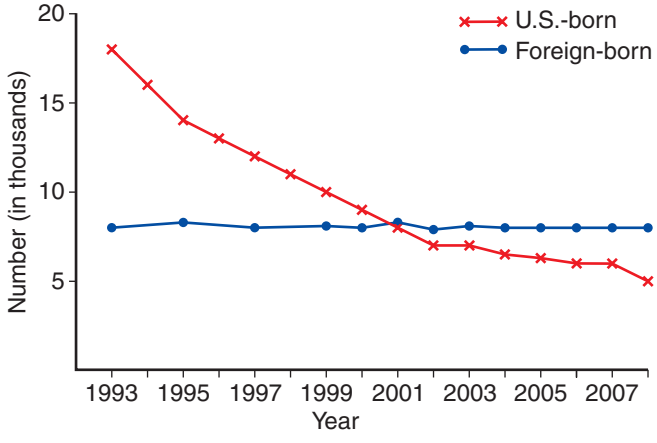

FIGURE 46-4 Number of cases of active tuberculosis reported in the United States from 1993 through 2006. (Adapted from Centers for Disease Control and Prevention, 2009a)

Treatment

Cure rates with 6-month short-course *directly observed therapy*—DOT—approach 90 percent for new infections. Resistance to antituberculosis drugs was first manifest in the United States in the early 1990s following the epidemic from 1985 through 1992 (Centers for Disease Control and Prevention, 2007b). Strains of *multidrug-resistant tuberculosis (MDR-TB)* increased rapidly as TB incidence fell during the 1990s (Fig. 46-4). Because of this, the Centers for Disease Control and Prevention (2003a) now recommends a four-drug regimen for initial empirical treatment of patients with symptomatic tuberculosis. Isoniazid, rifampin, pyrazinamide, and ethambutol are given until susceptibility studies are performed. Other second-line drugs may need to be added. Drug susceptibility is performed on all first isolates.

In 2005, there was a worldwide emergence of *extensively drug-resistant tuberculosis—XDR-TB.* This is defined as resistance in vitro to at least the first-line drugs isoniazid and rifampin as well as to three or more of the six main classes of second-line drugs—aminoglycosides, polypeptides, fluoroquinolones, thioamides, cycloserine, and para-aminosalicylic acid (Centers for Disease Control and Prevention, 2009b). Like their predecessor MDR-TB, these extensively resistant strains predominate in foreign-born persons (Tino and associates, 2007).

Tuberculosis and Pregnancy

The considerable influx of women into the United States from Asia, Africa, Mexico, and Central America has been accompanied by an increased frequency of tuberculosis in pregnant women. Sackoff and co-workers (2006) reported positive-tuberculin tests in half of 678 foreign-born women attending perinatal clinics in New York City. Almost 60 percent were newly diagnosed. Pillay and co-workers (2004) stress the prevalence of tuberculosis in HIV-positive pregnant women. Margono and colleagues (1994) reported that for two New York City hospitals, more than half of pregnant women with active tuberculosis were HIV positive. At Jackson Memorial Hospital in Miami, Schulte and associates (2002) reported that 21 percent of 207 HIV-infected pregnant women had a positive skin test.

Without antituberculosis therapy, pregnancy likely has adverse effects on the course of active tuberculosis (Anderson, 1997). Contemporaneous experiences are few, because chemotherapy has diminished severe disease. Outcomes are dependent on the site of infection and timing of diagnosis in relation to delivery. Jana and colleagues (1994) from India and Figueroa-Damian and Arrendondo-Garcia (1998) from Mexico City reported that active pulmonary tuberculosis was associated with increased incidences of preterm delivery, low-birthweight and growth-restricted infants, and perinatal mortality. From her review, Efferen (2007) cited twofold increased rates of low-birthweight and preterm infants as well as preeclampsia. The perinatal mortality rate was increased almost tenfold. Adverse outcomes correlate with late diagnosis, incomplete or irregular treatment, and advanced pulmonary lesions.

TABLE 46-5. Groups at High Risk for Having Latent Tuberculosis Infection

Healthcare workers
Contact with infectious person(s)
Foreign-born
HIV-infected
Working or living in homeless shelters
Alcoholics
Illicit drug use
Detainees and prisoners

From Centers for Disease Control and Prevention (2005a).

Extrapulmonary tuberculosis is less common. Jana and coworkers (1999) reported outcomes in 33 pregnant women with renal, intestinal, and skeletal tuberculosis, and a third had low-birthweight newborns. Llewelyn and associates (2000) reported that 9 of 13 pregnant women had extrapulmonary disease associated with delayed diagnoses. Prevost and Fung Kee Fung (1999) reviewed 56 cases of tuberculous meningitis, which were associated with maternal death in a third. Other presentations have included cervical spine tuberculosis with paraplegia, widespread intraperitoneal tuberculosis simulating ovarian carcinomatosis and degenerating leiomyoma, and hyperemesis gravidarum from tubercular meningitis (Kutlu, 2007; Moore, 2008; Nanda, 2002; Sherer, 2005, and all their colleagues).

Diagnosis

Current guidelines from the Centers for Disease Control and Prevention (2005a) include skin testing of pregnant women who are in any of the high-risk groups shown in **Table 46-5.** The preferred antigen is purified protein derivative (PPD) of intermediate strength of 5 tuberculin units. If the intracutaneously applied test is negative, no further evaluation is needed. A positive skin test measures ≥5 mm in diameter and requires evaluation for active disease, including a chest radiograph (Centers for Disease Control and Prevention, 2005b). It also may be interpreted according to risk factors proposed by the American Thoracic Society/Centers for Disease Control and Prevention (1990). For *very high-risk* patients—that is, those who are HIV-positive, those with abnormal chest radiography, or those who have a recent contact with an active case—5 mm or greater is considered treatable. For those at *high risk*—foreign-born individuals, intravenous drug users who are HIV-negative, low-income populations, or those with medical conditions that increase the risk for tuberculosis—10 mm or greater is considered treatable. For persons with none of these risk factors, 15 mm or greater is defined as requiring treatment.

The in vitro *QuantiFERON-TB Gold test* is recommended by the Centers for Disease Control and Prevention (2005a, b) for the same indications as skin testing to diagnosis latent infection. It has not been evaluated as extensively as tuberculin skin testing. Both the QuantiFERON-TB Gold test and the new T-Spot *TB* have been extensively reviewed by Lalvani (2007) and shown to be useful in identifying patients with latent TB and at risk for progression to active disease. They also distinguish between immune responses due to infection and responses resulting from bacille Calmette-Guérin (BCG) vaccination (Ernst and colleagues, 2007).

Essential laboratory methods for detection or verification of infection—both active and latent—include microscopy, culture, nucleic acid amplification assay, and drug-susceptibility testing (Centers for Disease Control and Prevention, 2009b).

Treatment

Different schemes are recommended for latent and active tuberculosis.

Latent Infection. In nonpregnant tuberculin-positive patients who are younger than 35 years and who have no evidence of active disease, isoniazid, 300 mg orally daily, is given for 1 year. Isoniazid has been used for decades, and it is considered safe in pregnancy (Briggs and colleagues, 2005). Compliance is a major problem, and Sackoff (2006) and Cruz (2005) and their associates reported a disappointing 10-percent treatment completion. One obvious disconnect is that care for tuberculosis is given in health systems different from prenatal care. These observations are important because most recommend that isoniazid therapy be delayed until after delivery. Because of possibly increased isoniazid-induced hepatitis risk in postpartum women, some recommend withholding treatment until 3 to 6 months after delivery. That said, neither method is as effective as antepartum treatment to prevent active infection. Boggess and colleagues (2000) reported that only 42 percent of 167 tuberculin-positive asymptomatic women delivered at San Francisco General Hospital completed 6-month therapy that was not given until the first postpartum visit.

There are exceptions to delayed treatment in pregnancy. Known recent skin-test convertors are treated antepartum because the incidence of active infection is 3 percent in the first year. Skin-test-positive women exposed to active infection are treated because the incidence of infection is 0.5 percent per year. Finally, HIV-positive women are treated because they have an 8-percent annual risk of active disease (Brost and Newman, 1997).

Active Infection. Recommended initial treatment for active tuberculosis in pregnant patients is a three-drug regimen with isoniazid, rifampin, and ethambutol. In areas in which the prevalence of isoniazid-resistant tuberculosis is high, pyrazinamide is added to the initial regimen until susceptibility testing is completed. If the organism is susceptible, the regimen is given for 9 months. Reports of MDR-TB during pregnancy are few, and Lessnau and Qarah (2003) and Shin and colleagues (2003) have reviewed treatment options. Breast feeding is not prohibited during antituberculous therapy. Pregnant women receiving isoniazid should also be given pyridoxine, 25 mg/day orally, to decrease hepatic toxicity.

For HIV-infected women, the use of rifampin or rifabutin may be contraindicated if certain protease inhibitors or nonnucleoside reverse transcriptase inhibitors are being administered. If there is resistance to rifabutin or rifampin, then pyrazinamide therapy is given. Of the second-line regimens, the aminoglycosides—streptomycin, kanamycin, amikacin, and capreomycin—are ototoxic to the fetus and are contraindicated (Briggs and associates, 2005).

Neonatal Tuberculosis

Tubercular bacillemia can infect the placenta, but in only a few of these, the fetus is also infected to cause *congenital tuberculosis.* The term also applies to newborns who are infected by aspiration of infected secretions at delivery. Each route of infection constitutes about half of the cases. Neonatal tuberculosis simulates other congenital infections and manifests with hepatosplenomegaly, respiratory distress, fever, and lymphadenopathy (Smith, 2002).

Cantwell and associates (1994) reviewed 29 cases of congenital tuberculosis reported since 1980. Only 12 of the mothers had active infection, and tuberculosis was commonly demonstrated by postpartum endometrial biopsy. Adhikari and colleagues (1997) described 11 South African postpartum women whose endometrial biopsy was culture-positive. Six of their neonates had congenital tuberculosis.

Neonatal infection is unlikely if the mother with active disease has been treated before delivery or if her sputum culture is negative. Because the newborn is susceptible to tuberculosis, most authors recommend isolation from the mother suspected of having active disease. If untreated, the risk of disease in the infant born to a woman with active infection is 50 percent in the first year (Jacobs and Abernathy, 1988).

SARCOIDOSIS

Sarcoidosis is a chronic, multisystem disease of unknown etiology characterized by an accumulation of T lymphocytes and phagocytes within noncaseating granulomas (Noor and Knox, 2007; Rossman and Kreider, 2007). Predisposition to the disease is genetically determined and characterized by an exaggerated response of helper T lymphocytes to environmental triggers (Grunewald and Eklund, 2007; Moller, 2007; Spagnolo and du Bois, 2007). Pulmonary involvement is most common, followed by skin, eyes, and lymph nodes. The prevalence of sarcoid in the United States is 10 to 40 per 100,000, with equal sex distribution, but it is 10 times more common for black compared with white persons (Crystal, 2005). Most patients are between 20 and 40 years. Clinical presentation varies, but more than half of patients have dyspnea and a dry cough without constitutional symptoms that develop insidiously over months. Disease onset is abrupt in about 25 percent of patients, and 10 to 20 percent are asymptomatic at discovery.

Pulmonary symptoms are dominant, and more than 90 percent of patients have an abnormal chest radiograph at some point (Lynch and associates, 2007). *Interstitial pneumonitis* is the hallmark of pulmonary involvement. Approximately 50 percent of affected patients develop permanent radiological changes. *Lymphadenopathy,* especially of the mediastinum, is present in 75 to 90 percent of cases, and 25 percent have *uveitis.* A fourth have skin involvement, usually manifest as *erythema nodosum.* In women, sarcoid causes about 10 percent of cases of erythema nodosum (Mert and colleagues, 2007). Finally, any other organ system may be involved. Confirmation of diagnosis is with biopsy, and because the lung may be the only obviously involved organ, tissue acquisition is often difficult.

The overall prognosis for sarcoidosis is good, and it resolves without treatment in 50 percent of patients. Still, there is diminished quality of life (de Vries and Drent, 2007). In the other 50 percent, permanent organ dysfunction, albeit mild and nonprogressive, persists. About 10 percent die because of their disease.

Glucocorticoids are the most widely used treatment, and methotrexate is second-line medication. Permanent organ derangement is seldom reversed by their use (Paramothayan and Jones, 2002). Thus, the decision to treat is based on symptoms, physical findings, chest radiograph, and pulmonary function tests. Unless respiratory symptoms are prominent, therapy is usually withheld for a several-month observation period. If inflammation does not subside, then prednisone, 1 mg/kg, is given daily for 4 to 6 weeks (Crystal, 2005).

Sarcoidosis and Pregnancy

Because sarcoidosis is uncommon and is frequently benign, it is not seen often in pregnancy. De Regt (1987) described 14 cases in 20,000 pregnancies over a 12-year period—almost 1 in 1500. Although sarcoidosis seldom affects pregnancy adversely, serious complications such as meningitis, heart failure, and neurosarcoidosis have been described (Cardonick, 2000; Maisel, 1996; Seballos, 1994, and all their colleagues).

In general, perinatal outcomes are unaffected by sarcoidosis. Selroos (1990) reviewed 655 patients with sarcoidosis referred to the Mjölbolsta Hospital District in Finland. Of 252 women between 18 and 50 years, 15 percent had sarcoidosis during pregnancy or within 1 year postpartum. There was no evidence for disease progression in the 26 pregnancies in women with active disease. Three aborted spontaneously, and the other 23 women were delivered at term. In 18 pregnancies in 12 women with inactive disease, pregnancy outcome was good. Agha and colleagues (1982) reported similar experiences with 35 pregnancies at the University of Michigan.

Active sarcoidosis is treated using the same guidelines as for the woman who is not pregnant. Severe disease warrants serial determination of pulmonary function. Symptomatic uveitis, constitutional symptoms, and pulmonary symptoms are treated with prednisone, 1 mg/kg orally per day.

CYSTIC FIBROSIS

One of the most common fatal genetic disorders in Caucasians, cystic fibrosis is caused by one of more than 1000 mutations in a 230-kb gene on the long arm of chromosome 7 that encodes a 1480–amino acid polypeptide (Rowe and co-workers, 2005). This peptide functions as a chloride channel and is termed the *cystic fibrosis transmembrane conductance receptor regulator (CFTR).* There is a wide phenotypic variation, even among homozygotes for the common ΔF508 mutation (Rowntree and Harris, 2003). This is discussed in greater detail in Chapter 13 (p. 298). Currently, nearly 80 percent of females with cystic fibrosis now survive to adulthood (Gillet and associates, 2002). Their median survival is about 30 years.

Pathophysiology

The mutations in the chloride channel cause altered epithelial cell membrane transport of electrolytes. This affects all organs

that express CFTR—secretory cells, sinuses, lung, pancreas, liver, and reproductive tract. Severity of the disease depends on which two alleles are inherited, and homozygosity for ΔF508 is one of the most severe (McKone and colleagues, 2003).

Exocrine gland ductal obstruction develops from thick, viscid secretions (Rowe and colleagues, 2005). In the lung, submucosal glandular ducts are affected. Eccrine sweat gland abnormalities are the basis for the diagnostic *sweat test*, characterized by elevated sodium, potassium, and chloride levels in sweat.

Lung involvement is commonplace and is frequently the cause of death. Bronchial gland hypertrophy with mucous plugging and small-airway obstruction lead to subsequent infection that ultimately causes chronic bronchitis and bronchiectasis. For complex and not completely explicable reasons, chronic inflammation from *Pseudomonas aeruginosa* occurs in more than 90 percent of patients. *Staphylococcus aureus, Haemophilus influenzae,* and *Burkholderia cepacia* are recovered in a minority (Rowe and associates, 2005). Colonization with the last has been reported to signify a worse prognosis, especially in pregnancy (Gillet and colleagues, 2002). Acute and chronic parenchymal inflammation ultimately causes extensive fibrosis, and along with airway obstruction, there is a ventilation–perfusion mismatch. Pulmonary insufficiency is the end result. Lung or heart–lung transplantation has a 5-year survival rate of 33 percent (Aurora and associates, 1999). A few women have successfully undergone pregnancy following lung transplantation (Kruszka and Gherman, 2002).

Preconceptional Counseling

Infertility

Women with cystic fibrosis are subfertile because of tenacious cervical mucus. Males have oligospermia or aspermia from vas deferens obstruction, and 98 percent are infertile (Boyd and co-workers, 1999). Despite this, the North American Cystic Fibrosis Foundation estimates that 4 percent of affected women become pregnant every year (Edenborough and colleagues, 1995). The endometrium and tubes express some CFTR but are normal functionally, and the ovaries do not express the *CFTR* gene (Edenborough, 2001). Both intrauterine insemination and in vitro fertilization have been used successfully in affected women (Rodgers and colleagues, 2000). A number of ethical considerations of undertaking pregnancy by these women were reviewed recently by Wexler and colleagues (2007). For male infertility, Sobczyńska-Tomaszewska and associates (2006) have emphasized the importance of molecular diagnosis.

Screening

The American College of Obstetricians and Gynecologists (2005) recommends that carrier screening be offered to at-risk couples. This is discussed in detail in Chapter 13 (p. 298). The Centers for Disease Control and Prevention have also recently added cystic fibrosis to newborn screening programs (Comeau and colleagues, 2007). This is discussed also in Chapter 28 (p. 598 and Table 28-5) and was recently the subject of a Cochrane Database review by Southern and associates (2009).

Pregnancy with Cystic Fibrosis

Pregnancy outcome is inversely related to severity of lung dysfunction. Severe chronic lung disease, hypoxia, and frequent infections may prove deleterious. At least in the past, c*or pulmonale* was common, but even that does not preclude successful pregnancy (Cameron and Skinner, 2005). In some women, *pancreatic dysfunction* may cause poor maternal nutrition. Normal pregnancy-induced insulin resistance frequently results in gestational diabetes after midpregnancy (Hardin and associates, 2005; McMullen and co-workers, 2006).

Cystic fibrosis per se is not affected by pregnancy (Edenborough, 2001). Early reports of a deleterious effect on the course of cystic fibrosis were related to severe disease (Olson, 1997). An important factor to be considered in childbearing is the long-term prognosis for the mother. When matched with nonpregnant women by disease severity, recent reports indicate no deleterious effects on long-term survival (Goss and co-workers, 2003; McMullen and associates, 2006).

Management

Prepregnancy counseling is imperative as discussed in Chapter 7 (p. 178). Women who choose to become pregnant should have close surveillance for development of superimposed infection, diabetes, and heart failure. They are followed closely with serial pulmonary function testing, for management as well as for prognosis. When the FEV_1 is at least 70 percent, women usually tolerate pregnancy well. Emphasis is placed on postural drainage, bronchodilator therapy, and control of infection.

β-adrenergic bronchodilators help to control airway constriction. Inhaled recombinant human deoxyribonuclease I improves lung function by reducing sputum viscosity (Boucher, 2005). Inhaled 7-percent saline has been shown to produce short- and long-term benefits (Donaldson and colleagues, 2006; Elkins and co-workers, 2006). Nutritional status is assessed and appropriate dietary counseling given. Pancreatic insufficiency is treated with replacement of oral pancreatic enzyme.

Infection is heralded by increasing cough and mucus production. Oral semisynthetic penicillins or cephalosporins usually suffice to treat staphylococcal infections. *Pseudomonas* is most problematic in adults. Inhaled tobramycin and colistin have been used successfully to control this organism (Ratjen and Döring, 2003).

Immediate hospitalization and aggressive therapy are warranted for serious pulmonary infections. The threshold for hospitalization with other complications is low. For labor and delivery, epidural analgesia is recommended.

Pregnancy Outcome

When Cohen and colleagues (1980) conducted the first major survey of cystic fibrosis centers, severity was assessed by the *Schwachman-Kulezycki* or *Taussig* scores based on radiological and clinical criteria. Although pregnancy outcomes were not disastrous, 18 percent of 129 women died within 2 years of giving birth. In a later review through 1991, Kent and Farquharson (1993) described similar outcomes in 215 pregnancies in 160 women.

More recent reports describe better outcomes, but there still are serious complications (Tonelli and Aitken, 2007). Severity of disease is now quantified by pulmonary function studies, which are the best predictor of pregnancy and long-term maternal outcome. Edenborough and colleagues (2000) reported 69 pregnancies from 11 cystic fibrosis centers in the United Kingdom. If prepregnancy FEV_1 was less than 60 percent of predicted, there was substantive risk of preterm delivery, respiratory complications, and death of the mother within a few years of childbirth.

Fitzsimmons and co-workers (1996) performed a case-control study of 258 women with cystic fibrosis who had a live birth. The 889 matched controls were women with cystic fibrosis who had not been pregnant. Pregnancy had no effect on worsening of any serious complications, and 8 percent in both groups had died by 2 years. Gillet and co-workers (2002) reported 75 pregnancies from the French Cystic Fibrosis Registry. Almost 20 percent of infants were delivered preterm, and 30 percent had growth restriction. The one maternal death was due to pseudomonas sepsis in a woman whose prepregnancy FEV_1 was 60 percent. Long-term, however, 17 percent of women died and four infants had confirmed cystic fibrosis.

Lung Transplantation

Cystic fibrosis is a common antecedent disease leading to lung transplantation. Gyi and colleagues (2006) reviewed 10 pregnancies in such women and reported successful outcomes with nine liveborn infants. Maternal outcomes were less favorable—three developed rejection during pregnancy, and all had progressively declining pulmonary function and died of chronic rejection by 38 months after delivery.

CARBON MONOXIDE POISONING

Carbon monoxide is a ubiquitous gas, and most nonsmoking adults have a carbon monoxyhemoglobin saturation of 1 to 3 percent. In cigarette smokers, levels may be as high as 5 to 10 percent. Carbon monoxide is the most common cause of poisoning worldwide (Stoller, 2007). Toxic levels are frequently encountered in inadequately ventilated areas warmed by space heaters.

Carbon monoxide is particularly toxic because it is odorless and tasteless and has a high affinity for hemoglobin binding. Thus, it displaces oxygen and impedes its transfer with resultant hypoxia. Besides acute sequelae including death and anoxic encephalopathy, cognitive defects develop in as many as half of patients following loss of consciousness or in those with carbon monoxide levels greater than 25 percent (Weaver and colleagues, 2002). Hypoxic brain damage has a predilection for the cerebral cortex and white matter and for the basal ganglia (Lo and co-workers, 2007; Prockop and Chichkova, 2007).

Pregnancy and Carbon Monoxide Poisoning

Through a number of physiological alterations, the rate of endogenous carbon monoxide production almost doubles in normal pregnancy (Longo, 1977). Although the pregnant woman is not more susceptible to carbon monoxide poisoning, the fetus does not tolerate excessive exposure. With chronic exposure, maternal symptoms usually appear when the carboxyhemoglobin concentration is 5 to 20 percent. Symptoms include headache, weakness, dizziness, physical and visual impairment, palpitations, and nausea and vomiting. With acute exposure, concentrations of 30 to 50 percent produce symptoms of impending cardiovascular collapse. Levels greater than 50 percent may be fatal for the mother.

Because hemoglobin F has an even higher affinity for carbon monoxide, fetal carboxyhemoglobin levels are 10 to 15 percent higher than those in the mother. This may be due to facilitated diffusion (Longo, 1977). Importantly, the half-life of carboxyhemoglobin is 2 hours in the mother but 7 hours in the fetus. Because carbon monoxide is bound so tightly to hemoglobin F, the fetus may be hypoxic even before maternal carbon monoxide levels are appreciably elevated. A number of anomalies are associated with embryonic exposure, and anoxic encephalopathy is the primary sequela of later fetal exposure (Alehan and colleagues, 2007; Aubard and Magne, 2000).

Treatment

For all victims, treatment of carbon monoxide poisoning is supportive along with immediate administration of 100-percent inspired oxygen. Indications for hyperbaric oxygen treatment in nonpregnant individuals are unclear (Kao and Nañagas, 2005). Weaver and co-workers (2002) reported that hyperbaric oxygen treatment minimized the incidence of cognitive defects in adults at both 6 weeks and 1 year compared with that of normobaric oxygen. Hyperbaric oxygen is generally recommended in pregnancy if there has been "significant" carbon monoxide exposure (Aubard and Magne, 2000; Ernst and Zibrak, 1998). The problem is how to define significant exposure. Although maternal carbon monoxide levels are not accurately predictive of those in the fetus, some clinicians recommend hyperbaric therapy if maternal levels exceed 15 to 20 percent. Treatment of the affected newborn with hyperbaric oxygen is also controversial (Bar and co-workers, 2007).

Elkharrat and colleagues (1991) reported successful hyperbaric treatments in 44 pregnant women. Silverman and Montano (1997) reported successful management of a woman whose abnormal neurological and cardiopulmonary findings abated in a parallel fashion with resolution of associated fetal heart rate variable decelerations. Greingor and colleagues (2001) used 2.5-atm hyperbaric 100-percent oxygen for 90 minutes in a 21-week pregnant woman who was delivered of a healthy infant at term. According to the Divers Alert Network (DAN) at Duke University (2009), there are 700 chambers in North and Central America and the Caribbean. Consultation from DAN is available at 919-684-8111.

CHAPTER 47

Thromboembolic Disorders

PATHOPHYSIOLOGY 1013
THROMBOPHILIAS 1014
DEEP-VENOUS THROMBOSIS 1019
SUPERFICIAL VENOUS THROMBOPHLEBITIS 1024
PULMONARY EMBOLISM 1024
THROMBOPROPHYLAXIS 1027

The risk of venous thrombosis and pulmonary embolism in otherwise healthy women is considered highest during pregnancy and the puerperium. Indeed, the risk of pulmonary embolism has been estimated to be as much as four- to six-fold higher during pregnancy (Christiansen and Collins, 2006; Marik and Plante, 2008). The incidence of all thromboembolic events averages about 1 per 1000 pregnancies, and about an equal number are identified antepartum and in the puerperium. In a recent study from Norway of more than 600,000 pregnancies, Jacobsen and colleagues (2008) reported that deep-venous thrombosis alone was more common antepartum whereas pulmonary embolism was more common in the first 6 weeks postpartum. The frequency of venous thromboembolic disease during the puerperium has decreased remarkably as early ambulation has become more widely practiced. Even so, there is evidence that it has increased 50 percent from 1999 to 2005 (Kuklina and associates, 2009). Importantly, pulmonary embolism still remains a leading cause of maternal death in the United States (see Table 1-2). By way of example, pulmonary embolism caused approximately 9 percent of the 623 pregnancy-related deaths in the United States in 2005 (Kung and co-workers, 2008).

PATHOPHYSIOLOGY

In 1856, Rudolf Virchow postulated the conditions that predispose to the development of venous thrombosis: (1) stasis, (2) local trauma to the vessel wall, and (3) hypercoagulability. The risk for each increases during normal pregnancy. For example, compression of the pelvic veins and inferior vena cava by the enlarging uterus renders the venous system of the lower extremities particularly vulnerable to stasis (see Chap. 5, p. 119). From their review, Marik and Plante (2008) cite a 50-percent reduction in venous flow velocity in the legs that lasts from the early third trimester until 6 weeks postpartum. This stasis is the most constant predisposing risk factor for venous thrombosis. Venous stasis and delivery may also contribute to endothelial cell injury. Lastly, marked increases in the synthesis of most clotting factors during pregnancy favor coagulation.

As shown in Table 47-1, there are a number of factors associated with an increased risk of developing thromboembolism during pregnancy. Using data from the Agency for Healthcare Research and Quality that included 90 percent of all hospital discharges during 2000 and 2001, James and co-workers (2006) identified the diagnosis of venous thromboembolism in 7177 women during pregnancy and 7158 during the postpartum period. They calculated that risks for thromboembolism were approximately doubled in women with multifetal gestation, anemia, hyperemesis, hemorrhage, and cesarean delivery. The risk was even greater in pregnancies complicated by postpartum infection. These data are consistent with those reported by Ros and associates (2002), who studied a population-based cohort of more than 1 million deliveries in Sweden. Compared with uncomplicated delivery, they calculated the relative risk of pulmonary embolism to be 4.8 with severe preeclampsia, 3.8 with cesarean delivery, 2.7 with diabetes, and 2.3 with multifetal gestation. By contrast, analyzing data from the United Kingdom Obstetrical Surveillance System, Knight (2008) found significantly increased risk with a body mass index (BMI) $\geq$ 30 kg/m^2 or with multiparity.

TABLE 47-1. Some Risk Factors Associated with an Increased Risk for Thromboembolism.

Risk Factor	Chapter Referral
Obstetrical	
Cesarean delivery	25
Diabetes	52
Hemorrhage and anemia	35
Hyperemesis	49
Immobility—prolonged bed rest	47
Multifetal gestation	39
Multiparity	
Preeclampsia	34
Puerperal infection	31
General	
Age 35 years or older	12
Cancer	57
Connective-tissue disease	54
Dehydration	
Immobility—long-distance travel	8
Infection and inflammatory disease	58
Myeloproliferative disease	51
Nephrotic syndrome	48
Obesity	43
Oral contraceptive use	32
Orthopedic surgery	42
Paraplegia	
Prior thromboembolism	47
Sickle cell disease	51
Smoking	8
Thrombophilia	47

The likelihood of developing a thrombosis during pregnancy is especially increased in women with certain genetic risk factors. Indeed, the American College of Chest Physicians now estimates that approximately half of pregnant women with thrombosis have an identifiable underlying genetic disorder (Bates and co-workers, 2008). Importantly, 50 to 60 percent of patients with a hereditary basis for thrombosis probably do not experience a thrombotic event until one of the other risk factors is present (American College of Obstetricians and Gynecologists, 2007).

THROMBOPHILIAS

Several important regulatory proteins act as inhibitors in the coagulation cascade. Normal values for many of these proteins during pregnancy are found in the Appendix. Inherited or acquired deficiencies of these inhibitory proteins are collectively referred to as *thrombophilias.* These can lead to hypercoagulability and recurrent venous thromboembolism. Although these disorders are collectively present in about 15 percent of white European populations, they are responsible for more than 50 percent of all thromboembolic events during pregnancy (Lockwood, 2002). Some aspects of the more common inherited thrombophilias are summarized in Table 47-2 and Figure 47-1. Recommendations for antepartum and postpartum thromboprophylaxis for women diagnosed with a thrombophilia are discussed later in this chapter (p. 1018).

There is a considerable variety of opinion concerning which patients should be advised to undergo thrombophilia testing (Scifres and Malone, 2008). Lockwood (2007) concluded that it would be prudent to test pregnant women with a history of venous thromboembolism associated with temporary and reversible risk factors because the presence of a thrombophilic state would be an indication for antepartum thromboprophylaxis. The current recommendation of the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) is that women with a personal or family history of venous thromboembolic disease be evaluated for hereditary and acquired thrombophilic disorders. In addition to these indications, a consensus panel organized by Aventis Pharmaceuticals—the manufacturer of enoxaparin (see p. 1022)—listed additional indications. They concluded that women with unexplained fetal loss at 20 weeks' gestation or later; severe preeclampsia or hemolysis, elevated liver enzymes, low platelet count (HELLP) syndrome before 34 weeks; or severe fetal-growth restriction may also benefit from thrombophilia screening (Duhl and associates, 2007). The American College of Chest Physicians takes a more conservative stance (Bates and colleagues, 2008). Because of uncertainty associated with the magnitude of risk as well as uncertainty associated with any benefits of prophylaxis given to prevent pregnancy complications in women with heritable thrombophilias, it remains unproven that screening is in the best interests of these women. We agree with this position.

Antithrombin Deficiency

This protein, previously known as antithrombin III, is one of the most important inhibitors of thrombin in clot formation. Antithrombin functions as a natural anticoagulant by binding to, and inactivating, thrombin and the activated coagulation factors IXa, Xa, XIa, and XIIa (Franchini and coworkers, 2006). Antithrombin deficiency may result from numerous mutations that are almost always autosomal dominant. Homozygous antithrombin deficiency is lethal (Katz, 2002).

Antithrombin deficiency is rare—it affects about 1 in 5000 individuals, and it is the most thrombogenic of the heritable coagulopathies. Indeed, the risk of thrombosis during pregnancy among antithrombin-deficient women *without* a personal or family history is 3 to 7 percent, and it is 11 to 40 percent with such a history (Lockwood, 2007). Given this risk, many recommend that these women be treated during pregnancy with heparin regardless of whether a prior thrombosis has occurred.

Seguin and colleagues (1994) reviewed the outcomes of 23 newborns with antithrombin deficiency. There were 11 cases of thrombosis and 10 deaths.

TABLE 47-2. Inherited Thrombophilias and Their Association with Venous Thromboembolism (VTE) in Pregnancy

Thrombophilia	Percentage of VTE During Pregnancy	Relative Risk (95% CI) of VTE During Pregnancy	Probability of VTE During Pregnancy and Postpartum in Patients Without Personal or Family History (Percent)
Factor V Leiden (homozygous)	<1[a]	25.4 (8.8–66)	1.5
Factor V Leiden (heterozygous)	44	6.9 (3.3–15.2)	0.26
Prothrombin G20201A (homozygous)	<1[a]	NA	2.8
Prothrombin G20201A (heterozygous)	17	9.5 (2.1–66.7)	0.37
Factor V Leiden and prothrombin G20201A (compound heterozygous)	<1[a]	84 (19–369)	4.7
Hyperhomocyste-inemia			
Antithrombin deficiency[b] (heterozygous)	1–8	119 (N/A)	3–7.2
Protein S deficiency[c] (heterozygous)	12.4	NA	<1–6.6
Protein C deficiency[d] (heterozygous)	<14	13 (1.4–123)	0.8–1.7

[a] = Calculated based on Hardy-Weinbery equation.
[b] = Less than 60-percent activity.
[c] = Less than 55-percent activity.
[d] = Less than 50-percent activity.
CI = confidence interval; NA = not available; VTE = venous thromboembolism.
Adapted from Lockwood (2007).

Protein C Deficiency

When thrombin is bound to thrombomodulin on endothelial cells of small vessels, its procoagulant activities are neutralized. It also activates protein C, a natural anticoagulant that in the presence of protein S controls thrombin generation, in part, by inactivating factors Va and VIIIa (see Fig. 47-1). Activated protein C also inhibits the synthesis of plasminogen-activator inhibitor 1.

More than 160 different protein C gene mutations have been described. The prevalence of protein C deficiency is 2 to 3 per 1000, and inheritance is autosomal dominant. These prevalence estimates correspond with functional activity cutoff values of 50 to 60 percent, which are used by most laboratories and which are associated with a six- to 12-fold increased risk for venous thromboembolism (Lockwood, 2007).

Protein S Deficiency

This circulating anticoagulant is activated by protein C to decrease thrombin generation. Protein S deficiency may be caused by more than 130 different mutations with an aggregate prevalence of about 2 per 1000 (Lockwood, 2007). Protein S deficiency is measured by antigenically determined free, functional, and total S levels. All three of these levels decline substantively during normal gestation, thus the diagnosis in pregnant women—as well as in those taking certain oral contraceptives—is difficult (Archer and associates, 1999). Detection of free protein S antigen levels of less than 55 percent in nonpregnant patients and less than 30 percent in pregnant women appears to most closely correlate with a mutated gene. Using such criteria, the prevalence of free protein S deficiency is low—0.03 to 0.13 percent—and as shown in Table 47-2, its degree of thrombogenicity is modest (Lockwood, 2007).

Conard and colleagues (1990) described thrombosis in 5 of 29 pregnant women with protein S deficiency. One woman had a cerebral vein thrombosis. Similarly, Burneo and associates (2002) reported cerebral venous thrombosis at 14 weeks. Neonatal homozygous protein C or S deficiency is usually associated with a severe clinical phenotype known as *purpura fulminans*, which is characterized by extensive thromboses in the microcirculation soon after birth leading to skin necrosis (Salonvaara and colleagues, 2004).

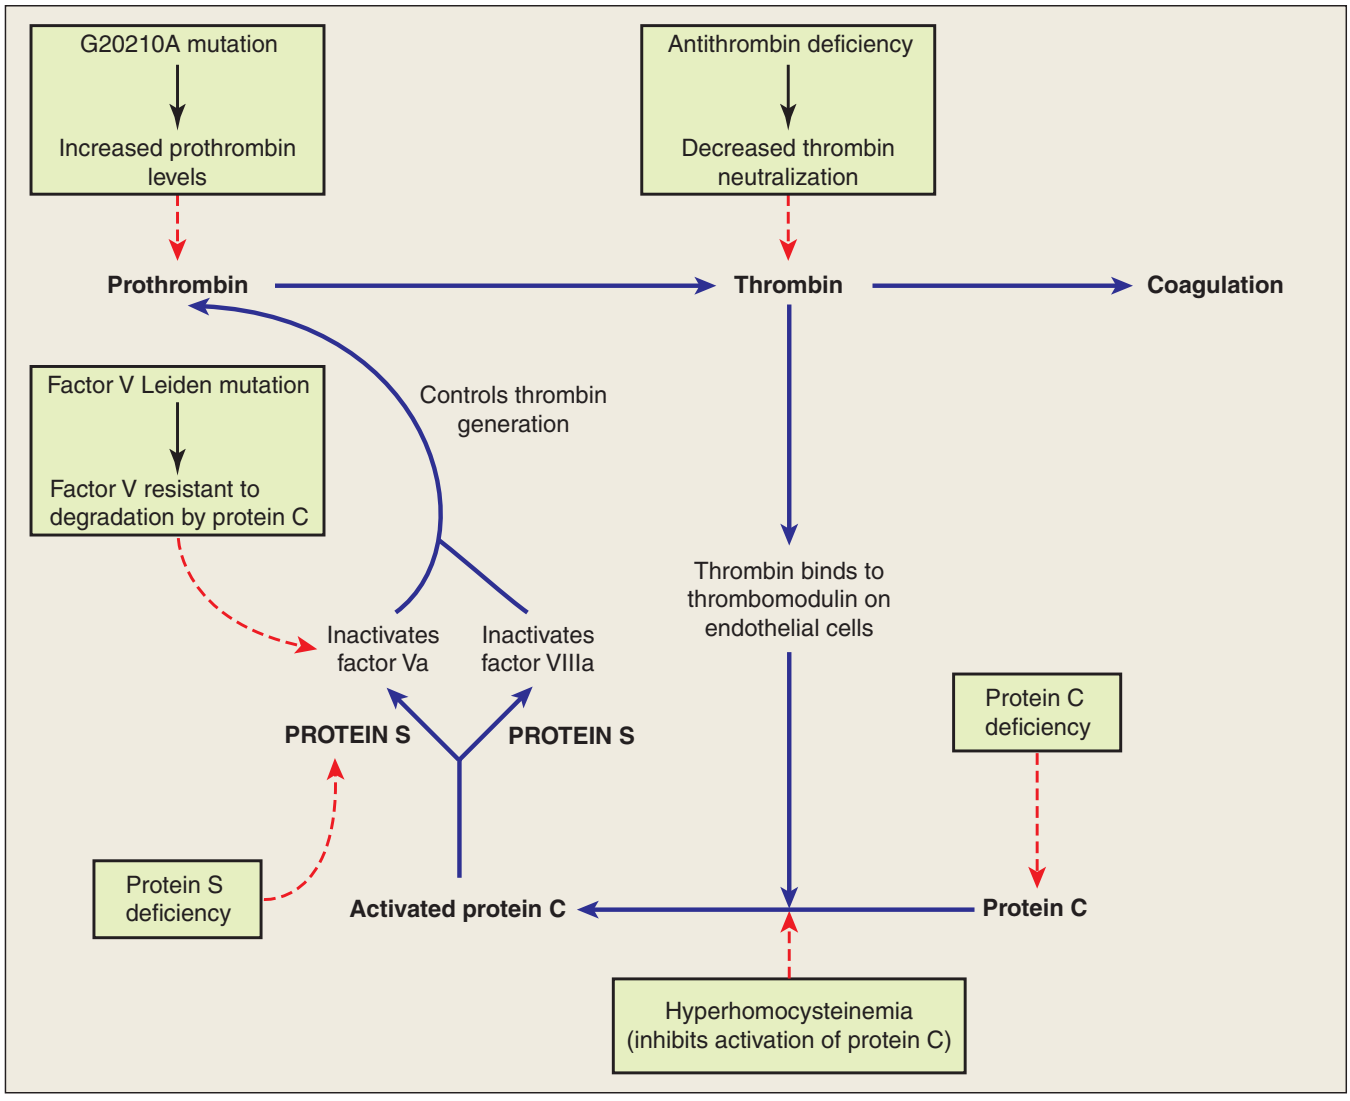

FIGURE 47-1 Overview of the inherited thrombophilias and their effect(s) on the coagulation cascade. (Adapted from Seligsohn and Lubetsky, 2001.)

Activated Protein C Resistance (Factor V Leiden Mutation)

The most prevalent of the known thrombophilic syndromes, this condition is characterized by resistance of plasma to the anticoagulant effects of activated protein C. A number of mutations have been described, but the most common is the factor V Leiden mutation, which was named after the city where it was described. This missense mutation in the factor V gene results in a substitution of glutamine for arginine at position 506 in the factor V polypeptide, which confers resistance to degradation by activated protein C (Kalafatis and colleagues, 1994). The unimpeded abnormal factor V protein retains its procoagulant activity and predisposes to thrombosis (see Fig. 47-1).

Heterozygous inheritance for factor V Leiden is the most common heritable thrombophilia. It is found in 3 to 15 percent of select European populations, 3 percent of African Americans, and it is virtually absent in African blacks and Asians (Lockwood, 2007). Moreover, factor V Leiden mutation is found in up to half of nonpregnant individuals with thromboembolic disease. Homozygous inheritance of two aberrant copies is rare and increases the risk of thrombosis during pregnancy by more than tenfold (Lockwood, 2007).

Diagnosis is made in one of two ways. In the bioassay, resistance to activated protein C is measured (Bloomenthal and colleagues, 2002). One caveat is that activated protein C resistance can also be caused by the antiphospholipid antibody syndrome (Eldor, 2001). More importantly, and as discussed in Chapter 5 (p. 117), resistance is normally increased after early pregnancy because of alterations in other coagulation proteins (Walker and associates, 1997). Thus, during pregnancy, DNA analysis for the mutant factor V gene is used to confirm the diagnosis.

In a comprehensive review of 63 studies, Biron-Andreani and associates (2006) reported that the Leiden mutation was associated with a four- to eightfold increased risk of a first-episode venous thromboembolism during pregnancy. Despite the large number of publications, however, they cautioned that data remain limited. One of the more meticulously executed studies was a prospective observational study of

approximately 5000 women conducted by the Maternal-Fetal Medicine Units Network (Dizon-Townson and associates, 2005). These investigators found that the heterozygous mutant gene incidence was 2.7 percent. Of the three pulmonary emboli and one deep-venous thrombosis—a rate of 0.8 per 1000 pregnancies—none were among these carriers. There was no increased risk of preeclampsia, placental abruption, fetal-growth restriction, or pregnancy loss in heterozygous women. The investigators concluded that universal prenatal screening for the Leiden mutation and prophylaxis for carriers without a prior venous thromboembolism is not indicated. Clark and colleagues (2002) concluded that such routine prenatal screening was not cost effective.

Prothrombin G20210A Mutation

This missense mutation in the prothrombin gene leads to excessive accumulation of prothrombin, which then may be converted to thrombin. Found in approximately 2 percent of the white population, it is extremely uncommon in nonwhites (Federman and Kirsner, 2001). Case-control studies suggest that the relative risk of thromboembolism is increased 3- to 15-fold during pregnancy (Gerhardt and associates, 2000; Martinelli and colleagues, 2002).

Homozygous patients and those who co-inherit a G20210A mutation with a factor V Leiden mutation have an even greater risk of thromboembolism. Stefano and associates (1999) performed a retrospective cohort study of 624 nonpregnant patients with one prior episode of deep-venous thrombosis. They found that those doubly heterozygous individuals had a 2.6-fold increased risk of recurrence relative to those with the homozygous Leiden mutation alone. They concluded that carriers of both mutations are candidates for lifelong anticoagulation after a first thrombotic episode.

Hyperhomocysteinemia

The most common cause of elevated homocysteine is the C667T thermolabile mutation of the enzyme 5,10-methylenetetrahydrofolate reductase (MTHFR). Inheritance is autosomal recessive, and Kupferminc and co-workers (1999) found a homozygote prevalence of 8 percent in normally pregnant women. Elevated levels of homocysteine may also result from deficiency of one of several enzymes involved in methionine metabolism and from correctible nutritional deficiencies of folic acid, vitamin B_6, or vitamin B_{12} (Hague, 2003; McDonald and Walker, 2001). During normal pregnancy, mean homocysteine plasma concentrations are decreased (López-Quesada and colleagues, 2003; McDonald and Walker, 2001). Thus, to make a diagnosis in pregnancy, Lockwood (2002) recommends a fasting cutoff level of >12 μmol/L to define hyperhomocysteinemia.

The precise pathological mechanism(s) by which high levels of homocysteine increase the risk of thromboembolism remains undefined. Possible pathways include decreased activation of protein C as well as interference with the ability of activated protein C to inactivate factor Va (Gatt and Makris, 2007). Although hyperhomocysteinemia is associated with an increased risk of venous thromboembolism in nonpregnant patients, it is unclear whether MTHFR C667T homozygotes have an increased risk during pregnancy. It may be that reduced risk is related to physiologically lower homocysteine levels during pregnancy and/or that most pregnant women take folic acid supplements (Bates and co-workers, 2008). Recall that folic acid serves as a cofactor in the remethylation reaction of homocysteine to methionine. Also of note, hyperhomocysteinemia increases the lifetime risk of having a fetus with a neural-tube defect as well as premature atherosclerosis (see Chap. 12, p. 281).

Other Thrombophilia Mutations

A number of potentially thrombophilic polymorphisms are being discovered at an ever-increasing rate. Unfortunately, information regarding the prognostic significance of such newly discovered rare mutations is limited.

Protein Z Deficiency

This vitamin K-dependent protein serves as a cofactor in the inactivation of factor Xa (see Chap. 5, p. 117). Studies in nonpregnant patients have found that low levels of protein Z are associated with an increased risk of thromboembolism (Santacroce and associates, 2006). Preliminary studies in pregnant women have suggested that low protein Z levels may be associated with early pregnancy losses, preterm labor, fetal-growth restriction, and late-pregnancy fetal demise (Bretelle and co-workers, 2005; Kusanovic and associates, 2007; Vasse, 2008).

Antiphospholipid Antibodies

These autoantibodies are detected in about 2 percent of patients who have nontraumatic venous thrombosis. The antibodies are directed against cardiolipin(s) or against phospholipid-binding proteins such as β_2-glycoprotein I. They are commonly found in patients with systemic lupus erythematosus and are described in Chapter 54 (see p. 1151). Women with moderate-to-high levels of these antibodies may have *antiphospholipid syndrome,* which is defined by a number of clinical features such as thromboembolism or certain obstetrical complications that include.

1. at least one otherwise unexplained fetal death at or beyond 10 weeks;
2. at least one preterm birth before 34 weeks; or
3. at least three consecutive spontaneous abortions before 10 weeks.

In these patients, thromboembolism—either venous or arterial—most commonly involves the lower extremities. Importantly, the syndrome also should be considered in women with thromboses in unusual sites, such as the portal, mesenteric, splenic, subclavian, and cerebral veins (American College of Obstetricians and Gynecologists, 2005). Antiphospholipid antibodies are also a predisposing factor for arterial thromboses. In fact, they account for up to 5 percent of arterial strokes in otherwise healthy young women (see Chap. 55, p. 1168). Thromboses may occur in relatively unusual locations, such as the retinal, subclavian, brachial, or digital arteries.

Branch and Khamashta (2003) and Levine and colleagues (2002) have reviewed a number of hypotheses proposed to

TABLE 47-3. Obstetrical Complications Associated with Some Inherited and Acquired Thrombophilias

Thrombophilia	Early Pregnancy Loss	Stillbirth	Preeclampsia	Placental Abruption	Fetal-Growth Restriction
FVL—homozygous	**2.7 (1.3–5.6)**	2.0 (0.4–9.7)	1.9 (0.4–7.9)	8.4 (0.4–171.2)	4.6 (0.2–115.7)
FVL—heterozygous	**1.7 (1.1–2.6)**	**2.1 (1.1–3.9)**	**2.2 (1.5–3.3)**	**4.7 (1.1–19.6)**	2.7 (0.6–12.1)
Prothrombin—heterozygous	**2.5 (1.2–5.0)**	**2.7 (1.3–5.5)**	**2.5 (1.5–4.2)**	**7.7 (3.0–19.8)**	2.9 (0.6–13.7)
MTHFR—homozygous	1.4 (0.8–2.6)	1.3 (0.9–1.1)	**1.4 (1.1–1.8)**	1.5 (0.4–5.4)	1.2 (0.8–1.8)
Hyperhomocysteinemia	**6.3 (1.4–28.4)**	1.0 (0.2–5.6)	**3.5 (1.2–10.1)**	2.4 (0.4–15.9)	N/A
Antithrombin deficiency	0.9 (0.2–4.5)	7.6 (0.3–196.4)	3.9 (0.2–97.2)	1.1 (0.1–18.1)	N/A
Protein C deficiency	2.3 (0.2–26.4)	3.1 (0.2–38.5)	5.2 (0.3–102.2)	5.9 (0.2–151.6)	N/A
Protein S deficiency	3.6 (0.4–35.7)	**20.1 (3.7–109.2)**	2.8 (0.8–10.6)	2.1 (0.5–9.3)	N/A
Acquired activated protein C resistance	**4.0 (1.7–9.8)**	0.9 (0.2–3.9)	1.8 (0.7–4.6)	1.3 (0.4–4.4)	N/A
Anticardiolipin antibody	**3.4 (1.3–8.7)**	**3.3 (1.6–6.7)**	**2.7 (1.7–4.5)**	1.4 (0.4–4.8)	**6.9 (2.7–17.7)**
Lupus anticoagulant	**3.0 (1.0–8.6)**	2.4 (0.8–7.0)	1.5 (0.8–2.8)	N/A	N/A

Data presented as odds ratios (95-percent confidence intervals). Bolded numbers are statistically significant.
FVL = factor V Leiden, MTHFR = methylenetetrahydrofolate reductase, N/A = data not available.
Data from Robertson and associates (2005).

explain mechanism(s) by which antiphospholipid antibodies promote thrombosis. For example, they may interfere with the normal function of phospholipids or phospholipid-binding proteins involved in coagulation regulation, including prothrombin, protein C, annexin V, and tissue factor. Many of these antibodies are directed against β_2-glycoprotein I, which may itself function as a natural anticoagulant (see Chap. 54, p. 1151). Another proposed mechanism is that these antibodies promote thrombosis through augmented platelet and/or complement activation.

Thrombophilias and Pregnancy Complications

Considerable attention has been directed recently toward a possible relationship between thrombophilias and certain pregnancy complications other than venous thrombosis (De Santis and associates, 2006). Table 47-3 summarizes the findings of 79 studies systematically reviewed by Robertson and associates (2005). The heterogeneity of these findings is apparent. For example, only heterozygous factor V Leiden and prothrombin gene mutations are consistently associated with most of these adverse outcomes. Recent investigations continue to underscore the heterogeneity of results. For example, Kahn and co-workers (2009) found no increased risk for early-onset or severe preeclampsia in women with factor V Leiden mutation, prothrombin G20210A mutation, MTHFR C677T polymorphism, or hyperhomocysteinemia. Falcao and associates (2009) found no association between the latter thrombophilia and the development of preeclampsia in an animal model. Conversely, Facchinetti and colleagues (2009) found that recurrent preeclampsia was significantly more common in Italian women diagnosed with a thrombophilia. The associations between thrombophilias and certain pregnancy complications are discussed in greater detail in other chapters: preeclampsia and *HELLP syndrome* (see Chap. 34, p. 748), fetal-growth restriction (see Chap. 38, p. 848), placental abruption (see Chap. 35, p. 764), recurrent miscarriage (see Chap. 9, p. 224), stillbirth (see Chap. 29, p. 631), and placental findings of intervillous or spiral artery thrombosis (see Chap. 27, p. 579).

Thrombophilia Prophylaxis to Prevent Adverse Pregnancy Outcomes

There are no randomized trials to guide prophylaxis to prevent recurrent adverse pregnancy outcomes in women with any of the inherited thrombophilias. Even so, some recommend consideration for empirical aspirin and/or low-molecular-weight heparin (Lockwood, 2002). There are a few observational studies designed to assess the efficacy of treatment during pregnancy. De Carolis and co-workers (2006) treated 38 women with an inherited thrombophilia and a prior thromboembolic event and/or poor obstetrical outcome during 39 consecutive pregnancies. Among the previous pregnancies, only 18 resulted in a live birth, and only 12 neonates survived. In general, treatment during subsequent pregnancies consisted of enoxaparin, 40 mg daily in those with previous pregnancy complications, and 60 mg daily in those with a prior thromboembolic event. Among the 39 subsequent pregnancies, 32 resulted in a term delivery, six delivered preterm, and there was one spontaneous abortion. There were no thromboembolic events. In another observational study, Folkeringa and associates (2007) observed that thromboprophylaxis resulted in a significant reduction in the rate of historical fetal loss in women with hereditary deficiencies of antithrombin, protein C, or protein S. Similarly, Leduc and colleagues (2007) in a retrospective chart review found that the combination of dalteparin (see p. 1022) and low-dose aspirin given to women with an inherited thrombophilia and a prior pregnancy complicated by fetal death, placental abruption, early-onset severe preeclampsia, or fetal-growth

restriction decreased the risks of the latter two in a subsequent pregnancy. Other observational studies have not found improved perinatal outcomes with heparin (Warren and co-workers, 2009).

DEEP-VENOUS THROMBOSIS

Clinical Presentation

Most cases of venous thrombosis during pregnancy are probably confined to the deep veins of the lower extremity. The frequency and extent to which they involve the pelvic veins is not known precisely, but preliminary observations indicate that iliac vein thrombosis may be frequent in those after cesarean delivery (Rodger and colleagues, 2006). The signs and symptoms vary greatly and depend in large measure on the degree of occlusion and the intensity of the inflammatory response. Interestingly, most cases during pregnancy occur in the left leg. Ginsberg and colleagues (1992) reported that 58 of 60 antepartum women—97 percent—had left leg thromboses. Blanco-Molina and co-workers (2007) reported that 78 percent were diagnosed in the left leg. Our experiences at Parkland Hospital are similar—90 percent of lower extremity thromboses involved the left leg. Greer (2003) hypothesizes that this may result from compression of the left iliac vein by the right iliac artery and ovarian artery, both of which cross the vein only on the left side. Yet, as described in Chapter 5 (p. 124), the ureter is compressed more on the right side!

Classical thrombosis involving the lower extremity is abrupt in onset, and there is pain and edema of the leg and thigh. The lower-extremity thrombus typically involves much of the deep venous system to the iliofemoral region. Occasionally, reflex arterial spasm causes a pale, cool extremity with diminished pulsations. Conversely, there may be appreciable clot, yet little pain, heat, or swelling. Importantly, calf pain, either spontaneous or in response to squeezing or to stretching the Achilles tendon—*Homans sign*—may be caused by a strained muscle or a contusion.

A fourth of untreated cases have an associated pulmonary embolism. Anticoagulation reduces this risk to less than 5 percent as discussed subsequently.

Diagnosis

Because clinical diagnosis of deep-venous thrombosis is difficult, other methods are imperative for confirmation. For example, in one study of pregnant women, clinical diagnosis was confirmed in only 10 percent of patients (Hull and co-workers, 1990). Shown in **Figure 47-2** is one algorithm promulgated by the American College of Obstetricians and Gynecologists that can be used for evaluation of pregnant women. With a few modifications, we follow a similar evaluation at Parkland Hospital. Importantly, many of the tests used commonly in various diagnostic algorithms that have been extensively investigated in nonpregnant patients have not been validated in pregnant women. These include compression ultrasonography (CUS), ventilation-perfusion scintigraphy, and helical computed tomography-angiography (Nijkeuter and co-workers, 2006).

Venography

Invasive contrast venography remains the standard to exclude lower extremity deep-venous thrombosis (Chunilal and Ginsberg, 2001). It has a negative-predictive value of 98 percent, and as discussed in Chapter 41 (p. 921), fetal radiation exposure without shielding is only about 300 mrad (Nijkeuter and co-workers, 2006). But venography is associated with significant

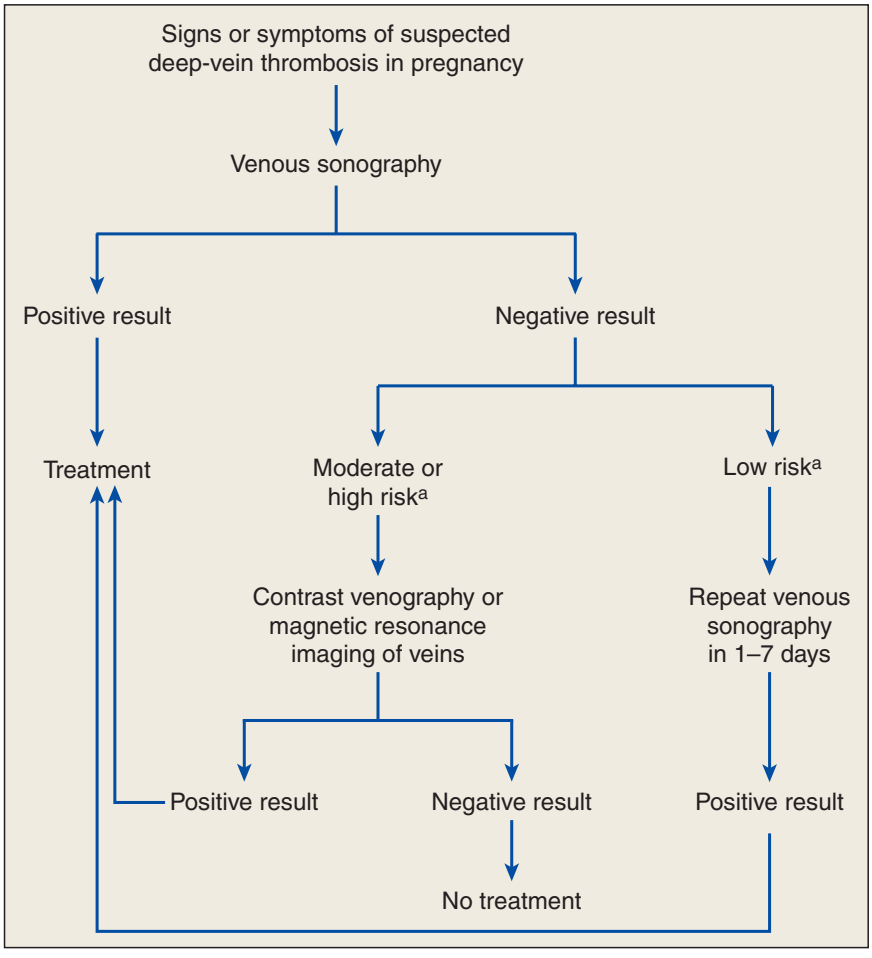

FIGURE 47-2 Algorithm for evaluation of suspected deep-venous thrombosis in pregnancy. *Pretest risk score calculated by assigning 1 point for each of the nine following characteristics: active cancer, immobilization, bed rest more than 3 days or surgery within 12 weeks, local tenderness, entire leg swollen, asymmetric calf swelling greater than 3 cm when measured 10 cm below tibial tuberosity, pitting edema only in symptomatic leg, collateral nonvaricose superficial veins, or prior deep-venous thrombosis. Two points are subtracted if an alternative diagnosis is at least as likely as deep-venous thrombosis. [a]High risk = 3 or more points, moderate risk = 1 or 2 points, low risk = 0 or less points. (From Lockwood, 2007, with permission.)

complications, including thrombosis, and it is time consuming and cumbersome. Thus, noninvasive methods are usually used to confirm the clinical diagnosis.

Impedance Plethysmography

This is an extremely accurate test to assess thromboses in the lower iliac, femoral, and popliteal veins. It is based on the observation that alterations in venous return in the calf, produced by inflation and deflation of a pneumatic thigh cuff, result in changes in electrical resistance detected at the skin surface. These changes occur when the popliteal or more proximal veins are obstructed (Chunilal and Ginsberg, 2001). Impedance plethysmography, however, is only 50-percent sensitive for detection of clots in the small calf veins (Davis, 2001). Moreover, because of decreased venous return of the lower extremities, it is associated with increased false-positive results during pregnancy (Andres and Miles, 2001). Given these limitations as well as the wide availability of ultrasonography, it is seldom used today.

Compression Ultrasonography

This noninvasive technique is currently the most-used first-line test to detect deep-venous thrombosis (Greer, 2003). The diagnosis is based on the noncompressibility and typical echoarchitecture of a thrombosed vein (Davis, 2001). In symptomatic nonpregnant patients, examination of the femoral, popliteal, and calf trifurcation veins is more than 90-percent sensitive and more than 99-percent specific for proximal thrombosis. Moreover, it has a negative-predictive value of 98 percent (American College of Obstetricians and Gynecologists, 2000a, b).

For *nonpregnant* patients with suspected thrombosis, the safety of withholding anticoagulation has been established for those who have normal serial compression examinations over a week (Birdwell and co-workers, 1998; Heijboer and associates, 1993). Specifically, in these nonpregnant patients, isolated calf thromboses extend into the proximal veins in up to a fourth of cases. They do so within 1 to 2 weeks of presentation and are usually detected by serial ultrasonographic compression.

In *pregnant* women, the important caveat is that normal findings with venous ultrasonography results do not always exclude a pulmonary embolism. This is because the thrombosis may have already embolized or because it arose from deep pelvic veins inaccessible to ultrasound evaluation (Goldhaber and colleagues, 2004). **In pregnant women, thrombosis associated with pulmonary embolism frequently originates in the iliac veins.** Moreover, the natural history of calf deep-venous thrombosis during pregnancy is unknown. Thus, the safety of withholding anticoagulation with negative compression ultrasonography has not been evaluated in pregnant women who may have an isolated iliac vein thrombosis that is less accessible for imaging (Bates and Ginsberg, 2002).

Computed Tomography

Spiral computed tomography (CT) scanning is widely available and very useful for detecting lower extremity deep-venous thrombosis as well as those within the vena cava and iliac and pelvic venous systems. Although radiation and contrast agents are required, the benefits of CT outweigh any theoretical risks if lead shielding is used. Fetal radiation exposure is negligible unless the pelvic veins are imaged (see Chap. 41, p. 918).

Magnetic Resonance (MR) Imaging

This imaging technique allows excellent delineation of anatomical detail above the inguinal ligament. Thus, in many cases, MR imaging is immensely useful for diagnosis of iliofemoral and pelvic vein thrombosis. The venous system can also be reconstructed using MR venography as discussed in Chapter 41 (see p. 921 and Fig. 41-5). Erdman and co-workers (1990) reported that MR imaging was 100-percent sensitive and 90-percent specific for detection of venographically proven deep-venous thrombosis in nonpregnant patients. Importantly, almost half of those without deep-venous thrombosis had detectable nonthrombotic conditions to explain the clinical findings. These included cellulitis, myositis, edema, hematomas, and superficial phlebitis. More recent studies have confirmed the high levels of sensitivity and specificity as well as the additional advantage of low interobserver variability (Palareti and associates, 2006).

D-Dimer Screening Tests

These specific fibrin degradation products are generated when fibrinolysin degrades fibrin, as occurs in thromboembolism. Their measurement is frequently incorporated into diagnostic algorithms for venous thromboembolism in nonpregnant patients (Kelly and Hunt, 2002; Wells and co-workers, 2003). Screening with the D-dimer test in pregnancy, however, is problematic for a number of reasons. Depending on assay sensitivity, D-dimer serum levels increase with gestational age along with substantively elevated plasma fibrinogen concentrations (Kenny and associates, 2009). In a serial study of 50 healthy women, Kline and colleagues (2005) found not only that D-dimer levels increased progressively during pregnancy, but that 22 percent of women in midpregnancy and no women in the third trimester had a D-dimer concentration below 0.50 mg/L—a conventional cut-off used to exclude thromboembolism. D-Dimer concentrations can also be elevated in certain pregnancy complications such as placental abruption, preeclampsia, and sepsis syndrome. For these reasons, their use during pregnancy remains uncertain, but a negative D-dimer test should be considered reassuring (Lockwood, 2007; Marik and Plante, 2008).

Management

Optimal management of venous thromboembolism during pregnancy has not undergone major clinical studies to provide evidence-based practices (Copplestone and colleagues, 2004). There is, however, consensus for treatment with anticoagulation and limited activity. If thrombophilia testing is performed, it is done before anticoagulation because heparin induces a decline in antithrombin levels, and warfarin decreases protein C and S concentrations (Lockwood, 2002).

Anticoagulation is initiated with either unfractionated or low-molecular-weight heparin. During pregnancy, heparin therapy is continued, and for postpartum women, anticoagulation is begun simultaneously with warfarin. Recall that pulmonary embolism develops in about 25 percent of patients with

untreated venous thrombosis, and anticoagulation decreases this risk to less than 5 percent. In nonpregnant patients, the mortality rate is less than 1 percent (Douketis and co-workers, 1998; Weiss and Bernstein, 2000).

Over several days, leg pain dissipates. After symptoms have abated, graded ambulation should be started. Elastic stockings are fitted and anticoagulation is continued. Recovery to this stage usually takes 7 to 10 days.

Heparinization

Treatment of thromboembolism during pregnancy is with either unfractionated or low-molecular-weight heparin. Although either type is acceptable, most recommend one of the low-molecular-weight heparins. In its recently revised guidelines, the American College of Chest Physicians suggests preferential use of this heparin class during pregnancy but scores this recommendation a Grade 2C level of evidence—the lowest quality (Bates and colleagues, 2008; Guyatt and co-workers, 2008).

Unfractionated Heparin (UFH)

Treatment is with an intravenous heparin bolus followed by continuous infusion titrated to achieve full anticoagulation. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) recommend an initial bolus of intravenous unfractionated heparin at a dose of 80 units/kg. This is followed by continuous infusion of at least 30,000 IU for 24 hours, titrated to achieve an activated partial thromboplastin time (aPTT) of 1.5 to 2.5 times control values. There are a number of protocols to accomplish this, and the one used at Parkland Hospital is shown in Table 47-4. Intravenous anticoagulation should be maintained for at least 5 to 7 days, after which, treatment is converted to subcutaneous heparin. Injections are then given every 8 hours to maintain the aPTT to at least 1.5 to 2.5 times control throughout the dosing interval. For women with antiphospholipid syndrome, aPTT does not accurately assess heparin anticoagulation, and thus anti-factor Xa levels are preferred.

The duration of full anticoagulation varies, and there are several acceptable schemes. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) recommend therapeutic anticoagulation for at least 3 months after the acute event. The American College of Chest Physicians (Bates and colleagues, 2008) recommends anticoagulation throughout pregnancy and for 6 weeks postpartum but for a minimum total duration of 6 months. Lockwood (2007) recommends full anticoagulation be continued for at least 20 weeks followed by prophylactic doses if the woman is still pregnant. Prophylactic doses of subcutaneous unfractionated heparin can range from 5000 to 10,000 units every 12 hours titrated to maintain an antifactor Xa level of 0.1 to 0.2 units, measured 6 hours after the last injection. If the venous thromboembolism occurs during the postpartum period, Lockwood (2007) recommends a minimum of 6 months of anticoagulation treatment.

Low-Molecular-Weight Heparin

This is a family of derivatives of unfractionated heparin, and their molecular weights average 4000 to 5000 daltons compared with 12,000 to 16,000 daltons for conventional heparin. None of these heparins cross the placenta, and all exert their anticoagulant activity by activating antithrombin. The primary difference is in their relative inhibitory activity against factor Xa and thrombin (Garcia and Spyropoulos, 2008). Specifically, unfractionated heparin has equivalent activity against factor Xa and thrombin, but low-molecular-weight heparins have greater activity against factor Xa than thrombin. They also have a more predictable anticoagulant response and fewer bleeding complications than unfractionated heparin because of their better bioavailability, longer half-life, dose-independent clearance, and decreased interference with platelets (Tapson, 2008). Their major drawback is expense.

A number of studies have shown that venous thromboembolism is treated effectively with low-molecular-weight heparin (Quinlan and colleagues, 2004; Tapson, 2008). Using serial venograms, Breddin and co-workers (2001) observed that low-molecular-weight heparins were more effective than the unfractionated form in reducing thrombus size without increasing mortality rates or major bleeding complications.

Pharmacokinetics in Pregnancy. Several low-molecular-weight heparins are available for use in pregnancy and include

TABLE 47-4. Parkland Hospital Protocol for Continuous Heparin Infusion for Patients with Venous Thromboembolism

Initial Heparin Dose:
_____units IV push (recommended 80 units/kg rounded to nearest 100, maximum 7500 units), then
_____units/hr by infusion (recommended 18 units/kg/hr rounded to nearest 50).

Infusion Rate Adjustments—based on partial thromboplastin time (PTT):

PTT (sec)[a]	Intervention[b]	Baseline Infusion Rate Change[c]
<45	80 units/kg bolus	↑ by 4 units/kg/hr
45–54	40 units/kg bolus	↑ by 2 units/kg/hr
55–84	None	None
85–100	None	↓ by 2 units/kg/hr
>100	Stop infusion 60 minutes	↓ by 3 units/kg/hr

[a]PTT goal 55–84; [b]Rounded to nearest 100; [c]Rounded to nearest 50.

enoxaparin, dalteparin, and tinzaparin. *Enoxaparin (Lovenox)* pharmacokinetics were studied by Casele and colleagues (1999) in 13 pregnant women. They were given 40 mg subcutaneously daily, and serial measurements of anti-factor Xa activity were determined during early pregnancy, the third trimester, and then postpartum. They concluded that, likely because of increased renal clearance, twice-daily dosing may be necessary to maintain anti-factor Xa activity above 0.1 U/mL. They also suggested that optimal dosing was best achieved with periodic monitoring of peak activity—about 3.5 hours after a dose—and predose anti-factor Xa activity.

Rodie and co-workers (2002) studied 36 women with venous thromboembolism during pregnancy or immediately postpartum who were treated with enoxaparin. The dose was approximately 1 mg/kg given twice daily based on early pregnancy weight. Treatment was monitored by peak anti-factor Xa activity 3 hours postinjection, with a target therapeutic range of 0.4–1.0 U/mL. In 33 women, enoxaparin provided satisfactory anticoagulation. In the other three women, dose reduction was necessary. None developed recurrent thromboembolism or bleeding complications.

Dalteparin (Fragmin) pharmacokinetics were studied by Sephton and associates (2003) in a longitudinal investigation of 24 pregnant women. Those given once-daily dalteparin subcutaneously had mean anti-factor Xa levels that were significantly lower across pregnancy compared with levels measured 6 weeks' postpartum.

Smith and co-workers (2004) reported similar results with *tinzaparin (Innohep)* given as a once-daily 50 U/kg dose. They found that a dosage of 75 to 175 U/kg/day was necessary to achieve peak anti-factor Xa levels of 0.1 to 1.0 U/mL.

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) recommend that anti-factor Xa levels be periodically reevaluated during pregnancy in a woman fully anticoagulated with these agents. Monitoring anti-Xa levels during pregnancy is especially important in women who also have impaired renal or hepatic function, weigh less than 50 kg or greater than 100 kg, or have risk factors for bleeding (Duhl and associates, 2007). Dosing should be enough to achieve a peak anti-factor Xa level of 0.5 to 1.2 U/mL. Importantly, each low-molecular-weight heparin compound has a somewhat different pharmacodynamic pattern. Thus, a peak concentration of 1.0 U/mL may be appropriate in an enoxaparin-treated patient but may be an overdose in a dalteparin-treated patient (Gris and associates, 2006).

For women given thromboprophylaxis, most authorities do not recommend monitoring anti-factor Xa levels. Fox and colleagues (2008) reviewed anti-factor Xa levels in 77 women given "pregnancy-adjusted" doses of either dalteparin or enoxaparin for thromboprophylaxis. They reported that a fourth of 321 determinations showed "subtherapeutic" levels defined as less than 0.2 to 0.4 units/mL. They called for consideration of such monitoring. At this time, however, this is considered unnecessary for prophylactic dosing because the "therapeutic range" is uncertain (Bates and associates, 2008).

Safety in Pregnancy. Early reviews by Sanson and associates (1999) and Lepercq and co-workers (2001) concluded that low-molecular-weight heparins were safe and effective. Despite this, in 2002, the manufacturer of Lovenox warned that its use in pregnancy had been associated with congenital anomalies and an increased risk of hemorrhage. After its own extensive review, the American College of Obstetricians and Gynecologists (2002) concluded that these risks were rare, that their incidence was not higher than expected, and that no cause-and-effect relationship had been established. The committee further concluded that enoxaparin and dalteparin could be given safely during pregnancy. A subsequent review by Deruelle and Coulon (2007) also confirmed their safety.

Caveats are that low-molecular-weight heparins should not be used in women with prosthetic heart valves because of reports of valvular thrombosis (see Chap. 44, p. 964). They also should be avoided in women with renal failure (Krivak and Zorn, 2007). When given within 2 hours of cesarean delivery, these agents increase the risk of wound hematoma (van Wijk and co-workers, 2002). Lee and Goodwin (2006) described development of a massive subchorionic hematoma associated with enoxaparin use. Frosnes and associates (2009) reported a woman who developed a spontaneous thoracolumbar epidural hematoma that required surgical drainage.

As discussed in Chapter 19 (p. 457), use of low-molecular-weight heparins may also increase the risk of *spinal hematoma* associated with regional analgesia. As a result, the American Academy of Pediatrics and American College of Obstetricians and Gynecologists (2007) advise that women receiving once-daily prophylactic low-dose low-molecular-weight heparin not be offered regional analgesia until at least 10 to 12 hours after the last injection. In addition, low-molecular-weight heparin should be withheld for at least 2 hours after the removal of an epidural catheter. The safety of regional analgesia in women receiving twice-daily therapeutic low-molecular-weight heparin has not been studied sufficiently, and it is not known whether delaying regional techniques for 24 hours after the last injection is adequate. Of note, *protamine sulfate* (see p. 1024) may help partially reverse the effects of low-molecular-weight heparin.

Anticoagulation with Warfarins

Warfarin derivatives are generally contraindicated because they readily cross the placenta and cause fetal death and malformations from hemorrhages (see Chap. 14, p. 325). Like unfractionated and low-molecular-weight heparin, however, they are safe during breast feeding (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2007; Bates and associates, 2004).

Postpartum venous thrombosis is usually treated with intravenous heparin and oral warfarin initiated simultaneously. To avoid paradoxical thrombosis and skin necrosis from the early anti-protein C effect of warfarin, these women are maintained on therapeutic doses of unfractionated or low-molecular-weight heparin for 5 days and until the international normalized ratio (INR) is in a therapeutic range (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2007). The initial dose of warfarin is usually 5 to 10 mg for the first 2 days. Subsequent doses are titrated to achieve an INR of 2 to 3.

Brooks and colleagues (2002) compared anticoagulation in postpartum women with that of age-matched nonpregnant controls. Recently delivered women required a significantly larger median total dose of warfarin—45 versus 24 mg—and a longer time—7 versus 4 days—to achieve the target INR. Moreover, the mean maintenance dose was higher in postpartum women compared with that in the control group—4.9 versus 4.3 mg.

Duration of Therapy

The optimal duration of continued anticoagulation after delivery is uncertain, but anticoagulation with warfarin is continued for at least 4 to 6 weeks. Most recommendations have been extrapolated from studies in nonpregnant patients (Kearon and colleagues, 1999; Ridker and co-workers, 2003). This is problematic because most studies in nonpregnant patients included bedridden older patients with medical complications. The current consensus of the American College of Chest Physicians is that warfarin anticoagulation be given for at least 6 weeks postpartum, but to complete a minimum 6-month course following the initial episode (Bates and colleagues, 2008). Lockwood (2007) recommends a minimum of 6 weeks. As previously mentioned (see p. 1021), most agree that deep-venous thrombosis that develops postpartum requires a minimum of 6 months of anticoagulation (Lockwood, 2007).

Complications of Anticoagulation

Three significant complications associated with anticoagulation are hemorrhage, thrombocytopenia, and osteoporosis. The latter two are unique to heparin, and their risk may be reduced with low-molecular-weight heparins (American College of Obstetricians and Gynecologists, 2000). The most serious complication is hemorrhage, which is more likely if there has been recent surgery or lacerations. Troublesome bleeding also is more likely if the heparin dosage is excessive. Unfortunately, management schemes using laboratory testing to identify when a heparin dosage is sufficient to inhibit further thrombosis, yet not cause serious hemorrhage, have been discouraging.

Heparin-Induced Thrombocytopenia

There are two types of *heparin-induced thrombocytopenia*—commonly referred to as *HIT*. The most common is a *nonimmune*, benign, reversible form that occurs within the first few days of therapy and resolves in about 5 days without cessation of therapy (American College of Obstetricians and Gynecologists, 2000). The second is the more severe form of HIT, which results from an *immune* reaction involving IgG antibodies directed against complexes of platelet factor 4 and heparin. When most severe, HIT paradoxically causes thrombosis, which is the most common presentation. The American College of Chest Physicians advises that the diagnosis of HIT be considered when the platelet count decreases by 50 percent between 5 and 14 days after the initiation of heparin therapy (Greinacher and Warkentin, 2006).

The incidence of HIT is approximately 3 to 5 percent in nonpregnant individuals. Interestingly, however, Fausett and colleagues (2001) reported no cases of HIT among 244 heparin-treated pregnant women compared with 10 among 244 nonpregnant controls. The American College of Obstetricians and Gynecologists (2000) recommends that platelet counts be measured on day 5 and then periodically for the first 2 weeks of heparin therapy. If unchanged, further platelet counts are not indicated because most cases manifest within 15 days of standard heparin initiation.

If thrombocytopenia is severe, heparin therapy must be stopped and alternative anticoagulation initiated. Low-molecular-weight heparin may not be an entirely safe alternative because it has some cross reactivity with unfractionated heparin. In these cases, many recommend *danaparoid*—a sulfated glycosaminoglycan heparinoid. In a review of approximately 50 pregnant women with either HIT or skin rashes, Lindhoff-Last and associates (2005) also concluded that danaparoid was a reasonable alternative, however, *two fatal maternal hemorrhages and three fetal deaths were recorded.*

Direct thrombin inhibitors—examples include *hirudin*, *argatroban,* and *lepirudin*—also have been used as a heparin alternative (Chapman and associates, 2008; Tapson, 2008). There are reports, however, that hirudin crosses the placenta and is fetotoxic (Gris and associates, 2006; Mazzolai and co-workers, 2006). Lockwood (2007) recommends the use of *fondaparinux*—a pentasaccharide factor Xa inhibitor—in pregnant women for whom there are no alternatives. Successful use in pregnancy has been reported, including a case report describing a woman with an intolerance to both heparin and danaparoid (Mazzolai and colleagues, 2006). At least one recent report suggests that fondaparinux can rarely cause a disorder that resembles HIT (Warkentin and co-workers, 2007). Interestingly, heparin-dependent antibodies do not invariably reappear with subsequent heparin use (Warkentin and Kelton, 2001).

Heparin-Induced Osteoporosis

Bone loss may develop with long-term heparin administration—usually 6 months or longer—and is more prevalent in cigarette smokers (see Chap. 53, p. 1136). Low-molecular-weight heparins can cause osteopenia (Deruelle and Coulon, 2007), although such a result is less likely than with unfractionated heparin. Women treated with any heparin should be encouraged to take a daily supplement of 1500 mg of calcium (Cunningham, 2005; Lockwood, 2007). Low-molecular-weight heparins may cause less adverse effects. Rodger and colleagues (2007) found that longer-term use with a mean of 212 days with dalteparin, 5000 units subcutaneously given daily until 20 weeks and 5000 units twice daily thereafter, was not associated with a significant decrease in bone mineral density.

Anticoagulation and Abortion

The treatment of deep-venous thrombosis with heparin does not preclude termination of pregnancy by careful curettage. After the products are removed without trauma to the reproductive tract, full-dose heparin can be restarted in several hours.

Anticoagulation and Delivery

The effects of heparin on blood loss at delivery depend on a number of variables:

- Dose, route, and time of administration
- Number and severity of incisions and lacerations
- Intensity of postpartum myometrial contractions
- Presence of other coagulation defects.

Blood loss should not be greatly increased with vaginal delivery if the midline episiotomy is modest in depth, there are no lacerations, and the uterus promptly contracts. Unfortunately, such ideal circumstances do not always prevail. For example, Mueller and Lebherz (1969) described 10 women with antepartum thrombophlebitis treated with heparin. Three women who continued to receive heparin during labor and delivery bled remarkably and developed large hematomas. Thus, heparin therapy generally is stopped during labor and delivery. If the uterus is well contracted and there has been negligible trauma to the lower genital tract, it can be restarted after about 12 hours. Otherwise, a delay of 1 or 2 days may be prudent.

Protamine sulfate administered slowly intravenously generally reverses the effect of heparin promptly and effectively. It should not be given in excess of the amount needed to neutralize the heparin, because it also has an anticoagulant effect. Serious bleeding is likely when heparin in usual therapeutic doses is administered to a woman who has undergone cesarean delivery within the previous 24 to 48 hours.

SUPERFICIAL VENOUS THROMBOPHLEBITIS

Thrombosis limited strictly to the superficial veins of the saphenous system is treated with analgesia, elastic support, and rest. If it does not soon subside, or if deep-venous involvement is suspected, appropriate diagnostic measures are performed. Heparin is given if deep-venous involvement is confirmed. Superficial thrombophlebitis is typically seen in association with varicosities or as a sequela to an indwelling intravenous catheter.

PULMONARY EMBOLISM

Although it causes about 10 percent of maternal deaths, pulmonary embolism is relatively uncommon during pregnancy and the puerperium. The incidence averages about 1 in 7000 pregnancies. There is an almost equal prevalence for antepartum and postpartum embolism, but those developing postpartum have a higher mortality rate. According to Marik and Plante (2008), 70 percent of women presenting with a pulmonary embolism have associated clinical evidence of deep-venous thrombosis. In women presenting with a deep-venous thrombosis, almost half will have a silent pulmonary embolism.

Clinical Presentation

Findings from the international cooperative pulmonary embolism registry were reported by Goldhaber and colleagues (1999). Over a 2-year period, almost 2500 nonpregnant patients with a proven pulmonary embolism were enrolled. Common symptoms included dyspnea in 82 percent, chest pain in 49 percent, cough in 20 percent, syncope in 14 percent, and hemoptysis in 7 percent. Other predominant clinical findings typically include tachypnea, apprehension, and tachycardia. In some cases, there is an accentuated pulmonic closure sound, rales, and/or friction rub.

Right axis deviation and T-wave inversion in the anterior chest leads may be evident on the electrocardiogram. On chest radiography, there may be loss of vascular markings in the region of the lungs supplied by the obstructed artery. Although most women are hypoxemic, it is emphasized that a normal arterial blood gas analysis does not exclude pulmonary embolism. Approximately a third of patients younger than 40 years will have pO_2 values >80 mm Hg. In contrast, the alveolar-arterial oxygen tension difference is a more useful indicator of disease, as more than 86 percent of patients with acute pulmonary embolism will have an alveolar-arterial difference of more than 20 mm Hg (Lockwood, 2007). Even with massive pulmonary embolism, signs, symptoms, and laboratory data to support the diagnosis may be deceptively nonspecific.

Massive Pulmonary Embolism

This is defined as embolism causing hemodynamic instability (Tapson, 2008). Acute mechanical obstruction of the pulmonary vasculature causes increased vascular resistance and pulmonary hypertension. Acute right ventricular dilatation follows. In otherwise healthy patients, significant pulmonary hypertension does not develop until 60 to 75 percent of the pulmonary vascular tree is occluded (Guyton and colleagues, 1954). Moreover, circulatory collapse requires 75- to 80-percent obstruction. This is depicted schematically in **Figure 47-3** and emphasizes that most acutely symptomatic emboli are large and likely a saddle embolism. These are suspected when pulmonary artery pressure is substantively increased as estimated by echocardiography.

If there is evidence of right ventricular dysfunction, the mortality rate approaches 25 percent, compared with 1 percent without such dysfunction (Kinane and co-workers, 2008). It is important in these cases to infuse crystalloids carefully and to support blood pressure with vasopressors. Oxygen treatment, tracheal intubation, and mechanical ventilation are carried out preparatory to thrombolysis, filter placement, or embolectomy (Tapson, 2008).

Diagnosis

As with deep-venous thrombosis, the diagnosis of pulmonary embolism requires an initial high index of suspicion followed by objective testing (Chunilal and colleagues, 2003). As shown in **Figure 47-4**, the initial imaging evaluation for suspected pulmonary embolism during pregnancy generally includes ventilation-perfusion scintigraphy, computed tomography, or bilateral compression ultrasonography. Of note, a chest radiograph should be performed if there is underlying suspicion for other diagnoses. The current opinion of the American Academy of Pediatrics and American College of Obstetricians and Gynecologists (2007) is that, in contemporary practice, pulmonary embolism is commonly diagnosed with multidetector-row spiral computed tomography pulmonary angiography (MDCT).

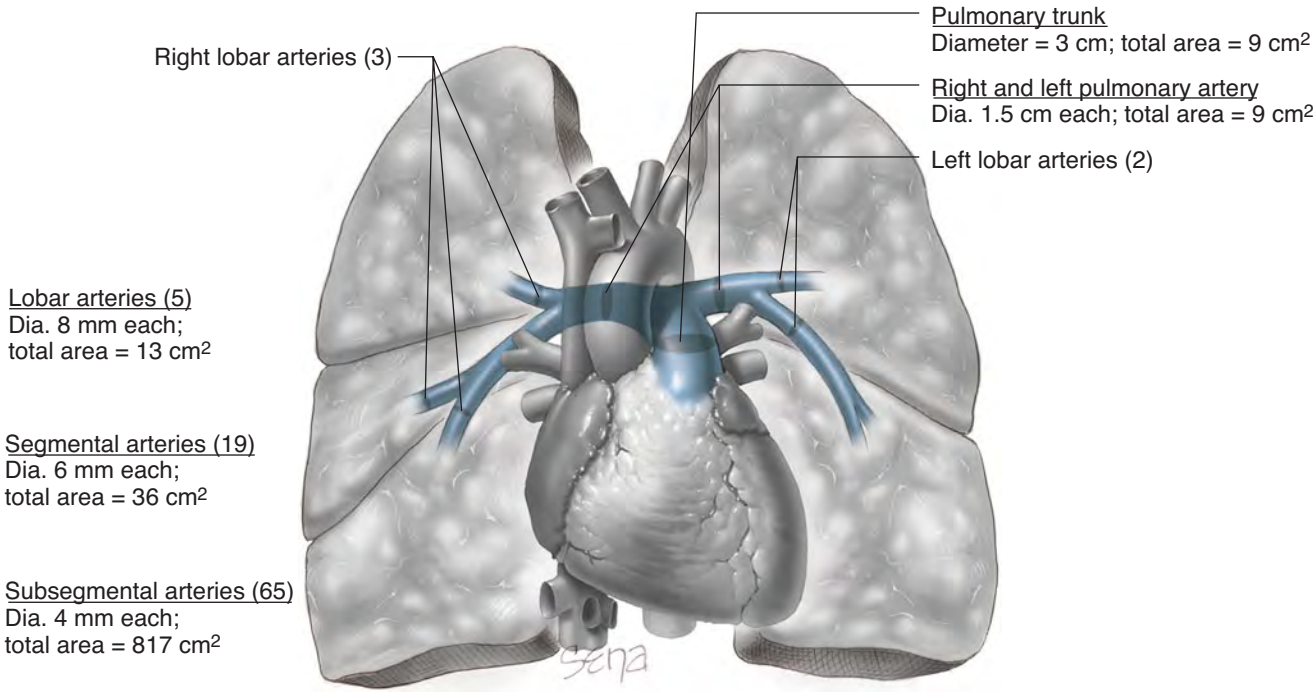

FIGURE 47-3 Schematic of pulmonary arterial circulation. Note that the cross-sectional area of the pulmonary trunk and the combined pulmonary arteries is 9 cm^2. A large saddle embolism could occlude 50 to 90 percent of the pulmonary tree causing hemodynamic instability. As the arteries give off distal branches, the total surface area rapidly increases, that is, 13 cm^2 for the combined five lobar arteries, 36 cm^2 for combined 19 segmental arteries, and more than 800 cm^2 for the total 65 subsegmental arterial branches. Thus, hemodynamic instability is less likely with emboli past the lobar arteries. (Data from Singhal and colleagues, 1973.)

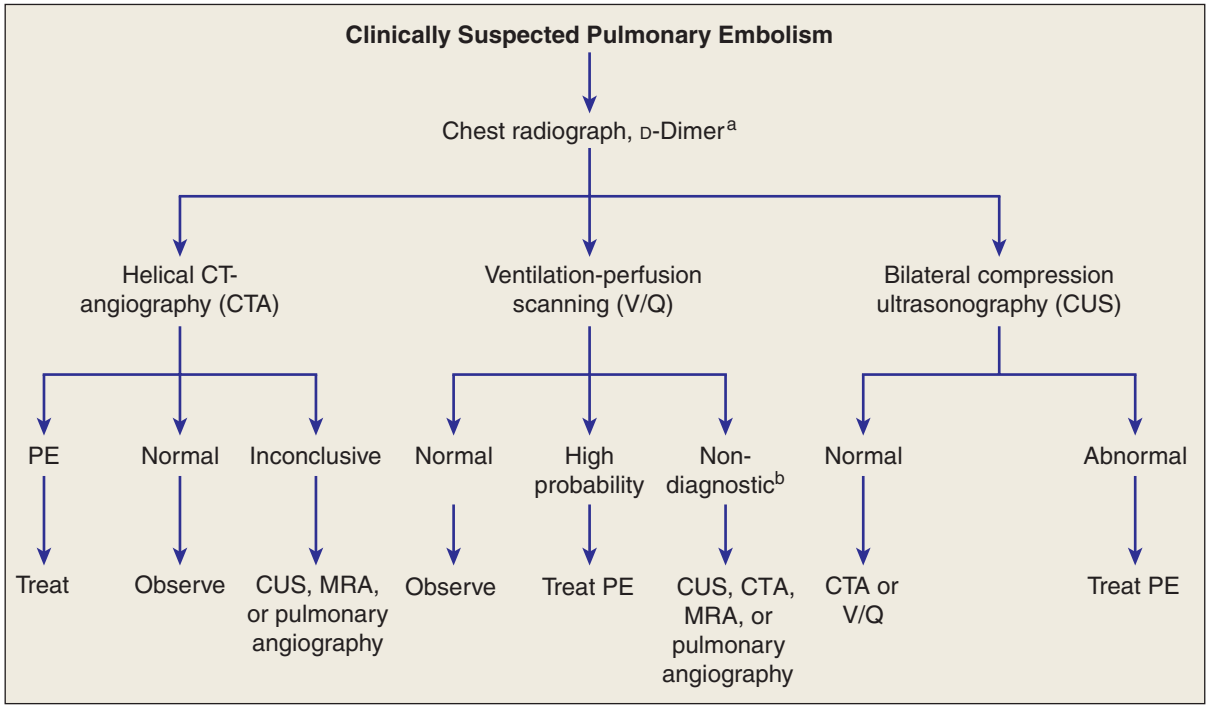

FIGURE 47-4 Evaluation of suspected pulmonary embolism during pregnancy. The decision to begin with helical computed tomography (CT), ventilation/perfusion (V/Q) scan, or bilateral CUS depends on local availability and expertise. CTA = CT angiography; CUS = compression ultrasonography; MRA = magnetic resonance angiography; PE = pulmonary embolism. [a]See text (p. 1020) for discussion. [b]Nondiagnostic results are those that indicate an intermediate or low probability of pulmonary embolism, or that do not indicate a high probability. (Adapted from Nijkeuter and colleagues, 2006, and Tapson, 2008.)

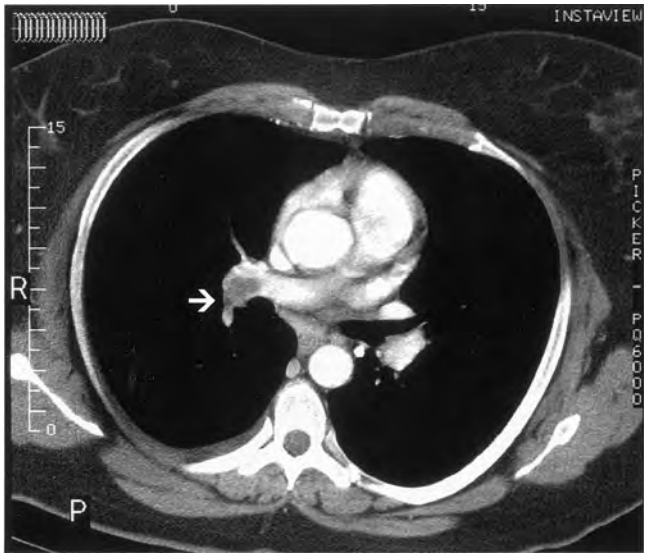

FIGURE 47-5 Axial image of the chest from a four-channel multidetector spiral computed tomographic scan performed after administration of intravenous contrast. There is enhancement of the pulmonary artery with a large thrombus on the right (*arrow*) consistent with pulmonary embolism. (Courtesy of Dr. Michael Landay.)

Computed Tomographic Pulmonary Angiography

It is likely that *multidetector spiral CT* will replace pulmonary angiography as the gold standard for diagnosis of pulmonary embolism (Goldhaber, 2004; Srivastava and colleagues, 2004). The technique is described further in Chapter 41 (p. 918), and an imaging example is shown in **Figure 47-5**. Except in late pregnancy, fetal x-ray exposure is less than with V/Q scanning (**Table 47-5**). In a prospective study of 102 consecutive nonpregnant patients with suspected pulmonary embolism who underwent multidetector spiral CT, Kavanagh and co-workers (2004) found that during a mean follow-up period of 9 months, only one patient had a false-negative scan. Stein and colleagues (2006) reported that combined MDCT angiography and venography was even more sensitive.

We now use multidetector spiral CT as first-line evaluation of pregnant women both at Parkland Hospital and at the University of Alabama at Birmingham Hospital. Although the technique has many advantages, we have found that the better resolution allows detection of previously inaccessible smaller distal emboli that have uncertain clinical significance. Similar observations have been reported by Anderson and associates (2007). Others have found that the hyperdynamic circulation and increased plasma volume associated with pregnancy lead to a higher number of nondiagnostic studies compared with nonpregnant patients (Scarsbrook and associates, 2006).

Ventilation–Perfusion Scintigraphy—Lung Scan

Although used less commonly in the past 5 years, ventilation–perfusion (V/Q) lung scanning is still used by some centers. As seen in Figure 47-4, V/Q scintigraphy may be used if compression ultrasonography results are negative. The technique involves a small dose of radiotracer such as intravenously administered ^{99m}technetium-macroaggregated albumin. As shown in Table 47-5, there is negligible fetal radiation exposure. The scan may not provide a definite diagnosis because many other conditions—for example, pneumonia or local bronchospasm—can cause perfusion defects. Ventilation scans with inhaled xenon-133 or technetium-99m were added to perfusion scans to detect abnormal areas of ventilation in areas with normal perfusion such as with pneumonia or hypoventilation. The method is not precise, and although ventilation scanning increased the probability of an accurate diagnosis with large perfusion defects and ventilation mismatches, normal V/Q scan findings do not exclude pulmonary embolism.

Because of these uncertainties, the National Heart, Lung and Blood Institute commissioned the Prospective Investigation of Pulmonary Embolism Diagnosis to determine sensitivities and specificities of V/Q lung scans (PIOPED, 1990). The investigators concluded that a high-probability scan usually indicates pulmonary embolism, but that only a small number of patients with emboli have a high-probability scan. A low-probability scan, combined with a strong clinical impression that embolism is unlikely, makes the possibility of pulmonary embolism remote.

TABLE 47-5. Estimated Mean Fetal Radiation Dosimetry from Ventilation-Perfusion (V/Q) Lung Scanning Compared with 4-Channel Multidetector Spiral Computed Tomography (CT) Scanning

	V/Q Scintigraphy		Spiral CT Scanning	
Pregnancy Duration	mGy	mrem	mGy	mrem
Early	0.46	46	0.04	4
First trimester	0.46	46	0.04	4
Second trimester	0.57	57	0.11	11
Third trimester[a]	0.45	45	0.31	31

[a]In late pregnancy, the maximum exposure with spiral CT scanning may exceed the estimated mean by a factor of 5 to 7 due to increased proximity of the fetus to the primary beam.
Data courtesy of Dr. Jon Anderson.

Similarly, near-normal or normal scans make the diagnosis very unlikely. Finally, an intermediate-probability scan is of no help in establishing the diagnosis. Thus, the V/Q lung scan combined with clinical assessment permits a noninvasive diagnosis or exclusion of pulmonary embolism for only a minority of patients. Indeed, two thirds of nonpregnant patients with a suspected pulmonary embolism have a nondiagnostic scan and require additional testing (Raj, 2003). In our experience, this proportion is smaller in pregnant women, probably because they are younger and usually healthy and less likely to have coexisting pulmonary disease. Similarly, Chan and associates (2002) reported that only 25 percent of 120 pregnant women had a nondiagnostic scan.

Magnetic Resonance Angiography (MRA)

Although conventional magnetic resonance angiography has a high sensitivity for detection of central pulmonary emboli, the sensitivity for detection of subsegmental emboli is less precise (Scarsbrook and associates, 2006). In a study of 141 nonpregnant patients with suspected pulmonary embolism, Oudkerk and co-workers (2002) performed MRA before conventional angiography. About a third of patients were found to have an embolus, and the sensitivity of MRA for isolated subsegmental, segmental, and central or lobar pulmonary embolism was 40, 84, and 100 percent, respectively. There are no currently published reports specifically involving magnetic resonance angiography during pregnancy.

Pulmonary Angiography

This requires catheterization of the right side of the heart and is the most definitive study for pulmonary embolism. In addition to being invasive, it is also time consuming, uncomfortable, and associated with dye-induced allergy and renal failure. The procedure-related mortality rate is about 1 in 200 (Stein and colleagues, 1992). If absolutely necessary for confirmation when less invasive tests are equivocal, angiography should be considered.

Management

Immediate treatment for pulmonary embolism is full anticoagulation similar to that for deep-venous thrombosis as discussed on page 1021. A number of complementary procedures may be indicated.

Vena Caval Filters

The woman who has very recently suffered a pulmonary embolism and who must undergo cesarean delivery presents a particularly serious problem. Reversal of anticoagulation may be followed by another embolus, and surgery while fully anticoagulated frequently results in life-threatening hemorrhage or troublesome hematomas. In these, placement of a vena caval filter should be considered before surgery (Marik and Plante, 2008). Routine filter placement has no added advantage to heparin given alone (Decousus and associates, 1998). In the very infrequent circumstances in which heparin therapy fails to prevent recurrent pulmonary embolism from the pelvis or legs, or when embolism develops from these sites despite heparin treatment, a vena caval filter may be indicated. Such filters can also be used with massive emboli in patients who are not candidates for thrombolysis (Deshpande and colleagues, 2002). The device may be inserted through either the jugular or femoral vein.

Retrievable filters may be used as short-term protection against embolism. These may be removed before they become endothelialized, or they can be left in place permanently (Tapson, 2008). Neill and colleagues (1997) placed a *Gunther Tulip filter* at 37 weeks, and it was removed 5 days postcesarean delivery at 38 weeks. Jamjute and co-workers (2006) described successful placement in a woman during labor.

Thrombolysis

Compared with heparin, thrombolytic agents provide more rapid lysis of pulmonary clots and improvement of pulmonary hypertension (Tapson, 2008). Konstantinides and colleagues (2002) studied 256 nonpregnant patients heparinized for an acute submassive pulmonary embolism. They also were assigned randomly to a placebo or the recombinant tissue plasminogen activator, *alteplase*. Those given the placebo had a threefold increased risk of death or treatment escalation compared with those given alteplase. Agnelli and associates (2002) performed a meta-analysis of nine randomized trials involving 461 nonpregnant patients. They reported that the risk of recurrence or death was significantly lower in patients given thrombolytic agents compared with those given heparin alone—10 versus 17 percent. Importantly, there were five—2 percent—fatal bleeding episodes in the thrombolysis group and none in the heparin-only group.

There are very few studies of thrombolysis during pregnancy. In their review of the literature, Leonhardt and associates (2006) identified 28 reports of thrombolytic therapy using tissue plasminogen activator during pregnancy. Ten of these cases were for thromboembolism. Complication rates were similar compared with reports from nonpregnant patients, and the authors concluded that such therapy should not be withheld during pregnancy if indicated. Tissue plasminogen activator does not cross the placenta. Our anecdotal experiences with these drugs has been favorable.

Embolectomy

Surgical embolectomy is uncommonly indicated with use of thrombolysis and filters. Published experience with emergency embolectomy during pregnancy is limited to case reports such as those by Funakoshi (2004) and Taniguchi (2008) and their co-workers. Based on their review, Ahearn and associates (2002) found that although the operative risk to the mother is reasonable, the stillbirth rate is 20 to 40 percent.

THROMBOPROPHYLAXIS

Thromboembolism Antedating Pregnancy

Optimal management of women with firm evidence of a prior thromboembolism is unclear. Most recommendations represent consensus guidelines, and some are diametrically opposed to others. The confusion that has ensued has provided fertile ground for the plaintiff bar to plow. Cleary-Goldman and colleagues (2007) surveyed 151 fellows of the American College of Obstetricians and Gynecologists and reported that intervention without firm indications is common. In Table 47-6 are listed a

TABLE 47-6. Various Recommendations for Thromboprophylaxis During Pregnancy

Clinical Scenario	Pregnancy[a]	Postpartum[b]
Prior single-episode VTE[c]		
Associated with a risk factor that is no longer present	Surveillance only[1,2,4] or prophylactic UFH or LMWH[4]	Warfarin or prophylactic LMWH 4[1] to 6[1,2,4] weeks
VTE in a prior pregnancy, estrogen-related, or with additional risk factors (such as obesity)	Surveillance only[1] or prophylactic or intermediate-dose UFH[1,2,4] or LMWH[1,2,3,4]	Prophylactic UFH or LMWH[1,3,4]
Idiopathic—no known associations	Surveillance only[1]; prophylactic UFH[1,2,4] or LMWH[1,2,3,4]	Postpartum anticoagulants[1,3] or postpartum UFH or LMWH prophylaxis[2,4]
Associated with a heterozygous thrombophilia trait or strong family history of thrombosis	Surveillance only[1]; prophylactic[1,2,3] or intermediate-dose[1] LMWH or UFH[1]	Postpartum anticoagulants[1,3] or postpartum UFH or LMWH prophylaxis[2]
Women with AT deficiency not receiving long-term anticoagulation; compound heterozygotes for prothrombin G20210A and FVL; FVL homozygous; or prothrombin G20210A homozygous	Prophylactic or intermediate-dose[1] or adjusted-dose[2,4] LMWH; or prophylactic or intermediate-dose[1] or adjusted-dose[2,4] UFH	Postpartum anticoagulants[1] or warfarin for 12 months[2](AT deficiency may require lifetime anticoagulation
Two or more prior episodes of VTE and/or women receiving long-term anticoagulation[c]	Adjusted-dose UFH or adjusted-dose LMWH[1,4]	Warfarin 6 weeks[4] or resumption of long-term anticoagulation[1]
No prior VTE and:		
Require prolonged bed rest and are at an increased risk for VTE due to obesity, thrombophilia, or strong family history	Graduated elastic compression stockings[2]	Graduated elastic compression stockings[2]
Delivery by elective cesarean		Risk assessment—see Table 47–7
Known thrombophilia and no prior VTE and:		
AT deficiency not receiving long-term anticoagulation	Prophylactic UFH or LMWH[1]; or adjusted-dose UFH or LMWH throughout pregnancy[2]	Prophylactic UFH or LMWH[1]; or warfarin 6 weeks or longer[4]; or adjusted-dose UFH or LMWH[2]
Compound heterozygotes for prothrombin G20210A and FVL; FVL homozygous; or prothrombin G20210A homozygous	Surveillance only[1]; prophylactic UFH or LMWH[1]; or adjusted-dose UFH or LMWH throughout pregnancy[2]	Prophylactic UFH or LMWH[1]; warfarin 6 weeks or longer[4]; or adjusted-dose UFH or LMWH[2]
Less thrombogenic thrombophilias—heterozygous FVL or heterozygous prothrombin gene mutations; protein C, S, or Z deficiencies	Surveillance only[1,2] or prophylactic UFH or LMWH[1]	Prophylactic UFH or LMWH[1]; or postpartum anticoagulation with cesarean delivery or with an affected first-degree relative[2]
Homozygous for thermolabile variant (C677T) of MTHFR	Folic acid supplementation prior to and throughout pregnancy	Consider warfarin for 6 weeks if homocysteine serum levels abnormally high(?)[2]
Antiphospholipid antibodies and:		
History of 3 or more early pregnancy losses; one or more late pregnancy loss	Prophylactic or intermediate-dose UFH or prophylactic LMWH combined with low-dose aspirin[1]	Prophylactic UFH or LMWH[1] for 6–8 weeks[5]
History of VTE	Prophylactic or intermediate-dose LMWH or UFH[1]; adjusted-dose LMWH or adjusted-dose UFH[5] plus low-dose aspirin after 1st trimester[1]	Full anticoagulation for 6–8 weeks and referral to specialist[5] or long-term anticoagulation[1,2]

(*Continued*)

TABLE 47-6. Various Recommendations for Thromboprophylaxis During Pregnancy (*Continued*)

Clinical Scenario	Pregnancy[a]	Postpartum[b]
No prior VTE or pregnancy loss	Surveillance only(1) or prophylactic LMWH(1,5) or UFH(1,5) and (5) low-dose aspirin	Prophylactic heparin and low-dose aspirin for 6–8 weeks(5)

AT = antithrombin; FVL = factor V Leiden; LMWH = low-molecular-weight heparin; UFH = unfractionated heparin; VTE = venous thromboembolism.

Various UFH and LMWH regimens:

- Prophylactic UFH—5000 units SC q 12h(1); 5000 to 10,000 units SC q 12h to maintain anti-Xa level of 0.1-0.2 units, 6h after the last injection(2); or 5000 to 7500 units q 12h during the 1st trimester, 7500 to 10,000 units q 12 hours during the 2nd trimester, and 10,000 units q 12h during the 3rd trimester unless the aPTT is elevated(4); or 5000 to 10,000 units q 12h throughout pregnancy(4).
- Intermediate-dose UFH-SC q 12h in doses adjusted to target anti-Xa level of 0.1-0.3 U/mL(1).
- Adjusted-dose UFH-SC q 12h in doses adjusted to target a mid-interval aPTT in the therapeutic range(1) or UFH SC q 8–12h to maintain the aPTT value at 1.5-2.0 times control, 6h after the injection(2).
- Prophylactic LMWH-dalteparin 5000 U SC q 12(4) or q 24h(1,4) or enoxaparin 40 mg SC q 12(4) or q 24h(1) or enoxaparin 40 mg SC q 12h adjusted to maintain anti-Xa levels at 0.12-0.2 unit/mL, 4h after an injection.(2) (At extremes of body weight, dose modification may be required.)
- Intermediate-dose—dalteparin 5000 units SC q 12h or enoxaparin 40 mg SC q 12h(1).
- Adjusted-dose LMWH—weight-adjusted, therapeutic doses of LMWH administered once or twice daily—dalteparin 200 units/kg q 12h or enoxaparin 1 mg/kg q 12h(1). The anti-Xa level is maintained at 0.6–1 unit/mL, 4–6h after an injection(2).

[a]Suggest LMWH over UFH for all pregnant patients(1).

[b]Postpartum anticoagulation—initial UFH or LMWH until the INR is ≥ 2.0 to overlap with warfarin for 4(1) to 6(1,3,4) weeks with a target INR of 2.0 to 3.0(1); or prophylactic LMWH for 4 to 6 weeks(1).

[c]Graduated elastic compression stockings both ante- and postpartum(1).

(5) American College of Obstetricians and Gynecologists (2005).

number of consensus recommendations for thromboprophylaxis from recognized experts. In some cases, a number of different options are listed, thus illustrating the confusion that currently reigns.

In general, and as shown in Table 47-6, either antepartum surveillance or heparin prophylaxis is recommended for women without a recurrent risk factor, including no known thrombophilia. The study by Tengborn and colleagues (1989) suggested that such prophylaxis is not effective. They reported outcomes in 87 pregnant Swedish women who had prior thromboembolic disease. Despite heparin prophylaxis which was usually 5000 U twice daily, three of 20—15 percent—of women developed antepartum recurrence, compared with eight of 67—12 percent—of women not given heparin. These women were not tested for thrombophilia.

Brill-Edwards and associates (2000) prospectively studied 125 pregnant women with a single previous episode of venous thromboembolism. Antepartum heparin was not given, but anticoagulant therapy was given for 4 to 6 weeks postpartum. A total of six women had a recurrent venous thrombosis—three antepartum and three postpartum. There were no recurrences in the 44 women without a known thrombophilia or whose prior thrombosis was associated with a temporary risk factor. These findings imply that prophylactic heparin may not be required for these two groups of women. In contrast, women with a prior thrombosis in association with a thrombophilia or in the absence of a temporary risk factor generally should be given both antepartum and postpartum prophylaxis (see Table 47-6).

More recently, De Stefano and co-workers (2006) studied 1104 women who had a first-episode venous thromboembolism before the age of 40 years. After excluding those with antiphospholipid antibodies, 88 women were identified who subsequently had a total of 155 pregnancies and who were not given antithrombotic prophylaxis. There were 19 women—22 percent—who had a subsequent pregnancy- or puerperium-related venous thromboembolism. Of 20 women whose original thrombosis was associated with a transient risk factor—not including pregnancy or oral contraceptive use—there were no recurrences during pregnancy, but two during the puerperium. Like the findings by Brill-Edwards and associates (2000), these data suggest that for women with a prior venous thromboembolism, antithrombotic prophylaxis during pregnancy could be tailored according to the circumstances of the original event. It is emphasized that more data are needed.

TABLE 47-7. Risk Assessment to Determine Thromboprophylaxis Following Uncomplicated Cesarean Delivery

Risk	Intervention
Low	Early ambulation In hospital, consider compression stockings
Medium or high	Early ambulation
Age older than 35 yrs BMI > 30 Multiparity (? 3) Varicosities Preeclampsia Postpartum hemorrhage Emergency delivery Hysterectomy	In hospital, consider compression or pneumatic stockings *or* In hospital, consider prophylactic LMWH or UFH (see Table 47-6)
Very high Multiple risk factors	Consider stockings as above and prophylactic heparin. For persistent risks, consider prophylactic heparin for 4-6 wks

BMI = body mass index; LMWH = low-molecular-weight heparin; UFH = unfractionated heparin.
From Bates and colleagues (2008), Marik and Plante (2008), and the Royal College of Obstetricians and Gynecologists (2004).

Our practice at Parkland Hospital for many years for women with a history of prior thromboembolism has been to administer subcutaneous unfractionated heparin, 5000 to 7500 units two to three times daily. With this regimen, the recurrence of documented deep-venous thrombosis embolization has been rare. More recently, we have successfully used 40-mg enoxaparin given subcutaneously daily.

Cesarean Delivery and Antepartum Bed Rest

Currently in the United States, use of thromboprophylaxis for women undergoing cesarean delivery or antepartum bed rest is not widely employed. In a survey of 157 members of the Society for Maternal-Fetal Medicine, for example, Casele and Grobman (2007) found that only 8 percent of respondents routinely used thromboprophylaxis—defined as compression boots, stockings, or heparin—for women undergoing cesarean delivery. And only 25 percent routinely used such measures for pregnant women placed on bed rest for more than 72 hours.

The risk for deep-venous thrombosis and especially for fatal thromboembolism is increased manyfold in women following cesarean compared with vaginal delivery. When considering that a third of women giving birth in the United States yearly undergo cesarean delivery, it is easily understandable that pulmonary embolism is a major cause of maternal mortality (see Chap. 1, (p. 5). Because of this, the Royal College of Obstetricans and Gynaecologists (2004) now recommends risk assessment for women undergoing uncomplicated cesarean delivery. The American College of Chest Physicians (Bates and colleagues, 2008) *suggests* risk assessment with thromboprophylaxis—mechanical, pharmacological, or both—for factors such as those shown in Table 47-7. They note this to be Grade 2C level of recommendation because of "low- or very-low quality evidence." According to Clark and associates (2008), some prophylaxis scheme for all women undergoing cesarean delivery in the Hospital Corporation of America system likely would result in a substantively lower maternal mortality rate from pulmonary embolism.

CHAPTER 48

Renal and Urinary Tract Disorders

PREGNANCY-INDUCED URINARY TRACT CHANGES 1033
URINARY TRACT INFECTIONS 1034
NEPHROLITHIASIS 1038
CHRONIC RENAL DISEASE 1039
PREGNANCY AFTER RENAL TRANSPLANTATION 1042
POLYCYSTIC KIDNEY DISEASE 1042
GLOMERULOPATHIES 1043
ACUTE RENAL FAILURE 1045

Renal and urinary tract disorders are commonly encountered in pregnancy. Some precede pregnancy—one example being nephrolithiasis. In some women, pregnancy-induced changes may predispose to development or worsening of urinary tract disorders—an example is the markedly increased risk of pyelonephritis. Finally, there may be complications unique to pregnancy such as preeclampsia. With good prenatal care, most women with these disorders will likely develop no long-term serious consequences.

PREGNANCY-INDUCED URINARY TRACT CHANGES

Significant changes in both structure and function that take place in the urinary tract during normal pregnancy are discussed in Chapter 5 (p. 123). The kidneys become larger, and as shown in **Figure 48-1**, dilatation of the renal calyces and ureters can be striking. Some dilatation develops before 14 weeks and likely is due to progesterone-induced relaxation of the muscular layers. More marked dilatation is apparent beginning in midpregnancy because of ureteral compression, especially on the right side (Faúndes and associates, 1998). There is also some *vesicoureteral reflux* during pregnancy. An important consequence of these physiological changes is an increased risk of upper urinary infection, and occasionally erroneous interpretation of studies done to evaluate obstruction.

Evidence of functional hypertrophy becomes apparent very soon after conception. Glomeruli are larger, although cell numbers do not increase (Strevens and colleagues, 2003). Pregnancy-induced intrarenal vasodilatation increases effective renal plasma flow and glomerular filtration. By 12 weeks' gestation, the glomerular filtration rate is already increased 20 percent above nonpregnant values (Hladunewich and colleagues, 2004). Ultimately, plasma flow and glomerular filtration increase by 40 and 65 percent, respectively. Consequently, serum concentrations of creatinine and urea decrease substantively across pregnancy, and values within a nonpregnant normal range may be abnormal in pregnancy (see Appendix). Other alterations include those related to maintaining normal acid-base homeostasis, osmoregulation, and fluid and electrolyte retention.

Assessment of Renal Function During Pregnancy

The *urinalysis* is essentially unchanged during pregnancy, except for occasional glucosuria. Although *protein excretion* normally is increased, it seldom reaches levels that are detected by usual screening methods. Higby and colleagues (1994) reported 24-hour protein excretion to be 115 mg with a 95-percent confidence level at 260 mg/day (see Appendix). There were no significant differences by trimester. Albumin constitutes only a small part of total protein excretion and ranges from 5 to 30 mg/day. From their review, Airoldi and Weinstein (2007) concluded that proteinuria must exceed 300 mg/day to be considered abnormal. Most consider 500 mg/day to be important with gestational hypertension.

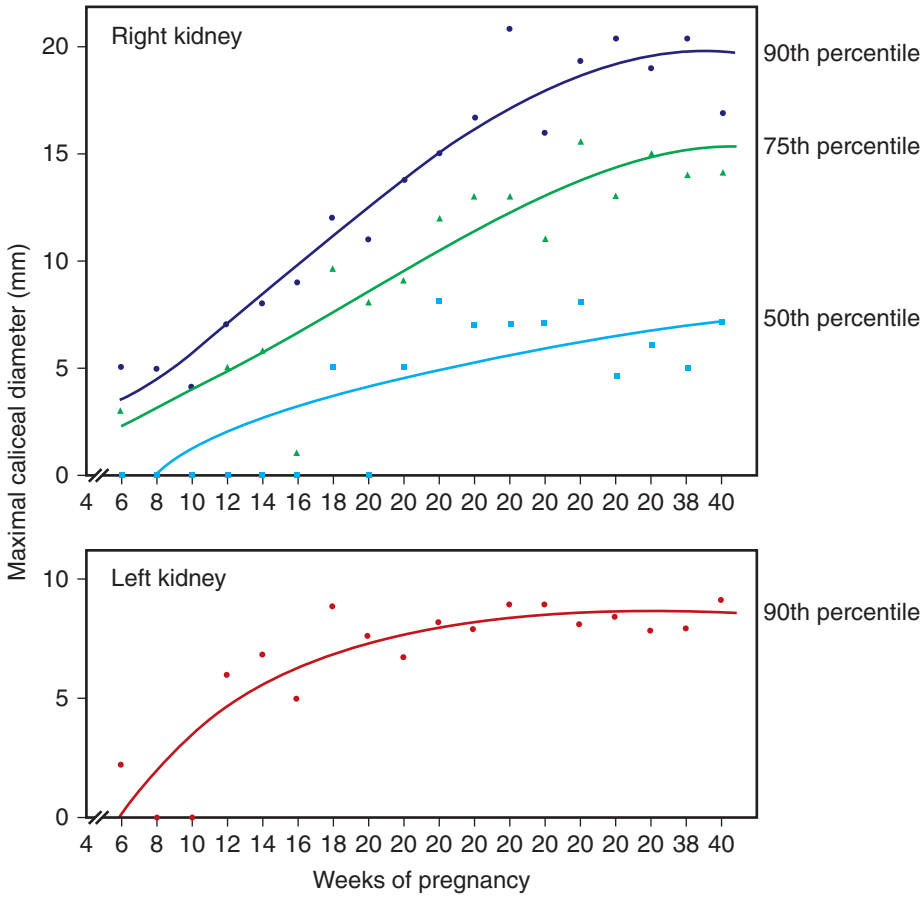

FIGURE 48-1 The 50th, 75th, and 90th percentiles for maternal renal caliceal diameters measured using sonography in 1395 pregnant women from 4 to 42 weeks. (Reprinted from *American Journal of Obstetrics & Gynecology*, Vol. 178, No. 5, A Faúndes, M Bricola-Filho, JC Pinto e Silva, Dilatation of the urinary tract during pregnancy: Proposal of a curve of maximal caliceal diameter by gestational age, pp. 1082–1086, Copyright 1998, with permission from Elsevier.)

Stehman-Breen and associates (2002) found that 3 percent of 4589 nulliparas had *idiopathic hematuria* defined as 1+ or greater blood on urine dipstick when screened before 20 weeks. They also reported that these women had a twofold risk of preeclampsia. In another study of 1000 women screened during pregnancy, Brown and colleagues (2005) reported a 15-percent incidence of dipstick hematuria. Most women had trace levels of hematuria, and the false-positive rate was 40 percent.

If the serum creatinine persistently exceeds 0.9 mg/dL (75 μmol/L), then intrinsic renal disease should be suspected. In these cases, some determine the creatinine clearance as an estimate of the glomerular filtration rate. *Sonography* provides imaging of renal size and relative consistency, as well as elements of obstruction (see Fig. 48-1). Full-sequence *intravenous pyelography* is not done routinely, but injection of contrast media with one or two abdominal radiographs may be indicated by the clinical situation (see Chap. 41, p. 918). The usual clinical indications for *cystoscopy* are followed. Semins and associates (2009) described an 8-percent complication rate in their review of 14 reports of *ureteroscopy* done for stone removal in 108 pregnancies.

Although *renal biopsy* is relatively safely performed during pregnancy, biopsy usually is postponed unless it would change therapy. Lindheimer and colleagues (2008) recommend its consideration for rapid deterioration of renal function with no obvious cause or for symptomatic nephrotic syndrome. We have found biopsy helpful in a few cases, and Chen and coworkers (2001) described 15 women in whom biopsy helped to direct management. Strevens and associates (2003) performed renal biopsy in 12 *normal* pregnant volunteers and reported that five had slight to moderate glomerular endotheliosis. In contrast, all 27 women with proteinuric hypertension had endotheliosis, and in all but one, it was moderate to severe.

Pregnancy after Unilateral Nephrectomy

In general, the excretory capacity of two kidneys exceeds ordinary needs. In addition, after nephrectomy, the surviving kidney undergoes pregnancy-induced hypertrophy of function (**Fig. 48-2**). Therefore, women with one normal kidney most often have no difficulty in pregnancy (Baylis and Davison, 1991). Thorough functional evaluation of the remaining kidney is essential. There are no long-term adverse consequences of kidney donation (Ibrahim and associates, 2009).

Orthostatic Proteinuria

Orthostatic or *postural proteinuria* has been observed in up to 5 percent of normal young adults. Without other evidence of renal disease, the pregnant woman with orthostatic proteinuria should be evaluated for bacteriuria, abnormal urinary sediment, reduced glomerular filtration, and hypertension. In the absence of these, orthostatic proteinuria is probably inconsequential.

URINARY TRACT INFECTIONS

These are the most common bacterial infections during pregnancy. Although *asymptomatic bacteriuria* is the most common, symptomatic infection includes *cystitis*, or it may involve the renal calyces, pelvis, and parenchyma—*pyelonephritis*.

Organisms that cause urinary infections are those from the normal perineal flora. Approximately 90 percent of *Escherichia coli* strains that cause nonobstructive pyelonephritis have *adhesins* such as *P-* and *S-fimbriae* that enhance their virulence (Dodson and co-workers, 2001; Lügering and associates, 2003). These adhesins promote binding to vaginal and uroepithelial cells through expression of the *PapG gene* that encodes the P-fimbriae tip, as well as by production of hemolysin (Hooton and

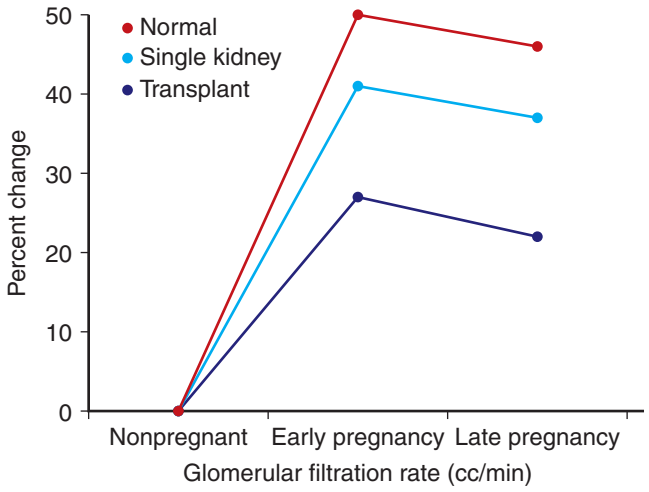

FIGURE 48-2 Glomerular filtration rate changes with pregnancy in normal women, those stable after unilateral nephrectomy, and those with a successful renal transplant. (Data from Newcastle-upon-Tyne, 1974–2006, courtesy of Dr. John Davison.)

co-workers, 2000). The expression of the *dra gene cluster* has been associated with ampicillin-resistant *E. coli* (Hart and colleagues, 2001). Although pregnancy itself does not enhance these virulence factors, urinary stasis and vesicoureteral reflux predispose to symptomatic upper urinary infections (Twickler and associates, 1994). Diabetics are especially susceptible to developing pyelonephritis (Czaja and colleagues, 2009).

In the puerperium, several risk factors exist that predispose a woman to urinary infections. Bladder sensitivity to intravesical fluid tension is often decreased as a consequence of the trauma of labor as well as conduction analgesia (see Chap. 30, p. 655). Sensation of bladder distension can also be diminished by discomfort caused by an episiotomy, periurethral lacerations, or vaginal wall hematomas. Normal postpartum diuresis may worsen bladder overdistension. Catheterization to relieve retention and distension commonly leads to urinary infection, however, there appear to be no long-term sequelae (Yip and colleagues, 2002).

Asymptomatic Bacteriuria

This refers to persistent, actively multiplying bacteria within the urinary tract in asymptomatic women. Its prevalence in nonpregnant women is 5 to 6 percent and depends on parity, race, and socioeconomic status (Hooton and colleagues, 2000). The highest incidence is in African-American multiparas with sickle-cell trait, and the lowest incidence is in affluent white women of low parity. Because most women have recurrent or persistent bacteriuria, it frequently is discovered during prenatal care. The incidence during pregnancy is similar to that in nonpregnant women and varies from 2 to 7 percent.

Bacteriuria is typically present at the time of the first prenatal visit, and if an initial positive urine culture is treated, fewer than 1 percent of women develop urinary infection (Whalley, 1967). A clean-voided specimen containing more than 100,000 organisms per milliliter is diagnostic. It may be prudent to treat when lower concentrations are identified, because pyelonephritis develops in some women with colony counts of 20,000 to 50,000 organisms/mL (Lucas and Cunningham, 1993).

Significance

If asymptomatic bacteriuria is not treated, approximately 25 percent of infected women will develop symptomatic infection during pregnancy. Eradication of bacteriuria with antimicrobial agents prevents most of these. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007), as well as a U.S. Preventative Task Force (2006), recommend screening for bacteriuria at the first prenatal visit (see Chap. 8, p. 194). The dipstick culture technique has excellent positive- and negative-predictive values (Mignini and co-workers, 2009). Standard urine cultures may not be cost-effective when the prevalence is low, but less expensive screening tests such as the leukocyte esterase-nitrite dipstick are when the prevalence is 2 percent or less (Rouse and colleagues, 1995). Because of a high prevalence—5 to 8 percent—at Parkland and the University of Alabama at Birmingham Hospitals, culture screening is done in most women. Susceptibility determination is not necessary because initial treatment is empirical, and these tests have variable sensitivity (Bachman and co-workers, 1993).

In some, but not all studies, covert bacteriuria has been associated with preterm or low-birthweight infants (Kass, 1962). It is even more controversial whether eradication of bacteriuria decreases these complications. Using multivariate analysis for a perinatal registry cohort of 25,746 mother-infant pairs, Schieve and colleagues (1994) reported increased risks for low-birthweight infants, preterm delivery, pregnancy-associated hypertension, and anemia. These findings are at variance with those of Gilstrap and colleagues (1981b) and Whalley (1967). In most studies, asymptomatic infection is not evaluated separately from acute renal infection (Banhidy and associates, 2007). Cochrane reviews by Vasquez and Villar (2006) found that benefits of treatment for asymptomatic bacteria are limited to the reduction of the incidence of pyelonephritis. In our opinion, it seems unlikely that asymptomatic bacteriuria has any significant impact on pregnancy outcome except for potentially serious urinary infections.

Bacteriuria that persists or recurs after delivery has been associated with pyelographic evidence of chronic infection, obstructive lesions, and congenital abnormalities (Kincaid-Smith and Bullen, 1965; Whalley and associates, 1965).

Treatment

Bacteriuria responds to empirical treatment with any of several antimicrobial regimens listed in **Table 48-1**. Although selection can be based on in vitro susceptibilities, in our extensive experience, empirical oral treatment for 10 days with nitrofurantoin macrocrystals, 100 mg at bedtime, is usually effective. Lumbiganon and colleagues (2009) reported satisfactory results with a 7-day course of nitrofurantoin, 100 mg given twice daily. Single-dose antimicrobial therapy has also been used with success for bacteriuria. The important caveat is that, regardless of regimen given, the recurrence rate is approximately 30 percent. This may indicate covert upper tract infection and the need for longer therapy. For recurrences, we have had success with nitrofurantoin, 100 mg orally at bedtime for 21 days (Lucas and Cunningham, 1994). For women with persistent or frequent bacteriuria recurrences, suppressive therapy for the

TABLE 48-1. Oral Antimicrobial Agents Used for Treatment of Pregnant Women with Asymptomatic Bacteriuria

Single-dose treatment
Amoxicillin 3 g
Ampicillin 2 g
Cephalosporin 2 g
Nitrofurantoin 200 mg
Trimethoprim-sulfamethoxazole 320/1600 mg
3-day course
Amoxicillin 500 mg three times daily
Ampicillin 250 mg four times daily
Cephalosporin 250 mg four times daily
Ciprofloxacin 250 mg twice daily
Levofloxacin 250 mg daily
Nitrofurantoin 50 to 100 mg four times daily; 100 mg twice daily
Trimethoprim-sulfamethoxazole 160/800 mg two times daily
Other
Nitrofurantoin 100 mg four times daily for 10 days
Nirofurantoin 100 mg twice daily fo 7 days
Nitrofurantoin 100 mg at bedtime for 10 days
Treatment failures
Nitrofurantoin 100 mg four times daily for 21 days
Suppression for bacterial persistence or recurrence
Nitrofurantoin 100 mg at bedtime for remainder of pregnancy

remainder of pregnancy can be given. We routinely use nitrofurantoin, 100 mg orally at bedtime. This drug may rarely cause an acute pulmonary reaction that dissipates on its withdrawal (Boggess and colleagues, 1996).

Cystitis and Urethritis

Lower urinary infection during pregnancy may develop without antecedent covert bacteriuria (Harris and Gilstrap, 1981). Cystitis is characterized by dysuria, urgency, and frequency, but with few associated systemic findings. Pyuria and bacteriuria are usually found. Microscopic hematuria is common, and occasionally there is gross hematuria from hemorrhagic cystitis (Fakhoury and co-workers, 1994). Although cystitis is usually uncomplicated, the upper urinary tract may become involved by ascending infection. Almost 40 percent of pregnant women with acute pyelonephritis have preceding symptoms of lower tract infection (Gilstrap and associates, 1981a).

Treatment

Women with cystitis respond readily to any of several regimens. Most of the three-day regimens listed in Table 48-1 are usually 90-percent effective (Fihn, 2003). Single-dose therapy is less effective, and if it is used, concomitant pyelonephritis must be confidently excluded.

Lower urinary tract symptoms with pyuria accompanied by a sterile urine culture may be from urethritis caused by *Chlamydia trachomatis*. Mucopurulent cervicitis usually coexists, and erythromycin therapy is effective.

Acute Pyelonephritis

Renal infection is the most common serious medical complication of pregnancy. In a study of the California Pregnancy Complication Surveillance System by Scott and associates (1997), genitourinary infection was the second most common reason for a nondelivery admission. The rate was 4 per 100 for nearly 150,000 pregnancies. In a study of more than 70,000 pregnancies in a managed care organization, Gazmararian and colleagues (2002) reported that 3.5 percent of antepartum admissions were for urinary infections. The potential seriousness is underscored by the observations of Mabie and associates (1997) that pyelonephritis was the leading cause of septic shock during pregnancy. And in a 2 year audit of admissions to the Parkland Hospital Obstetrical Intensive Care Unit, 12 percent of antepartum admissions were for sepsis syndrome caused by pyelonephritis (Zeeman and co-workers, 2003). There is also concern that urosepsis may be related to an increased incidence of cerebral palsy in preterm infants (Jacobsson and colleagues, 2002). Fortunately, there appear to be no serious long-term maternal sequelae (Raz and co-workers, 2003).

Clinical Findings

Renal infection develops more frequently in the second trimester, and nulliparity and young age are associated risk factors (Hill and associates, 2005). It is unilateral and right-sided in more than half of cases, and it is bilateral in a fourth. There is usually a rather abrupt onset with fever, shaking chills, and aching pain in one or both lumbar regions. Anorexia, nausea, and vomiting may worsen dehydration. Tenderness usually can be elicited by percussion in one or both costovertebral angles. The urinary sediment contains many leukocytes, frequently in clumps, and numerous bacteria. Bacteremia is demonstrated in 15 to 20 percent of these women. *E. coli* is isolated from urine or blood in 70 to 80 percent of infections, *Klebsiella pneumoniae* in 3 to 5 percent, *Enterobacter* or *Proteus* in 3 to 5 percent, and gram-positive organisms including group B *Streptococcus* in up to 10 percent of cases (Hill and co-workers, 2005; Wing and colleagues, 2000). The differential diagnosis includes, among others, labor, chorioamnionitis, appendicitis, placental abruption, or infarcted leiomyoma. Evidence of the *sepsis syndrome* is common, and this is discussed in detail in Chapter 42 (p. 932).

Plasma creatinine is monitored because early studies reported that 20 percent of pregnant women developed renal dysfunction. More recent findings, however, show this to be only 5 percent with aggressive fluid resuscitation (Hill and colleagues, 2005). Follow-up studies have demonstrated that this endotoxin-induced damage is reversible in the long term. Varying degrees of respiratory insufficiency from endotoxin-induced alveolar injury are manifest in up to 10 percent of women and may result in frank pulmonary edema (Hill and colleagues, 2005; Sheffield and Cunningham, 2005). In some cases, pulmonary injury may be so severe that it causes *acute respiratory distress syndrome* (*ARDS*) as shown in **Figure 48-3**.

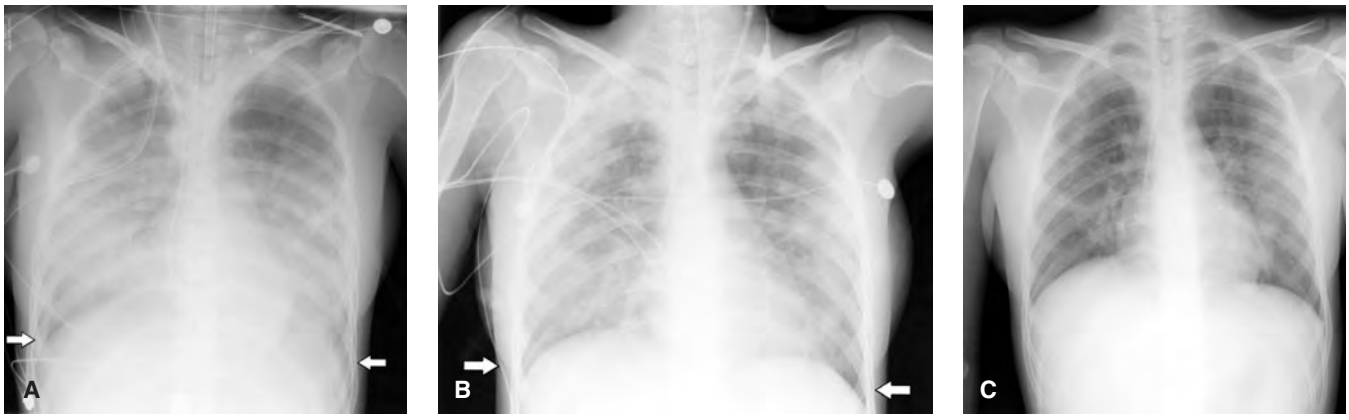

FIGURE 48-3 A series of anterior-posterior projection chest radiographs of improving acute respiratory distress syndrome (ARDS) in a second-trimester pregnant woman with severe pyelonephritis. **A.** An extensive infiltrative process and complete obliteration of the diaphragm (*white arrows*) is seen. **B.** Improved aeration of lung fields bilaterally is noted as pleural disease resolves (*arrows*). **C.** Markedly improved visualization of the lungs fields with residual platelike atelectasis and normal appearance of the diaphragm.

Uterine activity from endotoxin is common and is related to the severity of fever (Graham and associates, 1993). In the study by Millar and colleagues (2003), women with pyelonephritis averaged 5 contractions per hour at admission, and this decreased to 2 per hour within 6 hours of intravenous fluid and antimicrobial administration. As discussed in Chapter 42 (p. 929), β-agonist therapy for tocolysis increases the likelihood of respiratory insufficiency from permeability edema because of the sodium- and fluid-retaining properties of those agents (Lamont, 2000). The incidence of pulmonary edema in women with pyelonephritis who were given β-agonists was reported to be 8 percent—a fourfold increase over that expected (Towers and co-workers, 1991).

Endotoxin-induced *hemolysis* is common, and approximately a third of patients with pyelonephritis develop anemia (Cox and colleagues, 1991). With recovery, hemoglobin regeneration is normal because acute infection does not affect erythropoietin production (Cavenee and colleagues, 1994).

Management

One scheme for management of acute pyelonephritis is shown in Table 48-2. Although we routinely obtain urine and blood cultures, prospective trials show them to be of limited clinical utility (Wing and co-workers, 2000). **Intravenous hydration to ensure adequate urinary output is the cornerstone of treatment.** Antimicrobials are also begun promptly, however, their administration may initially worsen endotoxemia from bacterial lysis. Ongoing surveillance for worsening of sepsis syndrome is monitored by serial determinations of urinary output, blood pressure, pulse, and temperature. High fever should be lowered with a cooling blanket or acetaminophen. This is especially important in early pregnancy because of possible teratogenic effects of hyperthermia (see Chap. 12, p. 281).

Antimicrobial therapy usually is empirical, and ampicillin plus gentamicin; cefazolin or ceftriaxone; or an extended-spectrum antibiotic was 95-percent effective in randomized trials (Sanchez-Ramos and associates, 1995; Wing and colleagues, 1998, 2000). Fewer than half of *E. coli* strains are sensitive to ampicillin in vitro, but cephalosporins and gentamicin generally have excellent activity. Serum creatinine is monitored if nephrotoxic drugs are given. Initial treatment at Parkland Hospital is ampicillin plus gentamicin, and at the University of Alabama at Birmingham Hospital, cefotetan is given. Some recommend suitable substitutes if bacterial studies show in vitro resistance. With any of the regimens discussed, response is relatively prompt in most cases, and 95 percent of women are afebrile by 72 hours (Hill and associates, 2005; Sheffield and Cunningham, 2005; Wing and colleagues, 2000). After discharge, most recommend oral therapy for a total of 7 to 10 days.

Outpatient Management of Pyelonephritis. Wing and associates (1999) have described outpatient management in 92 women who were first given in-hospital intramuscular ceftriaxone, two 1-g doses 24 hours apart. At this point, a third were

TABLE 48-2. Management of the Pregnant Woman with Acute Pyelonephritis

1. Hospitalize patient
2. Obtain urine and blood cultures
3. Evaluate hemogram, serum creatinine, and electrolytes
4. Monitor vital signs frequently, including urinary output—consider indwelling catheter
5. Establish urinary output to ≥ 50 mL/hr with intravenous crystalloid
6. Administer intravenous antimicrobial therapy (see text)
7. Obtain chest radiograph if there is dyspnea or tachypnea
8. Repeat hematology and chemistry studies in 48 hours
9. Change to oral antimicrobials when afebrile
10. Discharge when afebrile 24 hours, consider antimicrobial therapy for 7 to 10 days
11. Repeat urine culture 1 to 2 weeks after antimicrobial therapy completed

Modified from Lucas and Cunningham (1994) and Sheffield and Cunningham (2005).

considered candidates for outpatient therapy and were randomized either to discharge and oral antimicrobials or to continued hospitalization with intravenous therapy. A third of the outpatient management group were unable to adhere to their treatment regimen and were admitted. These findings suggest that outpatient management is applicable to very few women.

Management of Nonresponders. If there is no clinical improvement by 48 to 72 hours, then sonography is recommended to look for urinary tract obstruction manifest by abnormal ureteral or pyelocaliceal dilatation (Seidman and co-workers, 1998). Although most women with continuing infection have no evidence of obstruction, some are found to have calculi. Even though renal sonography will detect hydronephrosis, stones are not always visualized in pregnancy (Butler and associates, 2000; Maikranz and colleagues, 1987). If stones are strongly suspected despite a nondiagnostic sonographic examination, a plain abdominal radiograph will identify nearly 90 percent. Intravenous pyelography is another option. The modified *one-shot pyelogram*—a single radiograph obtained 30 minutes after contrast injection—almost always provides adequate imaging (Butler and colleagues, 2000). Finally, magnetic resonance urography may be used (Spencer and associates, 2004). Other causes of persistent infection are an intrarenal or perinephric abscess or phlegmon (Cox and Cunningham, 1988).

Obstruction can be relieved by cystoscopic placement of a double-J ureteral stent (Rodriguez and Klein, 1988). Because these stents tend to become encrusted, we have found percutaneous nephrostomy to be a better option as the stents are easier to replace. Surgical removal of stones may be required in some cases.

Follow-Up

Recurrent infection—either covert or symptomatic—is common and develops in 30 to 40 percent of women following completion of treatment for pyelonephritis (Cunningham and associates, 1973). Unless other measures are taken to ensure urine sterility, nitrofurantoin, 100 mg orally at bedtime, is given for the remainder of the pregnancy. Van Dorsten and co-workers (1987) reported that this regimen reduces recurrence of bacteriuria.

Reflux Nephropathy

This is chronic interstitial nephritis that classically was thought to be due to infection, that is, *chronic pyelonephritis*. Because radiologically identified scarring is frequently accompanied by ureteral reflux with voiding, it is termed *reflux nephropathy*. Long-term complications include hypertension, which may be quite severe if there is demonstrable renal damage (Köhler and associates, 2003). In most cases, childhood renal infections are documented to precede these lesions. After surgical correction, half of these women have bacteriuria when pregnant (Mor and colleagues, 2003). That said, fewer than half of women have a clear history of preceding cystitis, acute pyelonephritis, or obstructive disease. Certainly, only a very few individuals with recurrent urinary infections develop progressive renal involvement.

Maternal and fetal prognosis depends on the extent of renal destruction. El-Khatib (1994), Jungers (1996), Köhler (2003), and their associates reported outcomes of 939 pregnancies in 379 women with reflux nephropathy. Impaired renal function and bilateral renal scarring were associated with increased maternal complications.

NEPHROLITHIASIS

Kidney stones develop in 7 percent of women during their lifetime with an average age of onset in the third decade (Asplin and colleagues, 2008). Calcium salts comprise approximately 80 percent of stones, and up to a half of affected women have polygenic *familial idiopathic hypercalciuria*. Hyperparathyroidism should be excluded. Although calcium oxalate stones in young nonpregnant women are most common, Ross and co-workers (2008) found that 75 percent of stones in pregnancy were calcium phosphate (hydroxyapatite). Patients who have a stone typically form another stone every 2 to 3 years.

Contrary to past teachings, a low-calcium diet *promotes* stone formation. Prevention of recurrences with hydration and a diet low in sodium and protein is currently recommended (Asplin and co-workers, 2008). Thiazide diuretics also diminish stone formation. In general, obstruction, infection, intractable pain, and heavy bleeding are indications for stone removal. Removal by a flexible basket via cystoscopy, although used less often than in the past, is still a reasonable consideration for pregnant women. In nonpregnant patients, stone destruction by *lithotripsy* is preferred to surgical therapy in most cases. There is limited information on the use of these procedures during pregnancy, and they are not recommended.

Stone Disease During Pregnancy

In a population-based study from Washington state, Swartz and colleagues (2007) reported that admissions for nephrolithiasis were 1.7 per 1000 pregnancies. Butler and colleagues (2000) found a 1 per 3300 incidence in more than 186,000 deliveries at Parkland Hospital. Lewis and associates (2003) reported an unprecedented incidence of 4 per 1000 deliveries that they attributed to their geographic location and predominantly Caucasian population.

Although it is generally accepted that stone disease does not have any adverse effects on pregnancy outcome—except for infection—Swartz and colleagues (2007) also reported an association with preterm delivery. In their case-control study of 2239 pregnant women with stone disease, the incidence of preterm delivery was 10.6 percent compared with 6.4 percent for matched controls. In the case-control Hungarian study, Banhidy and associates (2007) found similar outcomes in women with stones and normal controls. Pregnant women may have fewer symptoms with stone passage because of urinary tract dilatation (Hendricks and colleagues, 1991).

Diagnosis

More than 90 percent of pregnant women with nephrolithiasis present with pain. Gross hematuria was a presenting symptom in 23 percent of women described by Butler and associates (2000). In the report by Lewis and co-workers (2003), however, only 2 percent had hematuria. As discussed, sonography may confirm a suspected stone, but pregnancy hydronephrosis may obscure these findings (McAleer and Loughlin, 2004). If there is abnormal dilatation without stone visualization, then the one-shot pyelogram

may be useful. Transabdominal color Doppler sonography to detect *absence* of ureteral "jets" of urine into the bladder has been used to exclude obstruction (Asrat and colleagues, 1998).

In nonpregnant patients, helical computed tomographic (CT) scanning is the initial imaging method of choice (Asplin and associates, 2008). White and colleagues (2006) recommend unenhanced helical-CT in pregnancy, citing an average fetal dose to be 700 mrad (see Chap. 42, p. 918).

Management

Treatment depends on symptoms and gestational age. Intravenous hydration and analgesics are always given. Half of pregnant women with symptomatic stones have associated infection, which is treated vigorously. **Although calculi infrequently cause symptomatic obstruction during pregnancy, persistent pyelonephritis should prompt a search for obstruction due to nephrolithiasis.**

In approximately two thirds of women with symptoms, there is improvement with conservative therapy, and the stone usually passes spontaneously. The other third require an invasive procedure such as ureteral stenting, ureteroscopy, percutaneous nephrostomy, transurethral laser lithotripsy, or basket extraction (Butler, 2000; Carlan, 1995; Lewis, 2003, and all their coworkers). Of 623 procedures in the 2239 women with stones described by Swartz and associates (2007), only 1 to 2 percent underwent surgical exploration. In the report by Watterson and colleagues (2002), holmium:YAG laser lithotripsy was successful in nine of 10 women. The need for fluoroscopy limits the utility of percutaneous nephrolithotomy (Toth and colleagues, 2005).

CHRONIC RENAL DISEASE

Chronic renal disease is a pathophysiological process that ultimately results in end-stage renal disease (ESRD) through a progressive loss of nephron number and function. It can be caused by multiple etiologies and must be present for at least 3 months to be considered chronic. According to Skorecki and colleagues (2005), the most common causes of ESRD are diabetes—33 percent, hypertension—24 percent, glomerulonephritis—17 percent, and polycystic kidney disease—15 percent.

In most young women with these diseases, there is usually some renal insufficiency, proteinuria, or both. For counseling regarding fertility and pregnancy outcome, it is important to determine the degree of renal functional impairment and associated hypertension. Successful pregnancy outcome in general may be more related to these two factors than to the specific underlying disorder. A general prognosis can be estimated by considering women in arbitrary categories of renal function (Lindheimer and associates, 2008). These include normal or *mild impairment*, defined as a serum creatinine of less than 1.5 mg/dL; *moderate impairment*, defined as a serum creatinine of 1.5 to 3.0 mg/dL; and *severe renal insufficiency*, defined as a serum creatinine greater than 3.0 mg/dL.

Pregnancy and Chronic Renal Disease

Most women with chronic renal disease have relatively mild insufficiency, and the degrees of hypertension and renal insufficiency are prognostic of pregnancy outcome. Renal disease as part of a systemic disorder—diabetes and connective-tissue disorders—as well as other co-morbidities portend a worse prognosis (Fischer and colleagues, 2004; Lindheimer and Davison, 2007). For all women with chronic renal disease, despite the high incidence of hypertension and preeclampsia, preterm and growth-restricted infants, and other problems, the National High Blood Pressure Education Working Group (2000) has concluded that the prognosis has substantively improved over the past decades. This was verified in recent reviews by Hou (2007) and Ramin and colleagues (2006).

Physiological Changes

Loss of renal tissue is associated with compensatory intrarenal vasodilation and hypertrophy of the surviving nephrons. Eventually this compensation fails and the surviving nephrons sclerose, resulting in worsening renal function. With mild renal insufficiency, pregnancy causes greater augmentation of renal plasma flow and glomerular filtration (Baylis, 2003). With progressively worse degrees of renal function, augmented renal plasma flow becomes diminished to absent. For example, only half of pregnant women with moderate renal insufficiency demonstrate augmented glomerular filtration, and there is no increase in those with severe disease (Cunningham and colleagues, 1990).

Nonpregnant women with chronic renal insufficiency have blood volumes similar to those of healthy women. Blood volume expansion during pregnancy, however, is dependent on disease severity and correlates inversely with serum creatinine concentration. As shown in Figure 48-4, women with mild to moderate dysfunction have normal pregnancy-induced hypervolemia that averages 55 percent. In women with severe renal insufficiency, however, volume expansion averages only 25 percent—a degree of volume attenuation similar to women with eclampsia. Finally, because there is only minimal pregnancy-induced erythropoiesis in these women, preexisting anemia is intensified.

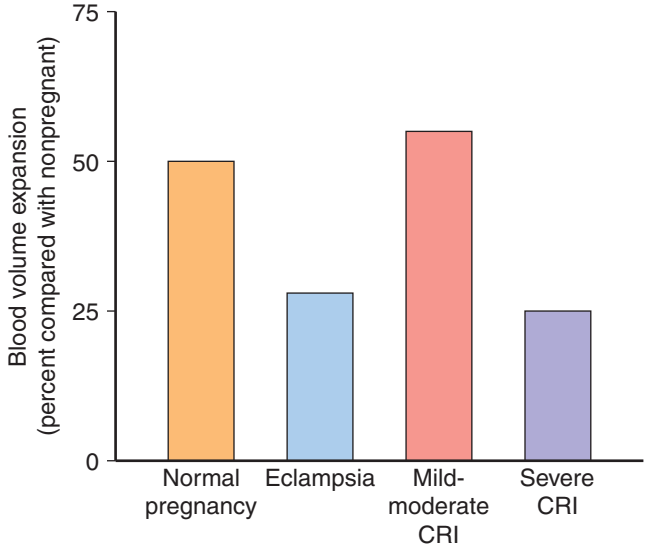

FIGURE 48-4 Comparison of blood volume expansion in 44 normally pregnant women at term with 29 who had eclampsia; 10 with moderate chronic renal insufficiency (CRI)—serum creatinine 1.5 to 2.9 mg/dL; and 4 with severe CRI—serum creatinine ≥3.0 mg/dL. (Data from Zeeman and colleagues, 2009, and Cunningham and associates, 1990.)

TABLE 48-3. Complications Associated with Chronic Renal Disease During Pregnancy

	Incidence in Percent		
	Preserved Renal Function	Renal Insufficiency	
Complication		Moderate and Severe	Severe
Chronic hypertension	25	30–70	50
Gestational hypertension	20–50	30–50	75
Worsening renal function	8–15	20–43	35
Permanent dysfunction	4–5	10–20	35
Preterm delivery	7	35–60	73
Fetal-growth restriction	8–14	30–37	57
Perinatal mortality	5–14	4–7	0

Data from Cunningham (1990), Hou (1985), Imbasciati (2007), Jones and Hayslett (1996), Packham (1989), Stettler and Cunningham (1992), Surian (1984), Trevisan (2004), and all their colleagues.

Chronic Renal Disease with Preserved Function

As emphasized, chronic renal disease is problematic in pregnancy even for women with preserved renal function. Reported complications and their incidences are shown in Table 48-3. Surian and colleagues (1984) described 123 pregnancies in 86 women with biopsy-proven glomerular disease in whom only a few had renal dysfunction. Forty percent developed obstetrical or renal complications, or both.

Packham and co-workers (1989) reported 395 pregnancies in 238 women with preexisting glomerulonephritis and minimal renal insufficiency. During pregnancy, 15 percent of these women developed impaired renal function, and 60 percent had worsening proteinuria. Although only 12 percent had hypertension antedating pregnancy, more than 50 percent of all these women developed gestational hypertension. These pregnancies were complicated by a high incidence of gestational hypertension—50 percent, irreversibly worsened renal function—5 percent, and perinatal mortality—140 per 1000. In the absence of early or severe hypertension or nephrotic-range proteinuria, the perinatal mortality rate was still 50 per 1000.

Chronic Renal Insufficiency

Overall, pregnancy complication rates in women with chronic renal disease who have renal insufficiency are greater than in women with preserved renal function (see Table 48-3). In general, adverse outcomes are directly related to the degree of renal impairment. Of the more recent reports shown in Table 48-3, outcomes of women with moderate versus severe renal insufficiency, as previously defined, are usually not separated. That said, Hou and colleagues (1985) described 25 pregnancies complicated by mild to moderate renal insufficiency—serum creatinine from 1.2 to 1.7 mg/dL. Gestational-induced or aggravated hypertension developed in slightly more than 50 percent of pregnancies. Primarily because of hypertension, 60 percent were delivered preterm.

Cunningham and associates (1990), Jones and Hayslett (1996), and Imbasciati and colleagues (2002) described pregnancies complicated by moderate or severe renal insufficiency. Despite a high incidence of chronic hypertension, anemia, preeclampsia, preterm delivery, and fetal-growth restriction, perinatal outcomes were generally good. As shown in Figure 48-5, fetal growth is, in general, impaired and related to severity of renal dysfunction.

Management

Frequent prenatal visits are scheduled to monitor blood pressure. Serial serum creatinine values are measured and protein excretion is quantified if indicated. Bacteriuria is treated to decrease the risk of pyelonephritis. Protein-restricted diets are not

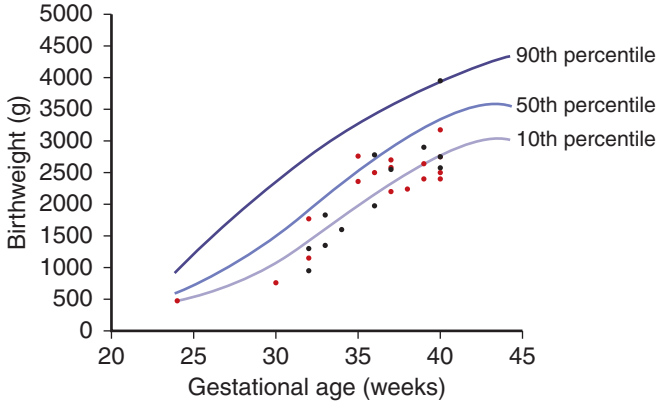

FIGURE 48-5 Birthweight percentiles of infants born to 29 women at Parkland Hospital with mild to moderate renal insufficiency—serum creatinine 1.4–2.4 mg/dL (*black points*) and severe renal insufficiency—serum creatinine ≥2.5 mg/dL (*red points*). (Data are from Cunningham and colleagues, 1990; and Stettler and Cunningham, 1992. Growth curves are those reported by Alexander and co-workers, 1996.)

recommended (Lindheimer and colleagues, 2000; Ruggenenti and associates, 2001). Anemia from chronic renal insufficiency responds to recombinant erythropoietin, however, hypertension is a well-documented side effect. Suspected fetal-growth restriction is managed as discussed in Chapter 38 (p. 843). If hypertension develops, it is managed as described in Chapter 34 (p. 708).

Follow-Up

At least in some women, pregnancy appears to accelerate chronic renal disease. Theoretically, renal hyperperfusion and increased glomerular blood pressure could accelerate nephrosclerosis (Baylis, 2003). In 360 women with chronic glomerulonephritis who mostly had normal renal function, there was little adverse long-term effect of pregnancy (Jungers and associates, 1995). In women with severe chronic renal insufficiency, however, pregnancy may worsen function (Abe, 1991; Jones and Hayslett, 1996). Imbasciati and colleagues (2007) reported that this was more likely to develop in women with a serum creatinine ≥1.4 mg/dL and proteinuria >1 g/day. It seems reasonable to conclude that, in the absence of superimposed preeclampsia or severe hemorrhage and hypovolemia, pregnancy does not usually accelerate renal insufficiency.

Even if there is no pregnancy-induced renal dysfunction in the short term, the natural history of many chronic renal disorders is one of long-term progression. Cunningham and associates (1990) reported that at least 20 percent of pregnant women with moderate to severe insufficiency developed end-stage renal failure by a mean of 4 years. In the report by Jones and Hayslett, 10 percent of pregnancies were followed by end-stage disease within 1 year. Imbasciati and co-workers (2007) reported that with a median follow-up of 3 years, 30 percent of women whose serum creatinine was ≥1.4 mg/dL and proteinuria >1 g/day had developed end-stage disease. Similarly, Stettler and Cunningham (1992) reported that at least 20 percent of women with chronic proteinuria discovered during pregnancy developed end-stage renal failure within several years.

Dialysis During Pregnancy

Significantly impaired renal function is accompanied by subfertility that may be corrected with chronic hemodialysis or peritoneal dialysis. Not unexpectedly, these pregnancies can be complicated. Okundaye and associates (1998) surveyed dialysis units between 1992 and 1995 listed by the Health Care Financing Administration. A total of 241 women became pregnant—60 percent were undergoing hemodialysis and 40 percent peritoneal dialysis. Almost 80 percent were hypertensive and 95 percent were anemic. Pregnancy outcomes included early losses in 42 percent, preterm births in 26 percent, and stillbirths in 8 percent. Infant survival was 40 percent in women who conceived during dialysis compared with 75 percent in those who commenced dialysis after becoming pregnant. The type of dialysis did not influence pregnancy outcome. Chou and colleagues (2008) reviewed 131 cases reported since 1990. They found that mean birthweight was higher in women who conceived while undergoing dialysis—1530 g versus 1245 g in women who conceived prior to starting dialysis. A number of reports from single centers since 1999 and shown in Table 48-4 have described similar outcomes.

Indications for Dialysis

Both hemodialysis and peritoneal dialysis are feasible. If peritoneal dialysis is ongoing, this can be continued during pregnancy. Lindheimer and colleagues (2008) recommend initiation of dialysis when serum creatinine levels are between 5 and 7 mg/dL. Abrupt volume changes that cause hypotension should be avoided. To accomplish this, dialysis frequency likely is extended to five to six times weekly (Reddy and Holley, 2007). Calciferol and erythropoietin doses may require increases. Maternal complications are common and include severe hypertension, placental abruption, heart failure, and sepsis.

TABLE 48-4. Pregnancy Outcomes in 118 Women Undergoing Dialysis During Pregnancy

	Pregnancies			Pregnancy Outcomes (Percent)

PREGNANCY AFTER RENAL TRANSPLANTATION

In 2007, there were approximately 75,000 registrants on the waiting list for renal transplantations through the Organ Procurement and Transplantation Network (OPTN) (2007). The 1-year graft survival rate is 95 percent for grafts from living donors and 89 percent from deceased donors (Carpenter and associates, 2008). Survival rates approximately doubled between 1988 and 1996, due in large part to the introduction of cyclosporine and muromonab-CD3 (OKT3 monoclonal antibody) to prevent and treat organ rejection. Since then, mycophenolate mofetil and tacrolimus have further reduced acute rejection episodes. Experience with these newer drugs during pregnancy is limited (Alston, 2001; Briggs, 2005; Le Ray, 2004, and all their co-workers). Importantly, resumption of renal function after transplantation promptly restores fertility in reproductive-aged women (Lessan-Pezeshki and associates, 2004).

Pregnancy Outcomes

Armenti and colleagues (2004) reviewed the outcomes of 1418 pregnancies in 919 transplant recipients as reported to the National Transplantation Pregnancy Registry. Most were treated with cyclosporine and tacrolimus. The incidence of miscarriage and therapeutic abortion was 20 percent. Overall, 76 percent of pregnancies resulted in a live birth. Preterm births were common, and half of the women were delivered before 37 weeks. Similarly, half of the infants were low birthweight—because of preterm birth as well as fetal-growth restriction. Importantly, the incidence of fetal malformations was not increased.

In the Registry results presented by Armenti and co-workers (2004), the incidence of preeclampsia was 30 percent. In some cases, rejection is difficult to distinguish from preeclampsia. That said, the incidence of rejection episodes was only 3 percent. Infections that developed in 22 percent and diabetes in 10 percent were thought to be likely related to immunosuppression therapy. Since that time, similar outcomes have been reported by Al Duraihimh (2008), Ghafari and Sanadgol (2008), Cruz Lemini (2007), Gutierrez (2005), and all their co-workers.

Lindheimer and colleagues (2008) and Hou (2003) recommend that women who have undergone transplantation satisfy the following requisites before attempting pregnancy:

1. They should be in good general health for at least 2 years after transplantation
2. There should be stable renal function without severe renal insufficiency—serum creatinine <2 mg/dL and preferably <1.5 mg/dL, none to minimal proteinuria, no evidence of graft rejection, and absence of pyelocalyceal distension by urography
3. Absent or easily controlled hypertension
4. Drug therapy reduced to maintenance levels.

Cyclosporine or tacrolimus is given routinely to renal transplantation recipients (Jain and associates, 2004). Cyclosporine blood levels decline during pregnancy, although this was not reported to be associated with rejection episodes (Thomas and co-workers, 1997). Unfortunately, these agents are nephrotoxic and also may cause renal hypertension. In fact, they likely contribute substantively to chronic renal disease that develops in 10 to 20 percent of patients with nonrenal solid-organ transplantation (Goes and Colvin, 2007).

Concern persists over the possibility of late effects in offspring subjected to immunosuppressive therapy in utero. These include malignancy, germ cell dysfunction, and malformations in the children of the *offspring*. In addition, cyclosporine is secreted in breast milk, and in at least one instance, it produced *therapeutic* serum levels in the nursing child (Moretti and associates, 2003).

Finally, although pregnancy-induced renal hyperfiltration theoretically may impair long-term graft survival, Sturgiss and Davison (1995) found no evidence for this in a case-control study of 34 allograft recipients followed for a mean of 15 years.

Management

Close surveillance is necessary. Covert bacteriuria is treated, and if it is recurrent, suppressive treatment is given for the remainder of pregnancy. Serial hepatic enzyme concentrations and blood counts are monitored for toxic effects of azathioprine and cyclosporine. Some recommend measurement of serum cyclosporine levels. Gestational diabetes is more common if corticosteroids are taken. Overt diabetes must be excluded, and glucose tolerance testing is done at approximately 26 weeks. Surveillance for opportunistic infections from herpesvirus, cytomegalovirus, and toxoplasmosis is important because they are more common.

Renal function is monitored, and as shown in Figure 48-2 the glomerular filtration rate usually increases 20 to 25 percent. If a significant increase in serum creatinine is detected, then its cause must be determined. Possibilities include acute rejection, cyclosporine toxicity, preeclampsia, infection, and urinary tract obstruction. Evidence of pyelonephritis or graft rejection should prompt admission for aggressive management. Imaging studies and kidney biopsy may be indicated. The woman is carefully monitored for development or worsening of underlying hypertension, and especially superimposed preeclampsia. Management of hypertension during pregnancy is the same as for nontransplanted patients.

Because of increased incidences of fetal-growth restriction and preterm delivery, vigilant fetal surveillance is indicated. Although cesarean delivery is reserved for obstetrical indications, occasionally the transplanted kidney obstructs labor. In all women with renal transplant, the cesarean delivery rate approaches 50 percent (Armenti and co-workers, 2004).

POLYCYSTIC KIDNEY DISEASE

This usually autosomally dominant systemic disease primarily affects the kidneys. The disease is found in 1 in 800 live births and causes approximately 10 percent of end-stage renal disease in the United States (Wilson, 2004). Although genetically heterogeneous, almost 85 percent of cases are due to *PKD1* gene mutations on chromosome 16, and the other 15 percent to *PKD2* mutations on chromosome 4 (Salant and Patel, 2008). Genetic and environmental influences on disease progression

were reviewed by Peters and Breuning (2001). Prenatal diagnosis is available if the mutation has been identified in a family member or if linkage has been established in the family.

Renal complications are more common in men than in women, and symptoms usually appear in the third or fourth decade. Flank pain, hematuria, nocturia, proteinuria, and associated calculi and infection are common findings. Hypertension develops in 75 percent, and progression to renal failure is a major problem. Superimposed acute renal failure may also develop from infection or obstruction from ureteral angulation by cyst displacement.

Other organs are commonly involved. Hepatic involvement is more common and more aggressive in women than in men (Chapman, 2003). Asymptomatic *hepatic cysts* coexist in a third of patients with polycystic kidneys. Hossack and colleagues (1988) reported a substantively increased incidence of *cardiac valvular lesions* with excessive rates of mitral, aortic, and tricuspid incompetence. The incidence of *mitral valve prolapse* was increased 13-fold. Importantly, approximately 10 percent of patients with polycystic kidney disease die from rupture of an associated *intracranial berry aneurysm.*

Polycystic Kidney Disease and Pregnancy

Pregnancy outcome depends on the degree of associated hypertension and renal insufficiency. Upper urinary tract infections are common. Chapman and co-workers (1994) compared pregnancy in 235 affected women who had 605 pregnancies with those of 108 unaffected family members who had 244 pregnancies. Composite perinatal complication rates were similar—33 versus 26 percent—but hypertension, including preeclampsia, was more common in women with polycystic kidneys. Pregnancy does not seem to accelerate the natural disease course (Lindheimer and colleagues, 2007).

GLOMERULOPATHIES

The kidney, especially the glomerulus and its capillaries, is subject to a large number and variety of acute and chronic diseases. They may result from a single stimulus such as poststreptococcal glomerulonephritis, or from a multisystem disease such as systemic lupus erythematosus or diabetes. Many first become apparent when chronic renal insufficiency is discovered. According to Lewis and Neilsen (2008), there are several distinct clinical glomerulopathic syndromes: acute nephritic, pulmonary-renal, nephrotic, basement membrane, glomerulovascular, and infectious-disease syndromes. The majority of these diseases are encountered in young women of childbearing age and thus are encountered during pregnancy.

Acute Nephritic Syndrome

Acute glomerulonephritis may result from any of several causes as shown in Table 48-5. They present with hypertension, hematuria, red-cell casts, pyuria, and proteinuria. There are varying degrees of renal insufficiency and salt and water retention, which causes edema, hypertension, and circulatory congestion (Lewis and Neilsen, 2008).

TABLE 48-5. Causes of Acute Nephritic Syndrome

Poststreptococcal infection
Subacute bacterial endocarditis
Systemic lupus erythematosus
Antiglomerular basement membrane disease
IgA nephropathy
ANCA small vessel vasculitis
Henoch-Schönlein purpura
Cryoglobulinemia
Membranoproliferative glomerulonephritis
Mesangioproliferative glomerulonephritis

ANCA = antineutrophil cytoplasmic antibodies.
Adapted from Lewis and Neilsen (2008).

Acute poststreptococcal glomerulonephritis is prototypical of these syndromes. Although it rarely develops during pregnancy, it is of historical interest because it was confused with eclampsia until the mid-1800s. In 1843, Lever discovered that the proteinuria of eclampsia was different from that due to *Bright disease* because it disappeared after delivery.

The prognosis and treatment of the other acute nephritic syndromes listed in Table 48-5 depend on their etiology. Renal biopsy may be necessary to determine etiology as well as to direct management (Lindheimer and colleagues, 2007; Ramin and colleagues, 2006). One relatively common example is systemic lupus erythematosus (Germain and Nelson-Piercy, 2006). As discussed in Chapter 54 (p. 1148), differentiation between lupus flare and preeclampsia is problematic. We have occasionally encountered *Goodpasture syndrome,* characterized by antibasement membrane autoantibodies, pulmonary hemorrhage, and glomerulonephritis. Vasilou and colleagues (2005) described maternal and neonatal morbidity in a woman in whom the diagnosis was established by renal biopsy performed at 18 weeks. In some patients, *rapidly progressive glomerulonephritis* leads to end-stage renal failure. In others, *chronic glomerulonephritis* develops with slowly progressive renal disease.

IgA Nephropathy

This condition, which is also known as *Berger disease*, is the most common form of acute glomerulonephritis worldwide. Its primary form is an immune-complex disease. *Henoch-Schönlein purpura* may be a systemic form of the disease (Donadio and Grande, 2002). In a review of more than 300 pregnancies complicated by IgA nephropathy, Lindheimer and colleagues (2000) concluded that pregnancy outcome depended on the degree of renal insufficiency and hypertension. Ronkainen and associates (2005) reported long-term outcomes in a cohort of patients with childhood IgA nephritis. During an average follow-up of 19 years, there were 22 pregnancies. Half had hypertension and a third delivered preterm.

Effect of Glomerulonephritis on Pregnancy

Whatever the underlying etiology, acute glomerulonephritis has profound effects on pregnancy outcome. Packham and colleagues (1989) described 395 pregnancies in 238 women with *primary* glomerulonephritis diagnosed before pregnancy. The most common lesions on biopsy were membranous glomerulonephritis, IgA glomerulonephritis, and diffuse mesangial glomerulonephritis. Most of these women had normal renal function, but still overall fetal loss was 25 percent, and the perinatal mortality rate after 28 weeks was 80 per 1000 (see Table 48-3). A fourth were delivered preterm, and 15 percent of fetuses were growth restricted. Overall, approximately half of these women developed hypertension, and it was severe in the majority who did. Proteinuria worsened in 60 percent of all women. The worst perinatal outcomes were in women with impaired renal function, early or severe hypertension, and nephrotic-range proteinuria.

Chronic Glomerulonephritis

Primary renal lesions that cause chronic nephritis shown in Table 48-5 are frequently not identified. Chronic disease is characterized by progressive renal destruction over years or decades, eventually producing ESRD. Persistent proteinuria and hematuria commonly accompany a gradual decline in renal function. Microscopically, the renal lesions are categorized as proliferative, sclerosing, or membranous. In most cases, proteinuria, anemia, or elevated creatinine is detected by screening in symptomatic patients, or it is found during evaluation for chronic hypertension. In some women, "typical" preeclampsia-eclampsia does not resolve postpartum, and they subsequently are found to have chronic glomerulonephritis. Its prognosis depends on its etiology, and renal biopsy may be helpful. In some patients, 10 to 20 years may elapse before end-stage renal failure supervenes.

Nephrotic Syndrome

This is a spectrum of renal disorders in which proteinuria is the hallmark. Some of the causes are shown in **Table 48-6**. Nephrotic syndrome is characterized by proteinuria in excess of 3 g/day, hypoalbuminemia, hyperlipidemia, and edema. There may be accompanying evidence of renal dysfunction. Most patients who undergo biopsy have microscopic renal abnormalities. The defects in the barriers of the glomerular capillary wall that allow excessive filtration of plasma proteins are caused by primary glomerular disease. These lesions may follow immunological or toxic injury, or they are from diabetes or vascular diseases.

Management depends on etiology. Edema is managed cautiously, especially during pregnancy. Jakobi and associates (1995) have described problems associated with massive vulvar edema that may complicate the nephrotic syndrome caused by diabetes. Another cause is viral, bacterial, or protozoal infections—the woman shown in **Figure 48-6** had nephrosis due to secondary syphilis. Normal amounts of dietary protein of high biological value are encouraged—high-protein diets only increase proteinuria. The incidence of thromboembolism is increased and varies in relation to the severity of hypertension, proteinuria, and renal insufficiency (Stratta and associates, 2006). Although both arterial and venous thrombosis occur, renal vein thrombosis is particularly worrisome. The value, if any, of prophylactic anticoagulation is unclear. Some cases of nephrosis from primary glomerular disease respond to corticosteroid or cytotoxic drug therapy. In most of those cases caused by infection or drugs, proteinuria recedes when the underlying cause is corrected.

TABLE 48-6. Causes of the Nephrotic Syndrome in Adults

Minimal change disease (MCD) (10–15%): primary idiopathic (most cases), drug-induced (NSAIDs), allergies, viral infections
Focal segmental glomerulosclerosis (FSGS) (33%): viruses, hypertension, reflux nephropathy, sickle-cell disease
Membranous glomerulonephritis (30%): idiopathic (majority), malignancy, infection, connective-tissue diseases
Diabetic nephropathy: most common cause of ESRD
Amyloidosis

ESRD = end-stage renal disease; NSAIDs = nonsteroidal anti-inflammatory drugs.
Adapted from Lewis and Neilsen (2008).

Nephrotic-Range Proteinuria in Pregnancy

When nephrosis complicates pregnancy, the maternal and fetal prognosis, as well as appropriate treatment, depends on the underlying cause and severity of the disease. Whenever possible, the specific cause should be ascertained, and renal biopsy may be indicated.

Approximately half of women with the nephrotic-range proteinuria have increased protein excretion during pregnancy (Packham and colleagues, 1989). In two thirds of women, protein excretion exceeds 3 g/day (Stettler and Cunningham, 1992). Despite this, pregnant women without appreciably diminished renal function usually have an augmented glomerular filtration rate (Cunningham and colleagues, 1990).

FIGURE 48-6 Massive vulvar edema in a pregnant woman with the nephrotic syndrome due to secondary syphilis.

TABLE 48-7. Causes and Outcomes of Obstetrical Acute Renal Failure

		Causes and Associated Factors (Percent)				
Study	N	Preeclampsia-Eclampsia	Obstetrical Hemorrhage	Abortion	Dialysis	Maternal Mortality Rate (Percent)
Turney (1989) Leeds, UK	142	50	35	25	NR	20
Sibai (1990)[a] Memphis, TN	31	100	Abruption (50) Postpartum (90)		15/31	10
Nzerue (1998) Atlanta, GA	21	38 (50% HELLP)	14	14	2/21	16
Drakeley (2002) Cape Town, SA	72	93	32 Abruption (10)		10/72	0

[a] Review was limited to women with hypertension.
NR = not reported.

Most women with nephrosis who do not have severe hypertension or renal insufficiency have a successful pregnancy outcome. With renal insufficiency, moderate to severe hypertension, or both, the prognosis is much worse. Our experience from Parkland Hospital indicates that women with proteinuria before pregnancy frequently develop a number of complications during pregnancy (Stettler and Cunningham, 1992). Protein excretion in 65 pregnancies averaged 4 g/day, and 33 percent of these women had classic nephrotic syndrome. Some degree of renal insufficiency was found in 75 percent, chronic hypertension in 40 percent, and persistent anemia in 25 percent. Importantly, preeclampsia developed in 60 percent, and 45 percent had preterm deliveries. Excluding abortions, however, 53 of 57 infants were born alive. A third of these infants are reported to be growth restricted (Stratta and associates, 2006).

Long-term follow-up in women with chronic proteinuria during pregnancy is important. In the 21 women who subsequently underwent renal biopsy reported by Stettler and Cunningham (1992), histological evidence of renal disease was found. Long-term follow-up indicated that at least 20 percent of women had progressed to end-stage renal failure. Similarly, Chen and colleagues (2001) reported that eight of 15 women undergoing biopsy during pregnancy for the nephrotic syndrome either had died (three), had developed chronic renal failure (three), or had end-stage disease (two) by 2 years following delivery. In the report by Imbasciati and associates (2007), women whose serum creatinine was >1.4 mg/dL and whose 24-hour protein excretion exceeded 1 g/day had the shortest renal survival times after pregnancy.

ACUTE RENAL FAILURE

Defined as a rapid decrease in the glomerular filtration rate over minutes to days, acute renal failure is termed *acute kidney injury* by the American Society of Nephrology (2005). Fortunately, the incidence of renal failure associated with pregnancy has decreased substantively over the past 30 years. Despite this, it remains a significant source of obstetrical morbidity in this country (Kuklina and co-workers, 2009). Associated mortality depends on its severity and whether dialysis is needed (Singri and colleagues, 2003). Pregnancy outcomes from four studies are shown in Table 48-7. Except for a decreased incidence of abortion-related renal failure, the etiology has not changed dramatically over the past several decades. Turney and colleagues (1989) described findings from the Renal Unit in Leeds, England. Whereas in earlier years obstetrical cases composed 33 percent of all patients requiring dialysis, more recently these accounted for only 10 percent.

Today, renal failure is most often associated with severe preeclampsia-eclampsia. Frangieh and co-workers (1996) reported that 3.8 percent of eclamptic women from the University of Tennessee had acute renal failure. From the same institution, Audibert and colleagues (1996) reported that 3 percent of 69 women with hemolysis, elevated liver enzymes, and low platelets (*HELLP syndrome*) developed renal failure. Obstetrical hemorrhage, notably placental abruption, alone or in concert with severe preeclampsia, is strongly linked to severe renal failure (Drakeley and co-workers, 2002). Septicemia is another common co-morbidity (Zeeman and colleagues, 2003). From his review, Sibai (2007) reported a 44-percent increase of acute renal failure with acute fatty liver of pregnancy (see Chap. 50, p. 1065). In one unusual case, Hill and associates (2002) described a woman managed at Parkland Hospital with acute renal failure caused by hyperemesis gravidarum at 15 weeks. Her serum creatinine level was 10.7 mg/dL and she required hemodialysis for 5 days.

Management

In most women, renal failure develops postpartum, thus management is not complicated by fetal considerations. An acute increase in serum creatinine is usually due to renal ischemia (Abuelo, 2007). Oliguria is an important sign of acutely impaired renal function. In obstetrical cases, both prerenal and intrarenal factors are commonly operative. For example, with total placental abruption, severe hypovolemia is common from massive hemorrhage. Superimposed preeclampsia may cause oliguria.

When azotemia is evident and severe oliguria persists, some form of hemofiltration or dialysis is initiated before marked deterioration occurs. Medication dose adjustments are imperative

(Singri and associates, 2003). Early dialysis appears to reduce the mortality rate appreciably and may enhance the extent of recovery of renal function. With time, renal function usually returns to normal or near normal.

Prevention

Acute tubular necrosis may often be prevented by the following means:

1. Prompt and vigorous replacement of blood in instances of massive hemorrhage, such as in placental abruption, placental previa, uterine rupture, and postpartum uterine atony
2. Termination of pregnancies complicated by severe preeclampsia or eclampsia and careful blood replacement if loss is excessive
3. Close observation for early signs of sepsis syndrome and shock in women with pyelonephritis, septic abortion, chorioamnionitis, or sepsis from other pelvic infections
4. Avoidance of potent diuretics to treat oliguria before initiating appropriate efforts to ensure that cardiac output is adequate for renal perfusion
5. Avoidance of vasoconstrictors to treat hypotension, unless pathological vasodilation is unequivocally the cause of the hypotension.

Renal cortical necrosis has become exceedingly uncommon. Before widespread availability of dialysis, it complicated a fourth of cases of obstetrical renal failure (Grünfeld and Pertuiset, 1987; Turney and colleagues, 1989). Most cases followed placental abruption, preeclampsia-eclampsia, and endotoxin-induced shock. Histologically, the lesion appears to result from thrombosis of segments of the renal vascular system. The lesions may be focal, patchy, confluent, or gross. Clinically, renal cortical necrosis follows the course of acute renal failure, and its differentiation from acute tubular necrosis is not possible during the early phase. The prognosis depends on the extent of the necrosis. There is variable recovery of function and stable renal insufficiency results (Lindheimer and colleagues, 2007).

Obstructive Renal Failure

Rarely, bilateral ureteral compression by a very large pregnant uterus is greatly exaggerated, causing ureteral obstruction and in turn, severe oliguria and azotemia. Brandes and Fritsche (1991) reviewed 13 cases that were the consequence of a markedly overdistended uterus. They described a woman with twins who developed anuria and a serum creatinine level of 12.2 mg/dL at 34 weeks. After amniotomy, urine flow resumed at 500 mL/hr and was followed by rapid return to normal of the serum creatinine. Eckford and Gingell (1991) described 10 women in whom ureteral obstruction was relieved by stenting. The stents were left in place for a mean of 15.5 weeks and removed 4 to 6 weeks postpartum. Sadan and associates (1994) reported a similar experience in eight such women who underwent stent placement at a mean of 29 weeks for moderate to severe hydronephrosis. The stents remained in situ for a mean of 9 weeks, during which time renal function remained normal.

We have observed this phenomenon on several occasions (Satin and colleagues, 1993). Partial ureteral obstruction may be accompanied by fluid retention and significant hypertension. When the obstructive uropathy is relieved, diuresis ensues and hypertension dissipates. In one woman with massive hydramnios (9.4 L) and an anencephalic fetus, amniocentesis and removal of some of the amnionic fluid was followed promptly by diuresis, decreasing plasma creatinine concentration, and improvement of hypertension. In our experience, women with previous urinary tract surgery are more likely to have such obstructions. Even so, the phenomenon appears uncommon. Vordermark and associates (1990) reviewed pregnancy following major urinary reconstruction and found minimal complications.

CHAPTER 49

Gastrointestinal Disorders

GENERAL CONSIDERATIONS 1049
DISORDERS OF THE UPPER GASTROINTESTINAL TRACT 1050
DISORDERS OF THE SMALL BOWEL AND COLON 1053

During normal pregnancy, the gastrointestinal tract and its appendages undergo remarkable anatomical, physiological, and functional changes. These changes, which are discussed in detail in Chapter 5 (p. 125), can appreciably alter clinical findings normally relied on for diagnosis and treatment of gastrointestinal disorders. One example is nausea and vomiting, which is frequent early in normal pregnancy. If these symptoms persist or develop later, they may be erroneously attributed to normal physiological changes, and a serious pregnancy complication or nonobstetrical problem may be overlooked. In another example, most obstetricians, but not most internists or gastroenterologists, are aware that epigastric or right upper quadrant pain can be an ominous sign of severe preeclampsia. Finally, as pregnancy progresses, gastrointestinal symptoms become more difficult to assess, and physical findings are often obscured by the large uterus, which displaces abdominal organs and can alter the location and intensity of pain and tenderness.

GENERAL CONSIDERATIONS

Diagnostic Techniques

In general, gastrointestinal tract evaluation can be completed without reliance on radiological techniques.

Endoscopy

Fiberoptic endoscopic instruments have revolutionized diagnosis and management of most gastrointestinal conditions. They are particularly well suited for use during pregnancy. Cappell (2006) estimates that nearly 20,000 pregnant women annually have indications for endoscopy to evaluate the esophagus, stomach, duodenum, and colon. The proximal jejunum can also be studied, and the ampulla of Vater cannulated to perform *endoscopic retrograde cholangiopancreatography—ERCP* (Al-Hashem and colleagues, 2008). Experience in pregnancy with *videocapsule endoscopy* for small-bowel evaluation is limited (Storch and Barkin, 2006). In most endoscopies, sedation is required, and especial considerations are given to complications unique to pregnancy.

Upper gastrointestinal endoscopy is used for management as well as diagnosis of a number of problems. Common bile duct exploration and drainage are used for choledocholithiasis as described in Chapter 50 (p. 1073). It is also used for sclerotherapy as well as placement of *percutaneous endoscopic gastrostomy (PEG)* tubes. A number of concise reviews have been provided (Bruno and Kroser, 2006; Cappell, 2006; Gilinsky and Muthunayagam, 2006).

Flexible sigmoidoscopy can be used safely in pregnant women (Siddiqui and Denise-Proctor, 2006). *Colonoscopy* is used to view the entire colon and distal ileum for diagnosis and management of inflammatory bowel disease. Bowel preparation is completed using polyethylene glycol electrolyte or sodium phosphate solutions with care to avoid serious maternal dehydration. Reports of colonoscopy during pregnancy are limited, but preliminary results are encouraging, and it should be performed if indicated (Cappell, 2003).

Noninvasive Imaging Techniques

The obvious technique for gastrointestinal evaluation is abdominal sonography. Because computed tomography (CT) use is limited in pregnancy due to radiation exposure, magnetic resonance (MR) imaging is now commonly used for evaluating the abdomen and retroperitoneal space. These and other imaging modalities, and their safety for use in pregnancy, are considered in detail in Chapter 41 (p. 915).

Laparotomy and Laparoscopy

Surgery is lifesaving for certain gastrointestinal conditions—perforative appendicitis being the most common example. In the first study using the Swedish Registry database through 1981, Mazze and Källén (1989) reported that abdominal exploration by laparotomy or laparoscopy was performed in 1331 of 720,000 pregnancies—approximately 1 in every 500. Kort and associates (1993) reported a similar incidence of 1 in 635 in nearly 50,000 pregnancies. In both studies, the most common indications for surgery were appendicitis, an adnexal mass, and cholecystitis.

Laparoscopic procedures have replaced traditional surgical techniques for many abdominal disorders during pregnancy (Carter and Soper, 2004). In the updated report from the Swedish Registry database, Reedy and associates (1997) described 2181 pregnant women who underwent laparoscopy and 1522 who had laparotomy for nonobstetrical indications. The incidence for all procedures was similar to their first study—approximately 1 in every 800 pregnancies. Both were mostly performed before 20 weeks, and they were found to be safe. Finally, long-term surveillance studies suggest no deleterious effects for either mother or child (Rizzo, 2003).

The most common nongynecological procedures performed during pregnancy are cholecystectomy and appendectomy (Fatum and Rojansky, 2001; Rollins and associates, 2004). For more details and for descriptions of surgical technique, see Chapter 41 (p. 913) as well as *Operative Obstetrics*, 2nd edition (Gilstrap and colleagues, 2002). Guidelines for diagnosis, treatment, and use of laparoscopy for surgical problems during pregnancy have been provided by the Society of American Gastrointestinal and Endoscopic Surgeons (2008).

Nutritional Support

Specialized nutritional support can be delivered *enterally,* usually via nasogastric tube feedings, or intravenously with peripheral or central venous access. When possible, enteral alimentation is preferable because it has fewer serious complications (Hamaoui and Hamaoui, 2003; Vaisman and co-workers, 2004). In obstetrical patients, very few conditions prohibit enteral nutrition as a first effort to prevent catabolism.

The purpose of *parenteral feeding*, or *hyperalimentation*, is to provide nutrition when the intestinal tract must be kept quiescent. Peripheral venous access may be adequate for short-term supplemental nutrition, which derives calories from isotonic fat solutions. Central venous access is necessary for total parenteral nutrition because its hyperosmolarity requires rapid dilution in a high-flow vascular system. These solutions provide 24 to 40 kcal/kg/day, principally as a hypertonic glucose solution. Heyland and colleagues (1998) reviewed 26 randomized trials involving more than 2200 critically ill nonpregnant patients and reported that overall mortality rates were not influenced by parenteral nutrition.

Parenteral Nutrition During Pregnancy

There have been a variety of conditions for which total parenteral nutrition was employed during pregnancy (Table 49-1). Gastrointestinal disorders are the most common indication, and in the many studies cited, duration of feeding averaged 33 days. **It is imperative to emphasize that complications of parenteral nutrition are frequent and they may be severe.** The myriad gastrointestinal complications were recently reviewed by Guglielmi and colleagues (2006). And Russo-Stieglitz and associates (1999) described 26 pregnancies with a 50-percent rate of complications, which include pneumothorax, hemothorax, and brachial plexus injury. The most frequent serious complication is catheter sepsis, and Folk and co-workers (2004) described a 25-percent incidence in 27 women with hyperemesis gravidarum. Although bacterial sepsis is most common, *Candida* septicemia has been described (Paranyuk and associates, 2006). The Centers for Disease Control and Prevention (2002) has published detailed guidelines for management to prevent catheter-related sepsis. Perinatal complications are uncommon, however, fetal subdural hematoma caused by maternal vitamin K deficiency was described by Sakai and colleagues (2003).

TABLE 49-1. Some Conditions Treated with Parenteral Nutrition During Pregnancy

Anorexia nervosa	Jejunoileal bypass
Appendiceal rupture	Malignancies
Bowel obstruction	Pancreatitis
Burns	Preeclampsia syndrome
Cholecystitis	Preterm labor/ruptured membranes
Crohn disease	Short bowel syndrome
Diabetic gastropathy	Small bowel obstruction
Esophageal injury	Stroke
Hyperemesis gravidarum	

From Kirby (1988), Ogura (2003), and Russo-Stieglitz (1999), and all their colleagues.

There is also appreciable morbidity from a *peripherally inserted central catheter (PICC)*. Ogura and colleagues (2003) reported infection with long-term access in 31 of 52 pregnant women. Holmgren and co-workers (2008) reported complications in 21 of 33 women in whom a PICC line was placed for hyperemesis. Infections were the most common, and half of infected women also had bacteremia. From their review of 48 reports of nonpregnant adults, Turcotte and associates (2006) concluded that there were no advantages to peripherally placed catheters compared with centrally placed ones.

DISORDERS OF THE UPPER GASTROINTESTINALTRACT

Hyperemesis Gravidarum

In most women, mild to moderate nausea and vomiting are especially common until approximately 16 weeks (see Chap. 8, p. 210). In some women, however, it is severe and unresponsive to simple dietary modification and antiemetics. In an attempt to quantify the severity of nausea and vomiting, Lacasse and colleagues (2008) have proposed a PUQE scoring index—Pregnancy-Unique Quantification of Emesis and Nausea. *Hyperemesis gravidarum* is defined variably as vomiting sufficiently severe to produce weight loss, dehydration, alkalosis from loss of hydrochloric acid, and hypokalemia. Acidosis develops from partial

starvation (Chihara and co-workers, 2003). In some women, transient hepatic dysfunction develops (see Chap. 50, p. 1063).

Population incidences vary, and there appears to be an ethnic or familial predilection (Grjibovski and co-workers, 2008). In population-based studies from California and Nova Scotia, the hospitalization rate for hyperemesis was 0.5 to 0.8 percent (Bailit, 2005; Fell and co-workers, 2006). Hospitalization is less common in obese women (Cedergren and associates, 2008). In women hospitalized in a previous pregnancy for hyperemesis, up to 20 percent require hospitalization in a subsequent pregnancy (Dodds and associates, 2006; Trogstad and co-workers, 2005).

Hyperemesis appears to be related to high or rapidly rising serum levels of pregnancy-related hormones. Although the exact stimulus is unknown, putative culprits include human chorionic gonadotropin (hCG), estrogens, progesterone, leptin, placental growth hormone, prolactin, thyroxine, and adrenocortical hormones (Verberg and associates, 2005). Studies by Goodwin and co-workers (2008) implicate the vestibular system. There seems to be no doubt that in some but not nearly all severe cases, there are interrelated psychological components (Buckwalter and Simpson, 2002). In some, hyperemesis is given as a reason for elective termination (Poursharif and colleagues, 2007). Other factors that increase the risk for admission include hyperthyroidism, previous molar pregnancy, diabetes, gastrointestinal illnesses, and asthma (Fell and co-workers, 2006). And for unknown reasons, a female fetus increases the risk by 1.5-fold (Schiff and colleagues, 2004; Tan and co-workers, 2006).

Helicobacter pylori Infection

An association of *H. pylori* infection has been proposed, but evidence is not conclusive. Goldberg and colleagues (2007) performed a scholarly systematic review of 14 case-control studies. Although the analysis indicated an association between *H. pylori* and hyperemesis, heterogenicity between study groups was extensive. At this time, we do not test for or treat for gastric infection in women with hyperemesis. Certainly, the "cocktail(s)" required for eradication would most likely *cause* vomiting in most pregnant women.

Somewhat unrelated, Ponzetto and colleagues (2006) reported that *H. pylori* seropositivity was linked to an increased risk for preeclampsia. In the population-based California study by Dodds and associates (2006), however, the incidence of gestational hypertension was not different from that in control women. *H. pylori* infection has also been linked to iron deficiency in pregnancy (Weyermann and associates, 2005).

Complications

Vomiting may be prolonged, frequent, and severe. Plasma zinc levels are increased, copper levels decreased, and magnesium levels unchanged (Dokmeci and associates, 2004). Preliminary findings are that a third of women with hyperemesis have an abnormal electroencephalogram (EEG) (Vaknin and colleagues, 2006). A list of potentially fatal complications is given in Table 49-2. Various degrees of acute renal failure from dehydration are encountered, and we have cared for a number of women with markedly impaired renal function. The extreme example, which was described by Hill and colleagues (2002), is a woman who required 5 days of dialysis when her serum creatinine level rose to 10.7 mg/dL. Life-threatening complications of continuous retching include *Mallory-Weiss tears,* such as shown in Figure 49-1. Others are *esophageal rupture*, *pneumothorax,* and *pneumomediastinum* (Schwartz and Rossoff, 1994; Yamamoto and colleagues, 2001).

TABLE 49-2. Some Life-Threatening Complications of Recalcitrant Hyperemesis Gravidarum

Depression—cause versus effect?
Esophageal rupture—Boerhaave syndrome
Hypoprothrombinemia—vitamin K
Hyperalimentation complications
Mallory-Weiss tears—bleeding, pneumothorax, pneumomediastinum, pneumopericardium
Renal failure—may require dialysis
Wernicke encephalopathy—thiamine deficiency

At least two serious vitamin deficiencies have been reported with hyperemesis in pregnancy. *Wernicke encephalopathy* from thiamine deficiency is not uncommon. Chiossi and colleagues (2006) reviewed 49 cases and reported that only half had the triad of confusion, ocular findings, and ataxia. Usually, there are MR imaging findings. At least three maternal deaths have been described, and long-term sequelae are common and include blindness, convulsions, and coma (Selitsky and co-workers, 2006). *Vitamin K deficiency* has been reported causing maternal coagulopathy and fetal intracranial hemorrhage (Kawamura, 2008; Robinson, 1998; Sakai, 2003, and all their colleagues).

Management

Methods to control nausea and vomiting of early pregnancy are discussed in Chapter 8 (see p. 210). A Cochrane Database review by Jewell and Young (2000) confirmed a salutary effect from a number of antiemetics given orally or by rectal suppository as first-line agents. When simple measures fail, intravenous

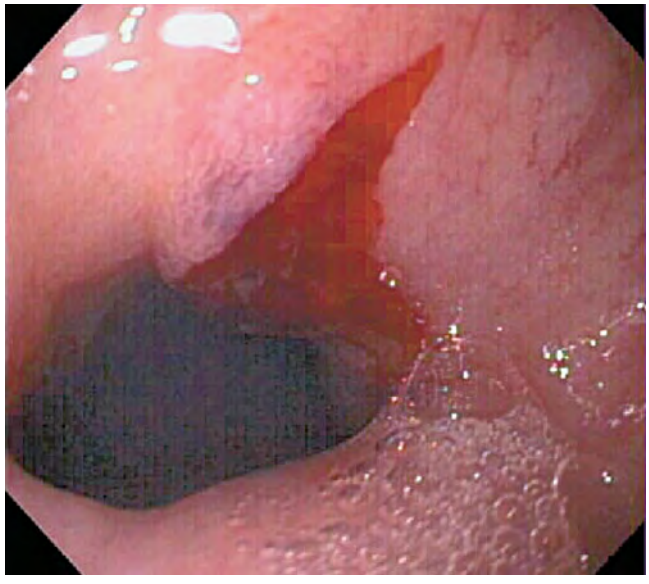

FIGURE 49-1 Endoscopic view of Mallory-Weiss tear. (From Michel and co-workers, 2008, with permission.)

crystalloid solutions are given to correct dehydration, ketonemia, electrolyte deficits, and acid-base imbalances. Thiamine, 100 mg, is given to prevent Wernicke encephalopathy previously discussed.

If vomiting persists after rehydration and failed outpatient management, hospitalization is recommended (American College of Obstetricians and Gynecologists, 2004). Antiemetics such as promethazine, prochlorperazine, chlorpromazine, or metoclopramide are given parenterally. There is little evidence that treatment with *glucocorticosteroids* is effective. Two small trials found no benefits of *methylprednisolone* compared with placebo, but the steroid-treated group had significantly fewer readmissions (Duggar and Carlan, 2001; Safari and co-workers, 1998). In a study of 110 women at Parkland Hospital, Yost and colleagues (2003) compared placebo with intravenous methylprednisolone plus tapered oral steroids. A third in each group required readmission. In a study by Bondok and co-workers (2006), pulsed hydrocortisone therapy was superior to metoclopramide to reduce vomiting and readmissions. *Serotonin antagonists* are the most effective agents for controlling chemotherapy-induced nausea and vomiting (Hesketh, 2008). When used in one trial for hyperemesis gravidarum, however, *ondansetron* was not superior to promethazine (Sullivan and associates, 1996). Reports of serotonin antagonist use in pregnancy are limited, but there is no evidence of teratogenicity (Briggs and associates, 2005; Mahadevan and Kane, 2006).

With persistent vomiting after hospitalization, appropriate steps should be taken to exclude possible underlying diseases as a cause of hyperemesis. Endoscopy did not change management in 49 women reported by Debby and co-workers (2008). Examples include gastroenteritis, cholecystitis, pancreatitis, hepatitis, peptic ulcer, and pyelonephritis. In addition, severe preeclampsia and fatty liver are considerations after midpregnancy. And although clinical thyrotoxicosis has been implicated as a cause of hyperemesis, it is more likely that abnormally elevated serum thyroxine levels are a surrogate for higher-than-average serum hCG levels (see Chap. 3, p. 63). Tan and colleagues (2002) have described this as "chemical hyperthyroidism." And of interest, Panesar and associates (2006) showed that a cohort of women with hyperemesis had lower serum thyrotropin levels. In our experiences, serum free thyroxine levels normalize quickly with hydration.

Following treatment, most women have had a salutary response and may be sent home with antiemetic therapy. Their readmission rate is 25 to 35 percent in most prospective studies.

If associated psychiatric and social factors contribute to the illness, the woman usually improves remarkably while hospitalized, but may relapse after discharge. In these women, assistance with psychosocial problems is beneficial (Swallow and co-workers, 2004).

Nutritional Support

In the small percentage of women who continue to have recalcitrant vomiting, consideration is given for enteral nutrition as discussed on page 1050. Vaisman and co-workers (2004) described successful use of nasojejunal feeding for up to 21 days in 11 such women. *Percutaneous endoscopic gastrostomy with a jejunal port—PEG (J) tube*—was described by Schrag and co-workers (2007).

In our experiences, only a very few women will require parenteral nutrition. In their study of 166 women, Folk and colleagues (2004) reported that in 16 percent, central venous access was established for nutrition. The litany of complications included line sepsis in 25 percent and thrombosis and infective endocarditis in one woman each.

Reflux Esophagitis

Heartburn, or *pyrosis*, is common in late pregnancy. The retrosternal burning sensation is caused by esophagitis from gastroesophageal reflux related to relaxation of the lower esophageal sphincter (Hytten, 1991). Common folklore has held that women with excessive heartburn give birth to infants with more hair. And although this may seem strange, Costigan and associates (2006) recently confirmed this! They proposed a shared biological mechanism. Pregnancy hormones caused both relaxation of the esophageal sphincter—thus more reflux, more heartburn, and they also modulated hair growth.

Symptoms usually respond to raising the head of the bed and treatment with oral antacids. If severe symptoms persist, an H_2-receptor antagonist such as *cimetidine* or *ranitidine* is prescribed. These are considered safe, but *misoprostol* is contraindicated because it may stimulate labor (see Chap. 22, p. 503). The commonly used proton-pump inhibitor, *omeprazole*, is also safe for use in pregnancy (Diav-Citrin and associates, 2005; Mahadevan and Kane, 2006). If there still is no relief, then endoscopy should be considered.

Biertho and associates (2006) described 25 women who had undergone laparoscopic Nissen fundoplication for reflux prior to pregnancy. Only 20 percent had reflux symptoms requiring antacids during pregnancy.

Hiatal Hernia

The older literature is informative here. Rigler and Eneboe (1935) performed upper gastrointestinal radiographs in 195 women in late pregnancy. Almost 20 percent of 116 multiparas and 5 percent of 79 nulliparas had a hiatal hernia. Notably, in only three of 10 women, a hernia persisted for 1 to 18 months postpartum.

The relationship of hiatal hernia with reflux esophagitis, and thus symptoms, is not clear. Cohen and Harris (1971) demonstrated no relationship between reflux and hernia and showed that the lower esophageal sphincter functioned effectively even when displaced intrathoracically. Nevertheless, during pregnancy, these hiatal hernias may cause vomiting, epigastric pain, and bleeding from ulceration. Curran and colleagues (1999) described a 30-week pregnancy complicated by gastric outlet obstruction from a paraesophageal hernia, which they subsequently successfully repaired. Biertho and associates (2006) reported a woman with a prior Nissen fundoplication whose pregnancy was complicated by gastric herniation into the thoracic cavity. Emergency surgical intervention was followed by spontaneous abortion.

Diaphragmatic Hernia

These are caused by herniations of abdominal contents through either the foramen of Bochdalek or foramen of Morgagni. Fortunately, they rarely complicate pregnancy. Kurzel and associates

(1988) reviewed the outcomes of 18 pregnant women with such a hernia and who developed acute obstruction. Because the maternal mortality rate was 45 percent, they recommend repair during pregnancy even if a woman is asymptomatic. Flick and co-workers (1999) reported a 23-week pregnancy complicated by maternal intrathoracic bowel herniation through an old traumatic diaphragmatic defect. Finally, several case reports describe spontaneous diaphragmatic rupture from increased intra-abdominal pressure during delivery (Ortega-Carnicer, 1998; Sharifah, 2003; Watkin, 1993, and all their colleagues).

Achalasia

The word literally means "failure to relax." Achalasia is a motility disorder in which the lower esophageal sphincter fails to relax properly with swallowing, and there are nonperistaltic contractions of the esophageal muscularis (Khudyak and colleagues, 2006). The defect is caused by inflammatory destruction of the myenteric, that is, Auerbach plexus, of smooth muscle of the lower esophagus and its sphincter. Postganglionic cholinergic neurons are unaffected; thus, there is unopposed sphincter stimulation. Symptoms are dysphagia, chest pain, and regurgitation. Barium swallow radiography demonstrates "bird beak" or "ace of spades" narrowing at the distal esophagus. Endoscopy is performed to exclude gastric carcinoma, and manometry is confirmatory. If dilatation of the esophagus and medical therapy does not provide relief, myotomy is considered (Torquati and associates, 2006).

Pregnancy

Normal relaxation of the lower esophageal sphincter during pregnancy theoretically should not occur with achalasia. Even so, in most women, pregnancy does not seem to worsen achalasia. Mayberry and Atkinson (1987) interviewed 20 affected women who reported no excessive reflux esophagitis. In their review of 35 pregnancies, Khudyak and colleagues (2006) described most as symptom free, although esophageal dilatation was needed in a few. A maternal death at 24 weeks associated with a 14-cm diameter megaesophagus was described by Fassina and Osculati (1995).

Management includes soft diet and anticholinergic drugs. With persistent symptoms, other options include nitrates, calcium-channel antagonists, and botulinum toxin injection (Khudyak and co-workers, 2006). Balloon dilatation of the sphincter may be necessary, and 85 percent of nonpregnant patients respond to this. Satin and colleagues (1992) and Fiest and associates (1993) reported successful use of pneumatic dilatation in pregnancy. It is important to remember that esophageal perforation is a serious complication of dilatation.

Peptic Ulcer

Erosive ulcer disease more often involves the duodenum rather than the stomach in young women. Gastroduodenal ulcers in nonpregnant women may be caused by chronic gastritis from *H. pylori,* or they develop from use of aspirin or other nonsteroidal anti-inflammatory drugs. Neither is common in pregnancy (McKenna and colleagues, 2003; Weyermann and associates, 2003). Acid secretion is also important, and thus the efficacy of antisecretory agents (Suerbaum and Michetti, 2002).

Gastroprotection during pregnancy is probably due to reduced gastric acid secretion, decreased motility, and considerably increased mucus secretion (Hytten, 1991). Despite this, Cappell and Garcia (1998) theorize that ulcer disease may be underdiagnosed because of frequent treatment for reflux esophagitis. In the past 40 years at Parkland Hospital, during which time we have cared for more than 400,000 pregnant women, we have encountered very few who had symptomatic ulcer disease. Before appropriate therapy was commonplace, Clark (1953) studied 313 pregnancies in 118 women with proven ulcer disease and reported a clear remission during pregnancy in almost 90 percent. Benefits were short lived, however, and symptoms recurred in over half by 3 months postpartum and in almost all by 2 years.

Management

Antacids are first-line therapy, and H_2-receptor blockers are prescribed for those who do not respond. Proton-pump inhibitors are effective, and at least two studies have shown no apparent teratogenic effects (Diav-Citrin and co-workers, 2005; Mahadevan and Kane, 2006). *Sucralfate* is the aluminum salt of sulfated sucrose that provides a protective coating at the ulcer base. Only approximately 10 percent of the aluminum salt is absorbed, and it is considered safe for pregnant women.

With active ulcers, a search for *H. pylori* is undertaken. Diagnostic aids include the urea breath test, serological testing, or endoscopic biopsy. If any of these are positive, antimicrobial therapy is indicated. There are a number of effective oral treatment regimens that do not include tetracycline and that can be used during pregnancy. These include amoxicillin, 1000 mg twice daily; clarithromycin, 500 mg twice daily; or metronidazole, 500 mg twice daily, used in paired combination for 7 days (Dzieniszewski and Jarosz, 2006).

Upper Gastrointestinal Bleeding

Occasionally, persistent vomiting is accompanied by worrisome upper gastrointestinal bleeding (see p. 1051). Occasionally, there is a bleeding peptic ulceration. However, most of these women have small linear mucosal tears near the gastroesophageal junction—*Mallory-Weiss tears* (see Fig. 49-1). Bleeding usually responds promptly to conservative measures, including iced saline irrigations, topical antacids, and intravenously administered H_2-blockers. Transfusions may be needed, and if there is persistent bleeding, then endoscopy is indicated (O'Mahony, 2007). With persistent retching, the less common, but more serious, esophageal rupture—*Boerhaave syndrome*—may develop from greatly increased esophageal pressure.

DISORDERS OF THE SMALL BOWEL AND COLON

The small bowel has diminished motility during pregnancy. Using a nonabsorbable carbohydrate, Lawson and colleagues (1985) showed that small bowel mean transit times were 99, 125, and 137 minutes in each trimester, compared with 75 minutes when nonpregnant. In a study cited by Everson (1992),

mean transit time for a mercury-filled balloon from the stomach to the cecum was 58 hours in term pregnant women compared with 52 hours in nonpregnant women.

Muscular relaxation of the colon is accompanied by increased absorption of water and sodium that predisposes to constipation, which is reported by almost 40 percent of women at some time during pregnancy (Everson, 1992). Such symptoms are usually only mildly bothersome, and preventive measures include a high-fiber diet and bulk-forming laxatives. Treatment options have been reviewed by Wald (2003). We have encountered several pregnant women who developed megacolon from impacted stool. These women almost invariably had chronically abused stimulatory laxatives.

Infectious Diarrhea

The large variety of viruses, bacteria, helminths, and protozoa that cause diarrhea in adults inevitably afflict pregnant women. For example, the incidence of *Clostridium difficile* pseudomembranous colitis has tripled in the past decade (Kelly and LaMont, 2008). Travelers diarrhea is usually mild and responds to loperamide (Medical Letter, 2008). These are discussed in Chapter 58.

Inflammatory Bowel Disease

The two presumably noninfectious forms of intestinal inflammation are *ulcerative colitis* and *Crohn disease*. The latter also is known as regional enteritis, Crohn ileitis, and granulomatous colitis. Differentiation between the two is important because treatment is not the same. That said, they both share common factors, and sometimes it is impossible to distinguish them if Crohn disease involves the colon. The salient clinical and laboratory features shown in **Table 49-3** permit a reasonably confident diagnostic differentiation in most cases. The etiopathogenesis of both disorders is enigmatic, but there is genetic predisposition toward either. Inflammation is thought to result

TABLE 49-3. Some Differentiating Characteristics of Ulcerative Colitis and Crohn Disease

Characteristic	Ulcerative Colitis	Crohn Disease
Genetics and heredity	Polygenic; 6–20% monozygous twin concordance; HLA Bw35, B27, DR2; chromosomes 3,5,7,12,16	Polygenic; 50–58% monozygous twins; HLA A2, B27, DR5, DQ1; chromosome 16 *(IBD1–IBD9)*
Natural History		
Bowel involvement	Large bowel mucosa and submucosa; continuous involvement beginning at rectum (40% proctitis only)	Small and large bowel mucosa and deeper layers; transmural involvement common; may affect small or large bowel only, or both; discontinuous and segmental involvement; strictures or fistulas common
Colonoscopy	Mucosal erythema with granularity and friability with superficial ulceration; rectal involvement almost always	Patchy involvement; rectum usually spared; perianal involvement common
Symptoms	Diarrhea with blood or mucus; tenesmus	Cramping abdominal pain and watery diarrhea; vomiting; malnutrition; low-grade fever; weight loss
Clinical course	Exacerbations and remission; acute and intermittent common; may be chronic and unremitting	Exacerbations and remission; surgery commonly required
Extraintestinal manifestations	Arthritis; erythema nodosum; pyoderma gangrenosum; uveitis	Arthritis; erythema nodosum; uveitis; anemia; carcinoma
Serum antibodies	Antineutrophil cytoplasm-antibody (pANCA) ~70%	Anti-*Saccharomyces cerevisiae* ~50%
Complications	Toxic megacolon (5%); strictures; reactive arthritis; sclerosing cholangitis; cancer (3–5%)	Fistulas; reactive arthritis; toxic megacolon
Management	Medical; proctocolectomy curative	Medical; segmental resection if indicated

HLA = human leukocyte antigen; IBD = inflammatory bowel disease.
From Farrell and Peppercorn (2002), Friedman and Blumberg (2008), Lichtenstein and colleagues, 2009; and Podolsky (2002).

from inappropriate response of the mucosal immune system to normal bacterial flora, with or without an autoimmune component (Friedman and Blumberg, 2008).

Ulcerative Colitis

Inflammation is confined to the superficial luminal layers of the colon, typically beginning at the rectum and extending proximally for a variable distance. Half of afflicted patients have disease confined to the rectum and rectosigmoid. Endoscopic findings include mucosal granularity and friability interspersed with mucosal ulcerations and a mucopurulent exudate. The extent of inflammation is proportional to symptoms, and bloody diarrhea is the cardinal presenting finding. The disease is characterized by exacerbations and remissions. For unknown reasons, prior appendectomy protects against development of ulcerative colitis (Selby and colleagues, 2002). *Toxic megacolon* is a particularly dangerous complication that frequently necessitates colectomy. *Extraintestinal manifestations* include arthritis, uveitis, and erythema nodosum. Another serious problem is that the risk of cancer approaches 1 percent per year.

Management. Ulcerative colitis is treated medically. Drugs that deliver 5-aminosalicyclic acid (5-ASA) or mesalamine are used for active colitis as well as maintenance therapy. *Sulfasalazine* is the prototype, and its 5-ASA moiety inhibits prostaglandin synthase in the colon. Glucocorticoids are given orally, parenterally, or by enema for more severe disease that does not respond to 5-ASA. Immunomodulating drugs, including *azathioprine*, *6-mercaptopurine*, *cyclosporine*, and *methotrexate,* are used in conjunction with prednisone in nonpregnant patients for maintenance. High-dose intravenous cyclosporine may be beneficial for severely ill patients and used in lieu of colectomy. For recalcitrant disease, proctocolectomy is performed, and a permanent ileostomy or an ileoanal anastomosis with a continent ileal pouch is created. Within the past few years, the anti-tumor necrosis factor (TNF) antibody *infliximab* has been reported to be modestly effective for treatment and maintenance of moderate to severe active disease (Rutgeerts and colleagues, 2005, 2009).

Crohn Disease

This disorder has more protean manifestations than ulcerative colitis. It involves not only the bowel mucosa but also the deeper layers, and sometimes there is transmural involvement. The disease is typically segmental. Approximately 30 percent of patients have small-bowel involvement, 25 percent have isolated colon involvement, and 40 percent have both, usually with the terminal ileum and colon involved.

Symptoms depend on which bowel segment(s) is involved. Thus, complaints may include cramping abdominal pain, diarrhea, weight loss, low-grade fever, and obstructive symptoms. The disease is chronic with exacerbations and remissions and importantly, it cannot be cured medically or surgically (Lichtenstein and associates, 2009). Almost 30 percent of patients require surgery during the first year after diagnosis, and thereafter, 5 percent per year require surgery. Reactive arthritis is common, and the risk of cancer, although not as great as with ulcerative colitis, is increased substantively.

Management. There is no regimen that is universally effective for maintenance during asymptomatic periods. *Sulfasalazine* is effective for some, but the newer 5-ASA formulations are better tolerated. As a class, they appear to be safe in pregnancy (Rahimi and associates, 2008). *Prednisone* therapy may control moderate to severe flares, but is less effective for small-bowel involvement. Immunomodulators such as *azathioprine*, *6-mercaptopurine*, *methotrexate*, and *cyclosporine* are used for active disease and for maintenance (Prefontaine and colleagues, 2009). With the exception of methotrexate, most of these drugs appear relatively safe during pregnancy (Briggs and co-workers, 2005; Moskovitz and associates, 2004). Methotrexate is category X as discussed in Chapter 14 (p. 320). In the past few years, anti-TNF-α antibodies, which include *infliximab, adatimumab*, and *certolizumab*, have been found effective for active Crohn disease and maintenance (Sandborn, 2007; Sands, 2004; Schreiber, 2007, and all their colleagues). This class of immunomodulators is considered category B, but data supporting safety in pregnancy are limited (Roux and colleagues, 2007).

Conservative surgery is indicated for complications. Patients with small-bowel involvement more likely will require surgery for complications that include fistulas, strictures, abscesses, and intractable disease. Some develop perineal communications that interfere with vaginal delivery (Forsnes and co-workers, 1999).

Inflammatory Bowel Disease and Fertility

Subfertility is commonly linked to any chronic medical disease (Bradley and Rosen, 2004). Despite this, Mahadevan (2006) cited a normal fertility rate unless surgery is performed for bowel disease. It may also be partially due to sulfasalazine, which causes reversible sperm abnormalities (Feagins and Kane, 2009). Alstead and Nelson-Piercy (2003) reported that decreased female fertility from active Crohn disease returned to normal with remission. After ileal pouch-anal anastomosis, however, up to half of women with ulcerative colitis are infertile (Waljee and associates, 2006). Thus, subfertility may be associated with active or severe disease.

Inflammatory Bowel Disease and Pregnancy

Both disorders are relatively common in young women and thus are encountered during pregnancy. In this regard, a few generalizations can be made. The consensus is that pregnancy does not increase the likelihood of an inflammatory bowel disease flare. Pertinent to this, Riis and colleagues (2006) performed a 10-year surveillance of women in the European Collaborative on Inflammatory Bowel Disease. The likelihood of a flare during pregnancy was decreased compared with their preconceptional course. This diminished rate persisted for years after pregnancy and was attributed to close attention and monitoring of enrolled patients. Although most women with quiescent disease in early pregnancy uncommonly have relapses, when a flare develops, it may be severe. Conversely, active disease in early pregnancy increases the likelihood of poor pregnancy outcome. In general, most usual treatment regimens may be continued during pregnancy. If needed to direct management, diagnostic evaluations should be undertaken, and if indicated, surgery should be performed.

Regarding effects on pregnancy, it is likely that overall, adverse perinatal outcomes are increased. Kornfeld and co-workers (1997) described outcomes in a population-based cohort study of 756 Swedish women with preexisting ulcerative colitis or Crohn disease. Rates of preterm birth, low birthweight, fetal-growth restriction, and cesarean delivery were all increased 1.5- to 2-fold. According to Reddy and associates (2008), these are more likely in women with multiple recurrences. Mahadevan and colleagues (2005) reported similar findings from a population-based Northern California study. Bush (2004) and Elbaz (2005) and their co-workers also confirmed these observations. Importantly, despite these results, perinatal mortality rates were not increased in either study. Also, there is evidence that much of this excessive morbidity is attributable to Crohn disease (Dominitz and associates, 2002; Fonager and co-workers, 1998).

Ulcerative Colitis and Pregnancy. There is no evidence to suggest that pregnancy has any significant effects on ulcerative colitis. In a meta-analysis of 755 pregnancies, Fonager and colleagues (1998) reported that ulcerative colitis quiescent at conception worsened in approximately a third of pregnancies. In women with active disease at the time of conception, approximately 45 percent worsened, 25 percent remained unchanged, and only 25 percent improved. These observations were similar to those previously described in an extensive review by Miller (1986).

Management for colitis for the most part is the same as for nonpregnancy. Flares may be caused by psychogenic stress and reassurance is important. *Calcium supplementation* is provided because osteoporosis is common. Maintenance of colitis is continued with 5-ASA derivatives, and flares are treated with corticosteroids. Recalcitrant disease is treated with immunomodulators as discussed on page 1055. Okada and associates (2006) described a dramatic response in a 13-week pregnant woman treated with *leukocytapheresis*. Parenteral nutrition may be necessary for women with prolonged exacerbations (see p. 1050).

Colorectal endoscopy is performed as indicated (Katz, 2002). Colectomy for fulminant colitis may be lifesaving, and it has been performed during each trimester. Dozois and colleagues (2005) reviewed 42 such cases and found that, in general, outcomes have been good in reports published after 1980. Most women underwent partial or complete colectomy, but decompression colostomy with ileostomy was described by Ooi and co-workers (2003) in a 10- and a 16-week pregnancy.

Proctocolectomy improves sexual function and fertility (Cornish and co-workers, 2007). Women who have had a colectomy and ileal pouch–anal anastomosis can safely deliver vaginally. Hahnloser and colleagues (2004) reviewed routes of delivery in women with 235 pregnancies before and 232 pregnancies after continent pouch surgery. Functional outcomes were similar, and these researchers concluded that cesarean delivery should be for obstetrical indications. In at least one case, however, adhesions to the growing uterus led to pouch perforation (Aouthmany and Horattas, 2004). *Pouchitis* is an inflammatory condition of the ileoanal pouch, probably due to bacterial proliferation, stasis, and endotoxin release. It usually responds to cephalosporins or metronidazole.

By most accounts, ulcerative colitis has minimal adverse effects on pregnancy outcome. Modigliani (2000) reviewed outcomes in 2398 pregnancies in women with colitis. Perinatal outcomes were not substantively different from those in the general obstetrical population. Specifically, the incidences of spontaneous abortion, preterm delivery, and stillbirths were remarkably low. In a population-based cohort study from Washington state, Dominitz and co-workers (2002) described pregnancy outcomes in 107 women with ulcerative colitis. With two exceptions, perinatal outcomes were similar to those of 1308 normal pregnancies. One exception was an inexplicably increased incidence of congenital malformations, and the other was a the cesarean delivery rate that was increased from 20 to 29 percent compared with controls.

Crohn Disease and Pregnancy. There is no evidence that pregnancy affects Crohn disease. One report suggested that disease activity might even be decreased (Agret and colleagues, 2005). In general, disease activity is related to its status around the time of conception. In their cohort study, Fonager and associates (1998) analyzed outcomes in 279 pregnancies based on disease activity at conception. For 186 women whose disease was inactive at conception, only a fourth relapsed during pregnancy. In contrast, of the 93 with active disease at conception, two thirds either worsened or had no change. Miller (1986) had described similar findings from his earlier review.

Maintenance therapy is similar to that for nonpregnant women. Oral or topical 5-ASA derivatives, usually with azathioprine, 6-mercaptopurine, or cyclosporine, are continued as they appear to be safe during pregnancy (Briggs and colleagues, 2005). Methotrexate is contraindicated, and recently mycophenolate mofetil and mycophenolic acid have been reported to cause serious congenital anomalies (Food and Drug Administration, 2008). These are discussed further in Chapter 14 (p. 317). Katz and co-workers (2004) described treatment with the monoclonal antibody infliximab in 96 pregnancies. In 31 of these, treatment was given in the first trimester with no adverse sequelae. Calcium supplementation is given to combat osteoporosis. Parenteral hyperalimentation has been used successfully during severe recurrences (Russo-Stieglitz and colleagues, 1999). Endoscopy or surgery is performed as indicated. An abdominal surgical procedure was required during 5 percent of pregnancies described by Woolfson and colleagues (1990). In one instance, a woman with known Crohn disease at 32 weeks underwent emergent cesarean delivery for a presumed abruption. Instead, an abscess was found around the hepatic flexure (Panayotidis and Triantafyllidis, 2006).

As discussed previously, Crohn disease is associated with increased adverse perinatal outcomes usually related to disease activity. Based on a 20-year review, Korelitz (1998) concluded that perinatal outcomes were generally good with quiescent disease. That said, in the case-control Danish study, Norgård and colleagues (2007) reported a twofold risk of preterm neonates. Dominitz and co-workers (2002) reported a two- to threefold increase in preterm delivery, low birthweight, and fetal-growth restriction in fetuses of 149 women with Crohn disease. The rate of cesarean delivery in this study was also increased compared with normal controls—28 versus 20 percent. As discussed

subsequently, women with an ileal loop colostomy may have significant problems. Women with perianal fistula—unless these are rectovaginal—usually can undergo vaginal delivery without complications (Takahashi and colleagues, 2007).

Ostomy and Pregnancy

A colostomy or an ileostomy can be problematic during pregnancy because of its location. Gopal and colleagues (1985) described 82 pregnancies in 66 women with an ostomy. Although stomal dysfunction was common, it responded to conservative management in all cases. But surgical intervention was necessary in three of six women who developed bowel obstruction and in another four with ileostomy prolapse—almost 10 percent overall. Although only a third of 82 women underwent cesarean delivery, Takahashi and associates (2007) described six of seven cesarean deliveries in women with enterostoma created for Crohn disease.

Colectomy with mucosal proctectomy and ileal pouch-anal anastomosis is the preferred surgical procedure for ulcerative colitis and familial colonic polyposis. As discussed on page 1056, Hahnloser (2004) and Ravid (2002) and their colleagues have described pregnancies in such women. Disadvantages include frequent bowel movements, fecal incontinence including nocturnal soilage in almost half of patients, and pouchitis.Although these disadvantages temporarily worsened during pregnancy, they abated postpartum. Importantly, Farouk and associates (2000) reported that pregnancy did not worsen long-term ostomy function. Most have concluded that vaginal delivery is acceptable in these women.

Intestinal Obstruction

The incidence of bowel obstruction is not increased during pregnancy, although it generally is more difficult to diagnose. Meyerson and colleagues (1995) reported a 20-year incidence of 1 in 17,000 deliveries at two Detroit hospitals. As shown in Table 49-4, approximately half of cases are due to adhesions from previous pelvic surgery that includes cesarean delivery. When women of all ages are considered, small-bowel obstruction eventually develops in only 1 per 1000 cesarean deliveries performed (Al-Sunaidi and Tulandi, 2006). Another 25 percent of bowel obstruction is caused by volvulus—sigmoid, cecal, or small bowel. These have been reported in late pregnancy or early puerperium (Alshawi, 2005; Biswas, 2006; Lal, 2006, and all their colleagues). Intussusception is occasionally encountered (Gould and co-workers, 2008). A degenerating uterine leiomyoma causing small-bowel obstruction was described by MacDonald and associates, (2004).

TABLE 49-4. Causes of Intestinal Obstruction During Pregnancy and the Puerperium

Cause of Obstruction	Percent
Adhesions:	~60
1st and 2nd trimester ~10–15%	
3rd trimester ~2%	
Postpartum ~10%	
Volvulus:	~25
Midgut ~2%	
Cecal ~5%	
Sigmoid ~10%	
Intussusception	~5
Hernia, carcinoma, other	~5

Data from Connolly (1995) and Redlich (2007) and all their colleagues.

Etiopathogenesis

Most cases of intestinal obstruction during pregnancy result from pressure of the growing uterus on intestinal adhesions. According to Davis and Bohon (1983), this more likely occurs: (1) around midpregnancy, when the uterus becomes an abdominal organ; (2) in the third trimester, when the fetal head descends; or (3) immediately postpartum, when there is an acute change in uterine size. Perdue and colleagues (1992) reported that 80 percent of pregnant women had nausea and vomiting. Importantly, 98 percent of all women had either continuous or colicky abdominal pain. Abdominal tenderness was found in 70 percent and abnormal bowel sounds in only 55 percent. Plain abdominal radiographs following soluble contrast showed evidence of obstruction in 90 percent of women. Plain radiographs are less accurate for diagnosing small-bowel obstruction, and CT and MR imaging are useful (Biswas, 2006; Essilfie, 2007; McKenna, 2007, and all their associates).

Pregnancy Outcomes

Mortality rates with obstruction during pregnancy can be excessive because of difficult and thus delayed diagnosis, reluctance to operate during pregnancy, and the need for emergency surgery (Firstenberg and Malangoni, 1998). Of 66 pregnancies, Perdue and associates (1992) described a 6-percent maternal mortality rate and 26-percent fetal mortality rate. Perforation from massively dilated bowel such as shown in Figure 49-2 causes sepsis. Two of the four women who died had sigmoid or cecal volvulus caused by adhesions late in pregnancy.

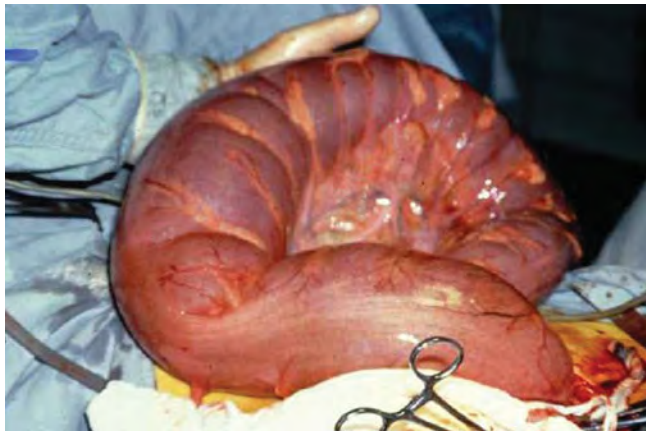

FIGURE 49-2 Massively dilated colon in a pregnant woman with colonic volvulus. (Courtesy of Dr. Lowell Davis.)

Colonic Pseudo-obstruction

Also known as *Ogilvie syndrome,* pseudo-obstruction is caused by adynamic colonic ileus. Approximately 10 percent of all cases are associated with pregnancy. The syndrome usually develops postpartum, but it has been reported occasionally antepartum (Tung and associates, 2008). It is characterized by massive abdominal distension with cecal dilatation. Although unusual, the large bowel may rupture (Singh and colleagues, 2005). In most cases, intravenous infusion of neostigmine, 2 mg, results in prompt decompression (Ponec and associates, 1999). In some cases, colonoscopic decompression is performed, but laparotomy is done for perforation. (De Giorgio and Knowles, 2009).

Appendicitis

Suspected appendicitis is one of the most common indications for abdominal exploration during pregnancy. Mazze and Källén (1991) reported this in approximately 1 in 1000 pregnant women in the Swedish registry of 720,000 pregnancies. Appendicitis was confirmed in 65 percent for an incidence of approximately 1 in 1500 pregnancies. It is interesting—and inexplicable—that the incidence was much lower in the Danish registry of more than 320,000 pregnancies. Hée and Viktrup (1999) reported the confirmed appendicitis rate of only 1 per 5500 pregnancies. There is some evidence that appendicitis is less common during pregnancy compared with its incidence in age-matched nonpregnant controls (Andersson and Lambe, 2001).

It is repeatedly—and appropriately—emphasized that pregnancy makes diagnosis of appendicitis more difficult. This is partly because nausea and vomiting accompany normal pregnancy. In addition, as the uterus enlarges, the appendix commonly moves upward and outward so that pain and tenderness are "displaced" (Baer and colleagues, 1932). These latter findings have been challenged (Mourad and associates, 2000). Another oft-stated reason is that some degree of leukocytosis accompanies normal pregnancy.

For all of these reasons, pregnant women—and especially those late in gestation—frequently do not have clinical findings "typical" for appendicitis. It commonly is confused with cholecystitis, preterm labor, pyelonephritis, renal colic, placental abruption, or degeneration of a uterine leiomyoma.

Most reports indicate increasing morbidity and mortality rates with increasing gestational age. And as the appendix is progressively deflected upward by the growing uterus, omental containment of infection becomes increasingly unlikely. It is indisputable that appendiceal perforation is more common during later pregnancy. In the studies by Andersson and Lambe (2001) and Ueberrueck and associates (2004), the incidence of perforation averaged approximately 8, 12, and 20 percent in successive trimesters.

Diagnosis

Persistent abdominal pain and tenderness are the most reproducible findings. As discussed, although most have reported

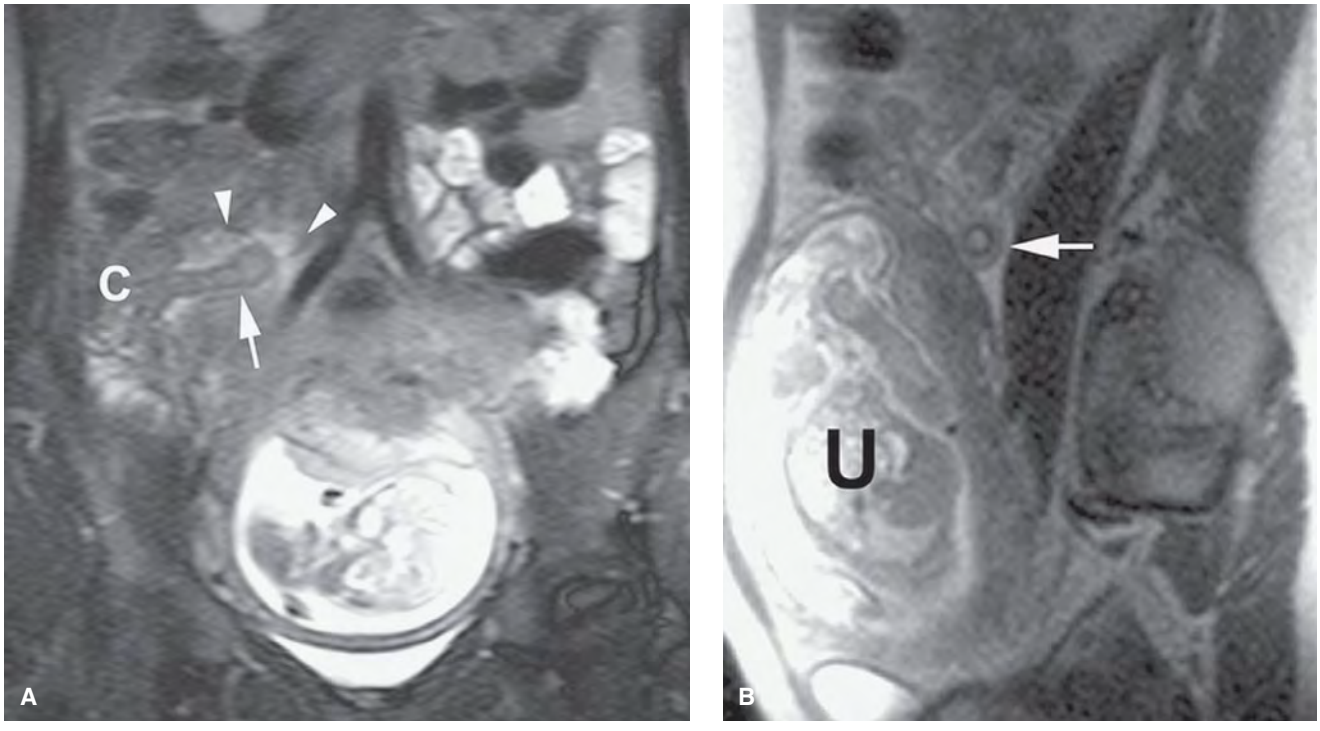

FIGURE 49-3 Magnetic resonance (MR) imaging in a woman with appendicitis at 20 weeks' gestation. **A.** The left coronal image shows an enlarged appendix (*arrow*) with high signal intensity within the lumen. Increased periappendiceal signal intensity (*arrowheads*) is due to inflammation. C = cecum. **B.** The right sagittal image demonstrates the high-intensity signal due to fluid in the distended, obstructed appendix (*arrow*) and the thickened wall. Nonperforative appendicitis was confirmed at surgery. U = uterus. (Reproduced from I Pedrosa, D Levine, AD Eyvazzadeh, et al., MR imaging evaluation of acute appendicitis in pregnancy, *Radiology,* 2006;238:891–899, with permission from The Radiological Society of North America (RSNA) and Dr. Ivan Pedrosa)

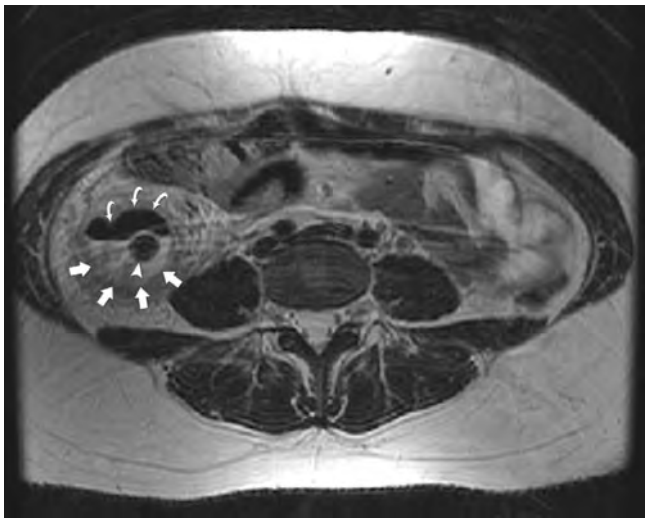

FIGURE 49-4 Appendiceal abscess in a pregnant woman at 14 weeks' gestation. Axial magnetic resonance (MR) image of the abdomen and pelvis shows air (*curved arrows*)-fluid (*arrows*) levels of the abscess surrounding the appendix (*arrowhead*). (Courtesy of Dr. R. Douglas Sims.)

that pain migrates upward with appendiceal displacement, this has been disputed.

Graded compression sonography during pregnancy is difficult because of cecal displacement and uterine imposition (Pedrosa and co-workers, 2009). *Appendiceal computed tomography* is more sensitive and accurate than sonography to confirm suspected appendicitis (Gearhart, 2008; Paulson, 2003; Raman, 2008, and all their colleagues). Specific views can be designed to decrease fetal radiation exposure (see Chap. 41, p. 918). In one study, Wallace and co-workers (2008) reported that the negative appendectomy rate was 54 percent with clinical diagnosis alone, but only 8 percent if sonography and CT scanning were used. *MR imaging* may be preferable, and we and others have had good results with its use (Israel and associates, 2008). Shown in **Figure 49-3** is an example of nonperforative appendicitis, whereas a periappendiceal phlegmon/abscess is shown in **Figure 49-4**. Although not as accurate as preliminary findings suggested, Pedrosa and associates (2009) reported no false-negative diagnoses with MR imaging, but a 30-percent false-positive rate in 140 pregnant women with suspected appendicitis. Finally, appendiceal scanning following administration of native leukocytes tagged with technetium-99 was not successful in 13 pregnant women reported by Stewart and associates (2006).

Management

When appendicitis is suspected, treatment is prompt surgical exploration. Although diagnostic errors sometimes lead to removal of a normal appendix, surgical evaluation is superior to postponed intervention and generalized peritonitis. In most reports, the diagnosis is verified in 60 to 70 percent of pregnant women who undergo surgical exploration. Related to the successive perforation rate by trimester discussed above, the accuracy of diagnosis is inversely proportional to gestational age. Mazze and Källén (1991) reported that 77 percent of first-trimester diagnoses were correct. In the latter two trimesters, however, only 57 percent were verified.

During the first half of pregnancy, laparoscopy for suspected appendicitis has become the norm. From the Swedish database, Reedy and colleagues (1997) reported similar perinatal outcomes in nearly 2000 laparoscopic appendectomies compared with those of more than 1500 laparotomies done before 20 weeks. In many centers, laparoscopic appendectomy is performed in the third trimester (Barnes and colleagues, 2004; Rollins and associates, 2004). Parangi and co-workers (2007) are less enthusiastic about this approach, and we are of the opinion that laparoscopic surgery in pregnancy past 26 to 28 weeks should be performed only by the most experienced surgeons. For laparotomy most surgeons prefer a McBurney incision.

Before exploration, intravenous antimicrobial therapy is begun, usually with a second-generation cephalosporin or third-generation penicillin. Unless there is gangrene, perforation, or a periappendiceal phlegmon, antimicrobial therapy can usually be discontinued after surgery. Without generalized peritonitis, the prognosis is excellent. Seldom is cesarean delivery indicated at the time of appendectomy. Uterine contractions are common, and although some clinicians recommend tocolytic agents, we do not. De Veciana and colleagues (1994) reported that tocolytic use increased the risk for maternal pulmonary-permeability edema with sepsis syndrome (see Chap. 42, p. 929).

If appendicitis is undiagnosed before delivery, often when the large uterus rapidly empties, walled-off infection is disrupted, causing an acute surgical abdomen. New-onset appendicitis during the immediate puerperium is uncommon. **However, it is important to remember that puerperal pelvic infections typically do not cause peritonitis**.

Effects on Pregnancy

Appendicitis increases the likelihood of abortion or preterm labor, especially if there is peritonitis. Mazze and Källén (1991) and Cohen-Kerem and associates (2005) reported that spontaneous labor ensued with greater frequency following surgery for appendicitis compared with other indications after 23 weeks. In the former study, fetal loss was 22 percent if surgery was performed after 23 weeks. McGory and colleagues (2007) surveyed the California Inpatient File of 3133 pregnant women undergoing surgery for suspected appendicitis. Overall, the fetal loss rate was 23 percent. The rate was doubled—6 versus 11 percent with simple versus complicated disease. Interestingly, it was higher in those with negative appendiceal pathology compared with those with simple appendicitis—4 versus 10 percent.

Mays and colleagues (1995) have suggested a link between sepsis and neonatal neurological injury. Viktrup and Hée (1998) found that appendicitis during pregnancy was not associated with subsequent infertility.

CHAPTER 50

Hepatic, Gallbladder, and Pancreatic Disorders

HEPATIC DISORDERS 1063
GALLBLADDER DISORDERS 1073
PANCREATIC DISORDERS 1074

Disorders of the liver, gallbladder, and pancreas together comprise a formidable list of complications that may arise in pregnancy, including some unique to pregnancy. Their relationships with pregnancy can be fascinating, intriguing, and challenging.

HEPATIC DISORDERS

It is customary to divide liver diseases complicating pregnancy into three general categories. The first includes those specifically related to pregnancy that resolve either spontaneously or following delivery. Examples are hepatic dysfunction from hyperemesis gravidarum, intrahepatic cholestasis, acute fatty liver, and hepatocellular damage with preeclampsia—the "HELLP syndrome" (Hay, 2008). The second category includes acute hepatic disorders that are coincidental to pregnancy, such as acute viral hepatitis. The third category includes chronic liver diseases that predate pregnancy, such as chronic hepatitis, cirrhosis, or esophageal varices.

Hepatic Physiology in Pregnancy

Pregnancy may induce appreciable changes in some clinical and laboratory manifestations related to the liver (see Chap. 5, p. 126 and Appendix). Findings such as elevated serum alkaline phosphatase, palmar erythema, and spider angiomas, which might suggest liver disease, are commonly found during normal pregnancy. However, histological liver findings with uncomplicated pregnancies are unchanged compared with those of nonpregnant subjects (Ingerslev and Teilum, 1945).

Hyperemesis Gravidarum

Pernicious nausea and vomiting are discussed in detail in Chapter 49 (p. 1050). The liver may be involved, and there may be mild hyperbilirubinemia with serum transaminase levels elevated in up to half of women hospitalized (Table 50-1). Levels, however, seldom exceed 200 U/L. Liver biopsy may show some fatty changes (Knox and Olans, 1996).

Intrahepatic Cholestasis of Pregnancy

This disorder also has been referred to as recurrent jaundice of pregnancy, cholestatic hepatosis, and icterus gravidarum. It is characterized clinically by pruritus, icterus, or both. It may be more common in multifetal pregnancy (Lausman and colleagues, 2008). There is a significant genetic influence, and thus the incidence of this disorder varies by population. For example, cholestasis is uncommon in North America, with an incidence of approximately 1 in 500 to 1000 pregnancies. In Israel, the incidence reported by Sheiner and associates (2006) is approximately 1 in 400. In Italy, the incidence is 1 percent; in Sweden, it is 1.5 percent; and in Chile, it is 4 percent (Glantz, 2004; Paternoster, 2002; Reyes, 1997, and all their colleagues).

Pathogenesis

The cause of obstetrical cholestasis is unknown, but it probably occurs in genetically susceptible women. Leslie and colleagues (2000) reported that plasma estrogen levels are *decreased* in affected women. Diminished secretion of sulfated progesterone metabolites

TABLE 50-1. Clinical and Laboratory Findings with Acute Liver Diseases in Pregnancy

			Hepatic		Renal	Hematological and Coagulation					
Disorder	Onset in Pregnancy	Clinical Findings	AST μ/L	Bili mg/dL	Cr mg/dL	Hct	Plat	Fib	DD	PT	Hemolysis
Hyperemesis	Early	Severe N&V	NL-300	NL-4	↑	↑↑	NL	NL	NL	NL	No
Cholestasis	Late	Pruritus, jaundice	NL-200	1–5	NL	NL	NL	NL	NL	NL	No
Fatty liver	Late	Moderate N&V, ± HTN, liver failure	200–800	4–10	↑↑↑	↑↑↑	↓↓	↓↓↓	↑	↑↑	↑↑↑
Preeclampsia	Mid to late	HA, HTN	NL-300	2–4	↑	↑	↓↓	NL	↑	NL	↑-↑↑
Hepatitis	Variable	Jaundice	2000+	5–20	NL	↑	↓	NL	NL	↑	No

↑ = increased levels; ↓ = decreased levels; AST = aspartate aminotransferase; Bili = bilirubin; Cr = creatinine; DD = D-dimers; Fib = fibrinogen; HA = headache; Hct = hematocrit; HTN = hypertension; N&V = nausea and vomiting; NL = normal; Plat = platelets; PT = prothrombin time.

may play a role (Mullally and Hansen, 2001; Reyes and Sjovall, 2000). At least some cases are related to the many gene mutations that control hepatocellular transport systems (Germain and associates, 2002; Hay, 2008). One example is mutation of the *multidrug resistance 3 (MDR3)* gene found with *progressive familial intrahepatic cholestasis.* (Gonzales and co-workers, 2009). Some drugs that similarly decrease canalicular transport of bile acids aggravate the disorder. For example, we have encountered impressive cholestatic jaundice in pregnant women taking azathioprine following renal transplantation.

Whatever the inciting cause(s), bile acids are cleared incompletely and accumulate in plasma. Of note, total bile acid concentration may already be elevated 10- to 100-fold in normal pregnancy (Lunzer and associates, 1986). Even *before* bile acid levels increase, associated dyslipidemia is apparent (Dann and colleagues, 2006). These researchers found that total cholesterol levels are significantly higher compared with those of normal pregnancy, and low-density lipoprotein (LDL) cholesterol levels become elevated earliest. Hyperbilirubinemia results from retention of conjugated pigment, but total plasma concentrations rarely exceed 4 to 5 mg/dL. Alkaline phosphatase is usually elevated even more so than in normal pregnancy. Serum transaminase levels are normal to moderately elevated but seldom exceed 250 U/L (see Table 50-1). Liver biopsy shows mild cholestasis with bile plugs in the hepatocytes and canaliculi of the centrilobular regions, but without inflammation or necrosis. These changes disappear after delivery but often recur in subsequent pregnancies or with estrogen-containing contraceptives.

Clinical Presentation

Pruritus develops in late pregnancy, although it occasionally begins in the late second trimester. Occasionally, it manifests even earlier, and Kirkinen and Ryynänen (1995) described a woman at 13 weeks with cholestasis associated with hyperplacentosis and a triploid fetus. There are no constitutional symptoms, and generalized pruritus develops with predilection for the soles of the feet. Skin changes are limited to excoriations from scratching. Biochemical tests may be abnormal at presentation, but pruritus usually precedes laboratory findings by a mean of 3 weeks and sometimes by months (Kenyon and colleagues, 2001, 2002). Approximately 10 percent of women develop jaundice.

With normal liver enzymes, the differential diagnosis of pruritus includes other skin disorders (see Chap. 56, p. 1187). Findings are unlikely to be due to preeclamptic liver disease if there are no blood pressure changes and proteinuria. Sonography may be warranted to exclude cholelithiasis and biliary obstruction. *Acute* viral hepatitis is an unlikely diagnosis because of the usually low serum transaminase levels seen with cholestasis. Conversely, asymptomatic *chronic* hepatitis C is associated with a 20-fold increased incidence of cholestasis (Locatelli and colleagues, 1999; Paternoster and associates, 2002).

Management

Pruritus may be troublesome and is thought to result from elevated serum bile salts. *Antihistamines* and *topical emollients* may provide some relief. Based on their review, Kroumpouzos and Cohen (2003) estimated that *cholestyramine* may be effective in 50 to 70 percent of women. This compound also causes further decreased absorption of fat-soluble vitamins, which may lead to vitamin K deficiency. Fetal coagulopathy may develop, and there are reports of intracranial hemorrhage and stillbirth (Matos and colleagues, 1997; Sadler and associates, 1995). Finally, the opioid antagonist *naltrexone* was found to be superior to placebo for pruritus (Terg and colleagues, 2002).

Some reports suggest that *ursodeoxycholic acid* quickly relieves pruritus and lowers serum enzyme levels (Germain and co-workers, 2002; Mazzella and associates, 2001). Lucangioli and colleagues (2009) documented an especially profound decrease in serum levels of lithocholic acid. Kondrackiene and colleagues (2005) randomized 84 symptomatic women to ursodeoxycholic acid (8 to 10 mg/kg/d) versus cholestyramine

(8 g/d) and reported superior relief with ursodeoxycholic acid—67 versus 19 percent, respectively. Glantz and co-workers (2005), however, found no benefits to women randomly assigned to ursodeoxycholic acid versus dexamethasone. The American College of Obstetricians and Gynecologists (2006) has concluded that ursodeoxycholic acid both relieves pruritus and improves fetal outcomes, although evidence for the latter is not compelling. Finally, Warren and associates (2005) reported dramatic relief in a woman with refractory pruritus who was treated by plasmapheresis and 5-percent albumin replacement.

Cholestasis and Pregnancy Outcomes

Most earlier reports described excessive adverse pregnancy outcomes in women with cholestatic jaundice. Data accrued over the past two decades are ambiguous concerning increased perinatal mortality rates and whether close fetal surveillance is preventative. A review of a few studies illustrates this. Rioseco and co-workers (1994) compared outcomes in 320 affected women with those of normal controls. They observed that rates of meconium-stained amnionic fluid—25 versus 16 percent, and preterm delivery—12 versus 4 percent, were significantly increased with cholestasis. They attributed equivalent perinatal mortality rates in these two groups to close pregnancy surveillance. In a prospective investigation of 70 women with cholestasis, Kenyon and co-workers (2002) found that weekly amnionic fluid assessment, every-other-day antepartum fetal testing, and elective delivery at 37 to 38 weeks resulted in zero perinatal mortalities. Glantz and associates (2004) described outcomes in 693 Swedish women. Perinatal mortality rates were slightly increased, but death was limited to infants of mothers with severe disease characterized by total bile acid levels ≥40 μmol/L. More recently, Sheiner and co-workers (2006) described no differences in perinatal outcomes in 376 affected pregnancies compared with their overall obstetrical population. There was, however, a significant increase in labor inductions and cesarean deliveries in affected women. Finally, Lee and associates (2009) described two cases of sudden fetal death not predicted by nonstress testing.

Gorelik and colleagues (2006) suggest that bile acids may cause fetal cardiac arrest after entering cardiomyocytes in abnormal amounts. Using fetal myocyte cultures, they showed expression of several genes that may play a role in bile transport.

Acute Fatty Liver of Pregnancy

The most common cause of acute liver failure during pregnancy is acute fatty liver—also called *acute fatty metamorphosis* or *acute yellow atrophy.* In its worst form, the incidence is probably approximately 1 in 10,000 pregnancies.

Fatty liver is characterized by accumulation of microvesicular fat that literally "crowds out" normal hepatocytic function (Fig. 50-1). Grossly, the liver is small, soft, yellow, and greasy.

Etiopathogenesis

Although much has been learned about this disorder, interpretation of conflicting data has led to incomplete but intriguing observations. For example, some if not most cases of maternal fatty liver are associated with recessively inherited mitochondrial abnormalities of fatty acid oxidation. These are similar to those in children with Reye-like syndromes. A number of mutations have been described for the mitochondrial trifunctional protein enzyme complex that catalyzes the last oxidative steps in the pathway. The most common are the G1528C and E474Q mutations of the gene on chromosome 2 that code for long-chain-3-hydroxyacyl-CoA-dehydrogenase—known as LCHAD. There are other mutations for medium- and short-chain dehydrogenase—MCHAD and SCHAD (Dann and colleagues, 2006). Similar findings have been reported with autosomal recessive carnitine palmitoyltransferase 1 (CPT1) deficiency (Ylitalo and co-workers, 2005).

Sims and co-workers (1995) observed that some *homozygous* LCHAD-deficient children with Reye-like syndromes had *heterozygous* mothers with fatty liver. This was also seen in women with a compound heterozygous fetus. Although some conclude that heterozygous LCHAD-deficient mothers are at risk *only* if their fetus is homozygous, this is not always the case (Blish and Ibdah, 2005; Tyni and colleagues, 1998).

There is a controversial association between fatty acid β-oxidation enzyme defects and

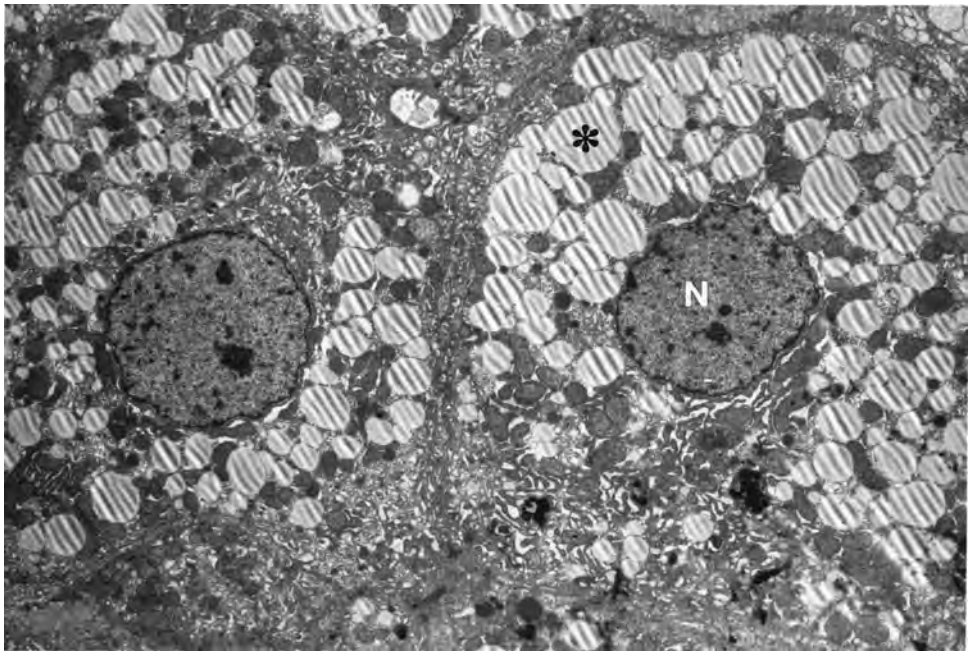

FIGURE 50-1 Fatty liver of pregnancy. Electron photomicrograph of two swollen hepatocytes containing numerous microvesicular fat droplets (*). The nuclei (N) remain centered within the cells, unlike with the case of macrovesicular fat deposition. (Used with permission from Dr. Donald A. Wheeler.)

severe preeclampsia—especially in women with *HELLP syndrome*—hemolysis, elevated serum liver transaminase levels, and low platelet counts (see Chap. 34, p. 720). Most of these observations have been arrived at by retrospectively studying mothers delivered of a child who later developed Reye-like syndrome. In the study by Tyni and associates (1998), 29 of 63 women with a clinically affected and presumably homozygous fetus had increased incidences of preeclampsia, HELLP syndrome, acute fatty liver, and cholestasis. More recently, Browning and co-workers (2006) performed a case-control study of 50 mothers of children with a fatty-acid oxidation defect and 1250 mothers of matched control infants. During their pregnancy, 16 percent of mothers with an affected child developed liver problems compared with only 0.9 percent of control women. These included HELLP syndrome in 12 percent and fatty liver in 4 percent. Despite these findings, the clinical, biochemical, and histopathological findings are sufficiently disparate to suggest that severe preeclampsia, with or without HELLP syndrome, and fatty liver are distinct syndromes (American College of Obstetricians and Gynecologists, 2006; Sibai, 2007).

Recurrence. Fatty liver recurring in subsequent pregnancy is uncommon, but a few cases have been described (Usta and colleagues, 1994). Recurrence appears to be more likely if the woman has a homozygous enzyme-deficient fetus (Tyni and colleagues, 1998).

Clinical and Laboratory Findings

Acute fatty liver almost always manifests late in pregnancy. Castro and colleagues (1996a) reported 28 women with a mean gestational age of 37.5 weeks—range 31 to 42. In 45 cases at Parkland Hospital, the earliest onset was at 31 weeks and a fourth of women presented at 34 weeks or earlier. Fatty liver is more common in nulliparas with a male fetus, and in 10 to 20 percent of cases there is a multifetal gestation (Davidson and associates, 1998; Fesenmeier and co-workers, 2005).

Fatty liver has a clinical spectrum of severity. In the worst cases, symptoms usually develop over several days. Persistent nausea and vomiting are major symptoms, and there are varying degrees of malaise, anorexia, epigastric pain, and progressive jaundice. Perhaps half of affected women have hypertension, proteinuria, and edema, alone or in combination—signs suggestive of preeclampsia. As shown in Tables 50-1 and **50-2**, there are variable degrees from moderate to severe liver dysfunction manifest with hypofibrinogenemia, hypoalbuminemia, hypocholesterolemia, and prolonged clotting times. Serum bilirubin levels usually are less than 10 mg/dL, and serum transaminase levels are modestly elevated and usually less than 1000 U/L.

In almost all severe cases, there is profound endothelial cell activation with capillary leakage causing hemoconcentration, hepatorenal syndrome, ascites, and sometimes permeability pulmonary edema. Fetal death is more common in cases with severe hemoconcentration. Stillbirth possibly follows diminished uteroplacental perfusion, but is also related to more severe disease and acidosis. There is maternal leukocytosis and thrombocytopenia. Hemolysis can be severe, and it is likely caused by the effects of hypocholesterolemia on erythrocyte membranes (Cunningham and colleagues, 1985). As a consequence, lactic acid dehydrogenase (LDH) levels are elevated, and the peripheral blood smear demonstrates echinocytosis and nucleated red cells.

Various liver imaging techniques have been used to confirm the diagnosis, however, none are particularly reliable. Specifically, Castro and associates (1996b) reported poor sensitivity with sonography—three of 11 patients, computed tomography (CT)—five of 10, and magnetic resonance imaging—none of five. Our experiences are similar.

The syndrome typically continues to worsen after diagnosis. Hypoglycemia is common, and obvious hepatic encephalopathy, severe coagulopathy, and some degree of renal failure each develop in approximately half of women. Fortunately, delivery arrests deterioration of liver function.

We have encountered a number of women with a *forme fruste* of this disorder. Clinical involvement is relatively minor and laboratory aberrations—usually only hemolysis and

decreased plasma fibrinogen—signify the problem. Thus, the spectrum of liver involvement varies from milder cases that go unnoticed or are attributed to preeclampsia, to overt hepatic failure with encephalopathy.

Coagulopathy. The degree of clotting dysfunction is also variable and can be serious and life threatening, especially if operative delivery is undertaken. Coagulopathy is caused by diminished hepatic procoagulant synthesis, although there is also some evidence for increased consumption. As shown in Table 50-2, hypofibrinogenemia sometimes is profound. Of 45 women with fatty liver cared for at Parkland Hospital, more than half had a plasma fibrinogen nadir <100 mg/dL. Modest elevations of serum D-dimers or fibrin split product levels indicate an element of consumptive coagulopathy. Although usually modest, occasionally there is profound thrombocytopenia (Table 50-2). The mean platelet count was 105,000/μL in 45 women from Parkland Hospital—in a fourth of these, the platelet nadir was less than 50,000/μL.

Management

The key to a good outcome is intensive supportive care and good obstetrical management. Spontaneous resolution usually follows delivery. In some cases, the fetus may be already dead when the diagnosis is made, and the route of delivery less problematic. Many viable fetuses tolerate labor poorly. Because significant procrastination in effecting delivery may increase maternal and fetal risks, we prefer a trial of labor induction with close fetal surveillance. Although some recommend cesarean delivery to hasten hepatic healing, this increases maternal risk when there is a severe coagulopathy. Transfusions with whole blood or packed red cells, along with fresh-frozen plasma, cryoprecipitate, and platelets, are usually necessary if surgery is performed or if obstetrical lacerations complicate vaginal delivery (see Chap. 35, p. 791).

Hepatic dysfunction begins to resolve postpartum. It usually normalizes within a week, and in the interim, intensive medical support may be required. There are two associated conditions that may develop around this time. Perhaps a fourth of women have evidence for *transient diabetes insipidus.* This presumably is due to elevated vasopressinase concentrations caused by diminished hepatic production of its inactivating enzyme. Another problem is *acute pancreatitis*, which develops in up to half of women.

With supportive care, recovery usually is complete. Maternal deaths are caused by sepsis, hemorrhage, aspiration, renal failure, pancreatitis, and gastrointestinal bleeding. In some women, heroic measures have included plasma exchange and even liver transplantation (Fesenmeier, 2005; Franco, 2000; Martin, 2008, and all their colleagues). In our now extensive experience, we have not found these necessary.

Maternal and Perinatal Outcomes

Although maternal mortality rates in the past approached 75 percent, the contemporaneous outlook is much better. From his review, Sibai (2007) cites an average mortality rate of 7 percent. He also cited a 70-percent preterm delivery rate and a perinatal mortality rate of approximately 15 percent, which in the past was nearly 90 percent.

The Liver in Preeclampsia–Eclampsia

Hepatic involvement is relatively common in women with severe preeclampsia and eclampsia (see Table 50-1). These changes are discussed in detail in Chapter 34 (p. 720).

Viral Hepatitis

Acute symptomatic hepatitis has become less common in the United States over the past 25 years (Centers for Disease Control and Prevention, 2008c). There are at least five distinct types of viral hepatitis: A (HAV), B (HBV), D (HDV) caused by the hepatitis B–associated delta agent, C (HCV), and E (HEV). During their acute phases, these disorders are similar, and the viruses themselves probably are not hepatotoxic, but rather the immune response to them causes hepatocellular necrosis (Dienstag, 2008a).

Acute infections are most often subclinical and *anicteric*. Annual rates of *new* infections in the United States for hepatitis A, B, and C are shown in **Figure 50-2**. When clinically apparent, nausea and vomiting, headache, and malaise may precede jaundice by 1 to 2 weeks. Low-grade fever is more common with hepatitis A. By the time jaundice develops, symptoms are usually improving. Serum transaminase levels vary, and their peaks do not correspond with disease severity (see Table 50-1). Peak levels that range from 400 to 4000 U/L are usually reached by the time jaundice develops. Serum bilirubin typically continues to rise, despite falling aminotransferase levels, and peaks at 5 to 20 mg/dL.

Any evidence for severe disease should prompt hospitalization. These include prolonged prothrombin time, low serum albumin level, hypoglycemia, high serum bilirubin level, or central nervous system symptoms. In most cases, however, there is complete clinical and biochemical recovery within 1 to 2 months in all cases of hepatitis A, in most cases of hepatitis B, but in only a small proportion of cases of hepatitis C.

When patients are hospitalized, their feces, secretions, bedpans, and other articles in contact with the intestinal tract should be handled with glove-protected hands. Extra precautions, such as double gloving during delivery and surgical procedures, are recommended. Due to significant exposure of healthcare personnel to hepatitis B, the Centers for Disease Control and Prevention (2006a, b) recommend active and passive vaccination. There is no vaccine for hepatitis C, so recommendations are for postexposure serosurveillance only.

Complications and Sequelae

Acute hepatitis has a case-fatality rate of 0.1 percent. For patients ill enough to be hospitalized, it is as high as 1 percent. Most fatalities are due to *fulminant hepatic necrosis,* which in later pregnancy may resemble acute fatty liver. Hepatic encephalopathy is the usual presentation, and the mortality rate is 80 percent. Approximately half of patients with fulminant disease have hepatitis B infection, and co-infection with the delta agent is common.

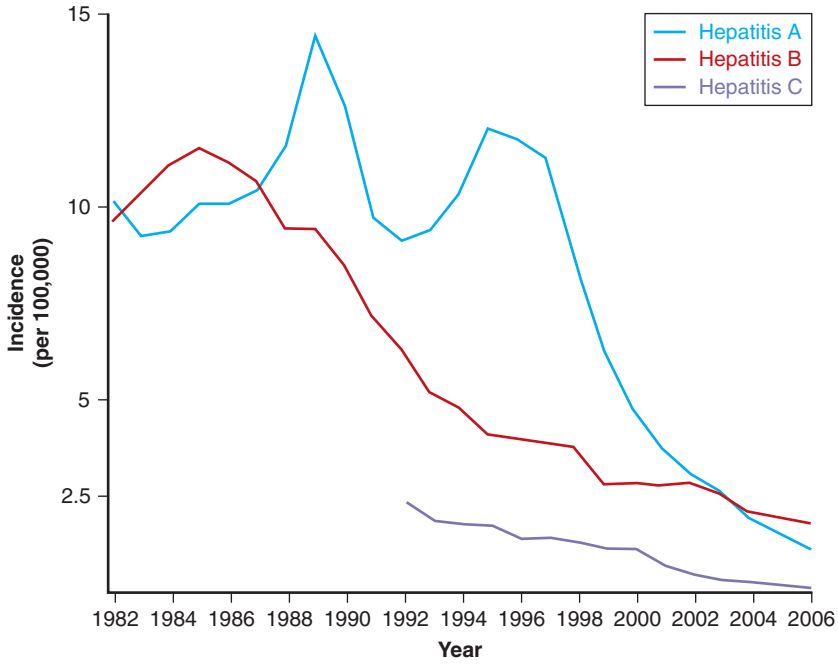

FIGURE 50-2 Annual incidence in the United States of new hepatitis A and B infection for 1982 through 2006, and for hepatitis C from 1991 through 2006. (Hepatitis C was reported as non-A, non-B hepatitis until 1995.) (Data from the Centers for Disease Control and Prevention, 2008c).

Chronic hepatitis is by far the most common complication of hepatitis B and C. It is diagnosed serologically in most cases (Table 50-3). Chronic infection follows acute hepatitis B in approximately 10 percent of cases in adults. Most become asymptomatic carriers, but a small percentage have low-grade chronic persistent hepatitis or chronic active hepatitis with or without cirrhosis. With acute hepatitis C, however, chronic hepatitis develops in the *majority* of patients. With persistently abnormal biochemical tests, liver biopsy usually discloses active inflammation, continuing necrosis, and fibrosis that may lead to cirrhosis. Chronic hepatitis is classified by cause; grade, defined by histological activity; and stage, that is, degree of progression (Dienstag and Isselbacher, 2005b). There is evidence that a cellular immune reaction is interactive with a genetic predisposition.

Although most chronically infected persons are asymptomatic, approximately 20 percent develop cirrhosis within 10 to 20 years (Dienstag, 2008a). When present, symptoms are nonspecific and usually include fatigue. Diagnosis can be confirmed by liver biopsy, however, treatment is usually given to patients after serological or virological diagnosis. In some patients, cirrhosis with liver failure or bleeding varices may be the presenting findings.

Treatment of Chronic Hepatitis

There is now considerable experience with treatment of chronic hepatitis B and C in nonpregnant patients. At least seven agents are approved for therapy of chronic hepatitis B (Sorrell and colleagues, 2009). There are two *interferons*—standard and pegylated—these are *cytokines* with antiviral, antiproliferative, and immunoregulatory effects. There are five antiviral agents approved for 6-month treatment. They have been shown to decrease viremia and improve histological findings in approximately 20 percent of patients per year. Their cure rate ranges from 30 to 40 percent. The nucleoside analog *lamivudine* is better tolerated than interferon, however, a major problem is viral resistance. The nucleotide analog *adefovir dipivoxil* has been used successfully for both e antigen– negative as well as antigen-positive hepatitis B (Hadziyannis and colleagues, 2003; Marcellin and associates, 2003). The guanosine analog *entecavir* was recently found to be superior to lamivudine for patients with hepatitis B—either HBeAg-negative or -positive (Chang and associates, 2006; Lai and co-workers, 2006). And, *telbivudine* is an L-nucleoside with potent anti-HBV activity. (Lai and colleagues, 2007). Finally, *tenofovir disoproxil fumarate* is another recently available nucleotide derivative.

Chronic Hepatitis and Pregnancy. Most young women with chronic hepatitis either are asymptomatic or have only mild liver disease. For seropositive asymptomatic women, there usually is no problem with pregnancy. With symptomatic chronic active hepatitis, pregnancy outcome depends primarily on the intensity of the disease and fibrosis, and especially whether there is portal hypertension. The few women who we

have managed have done well, but their long-term prognosis is poor. Accordingly, they should be counseled regarding possible liver transplantation as well as abortion and sterilization options.

Hepatitis A (HAV)

Because of vaccination programs, the incidence of hepatitis A has decreased 88 percent since 1995 (see Fig. 50-2). This 27-nm RNA picornavirus is transmitted by the fecal–oral route, usually by ingestion of contaminated food or water. The incubation period is approximately 4 weeks. Individuals shed virus in their feces, and during the relatively brief period of viremia, their blood is also infectious. Signs and symptoms are nonspecific, and most cases are anicteric and usually mild. Early serological detection is by identification of IgM anti-HAV antibody that may persist for several months. During convalescence, IgG antibody predominates, and it persists and provides subsequent immunity.

Pregnancy. Management of hepatitis A in pregnant women consists of a balanced diet and diminished physical activity. Women with less severe illness may be managed as outpatients. In developed countries, the effects of hepatitis A on pregnancy outcomes are not dramatic (American College of Obstetricians and Gynecologists, 2006, 2007). Both perinatal and maternal mortality rates, however, are substantively increased in third-world countries. There is no evidence that hepatitis A virus is teratogenic, and transmission to the fetus is negligible. Preterm birth may be increased, and neonatal cholestasis has been reported (Urganci and co-workers, 2003).

Immunization and Postexposure Prophylaxis. Childhood immunization with formalin-inactivated viral vaccine is more than 90-percent effective. HAV vaccination is recommended by the American College of Obstetricians and Gynecologists (2007) for high-risk adults, a category that includes behavioral and occupational risk populations and travelers to high-risk countries. These countries are listed by the Centers for Disease Control and Prevention (2008a) at www.cdc.gov/travel/contentdiseases.aspx. Passive immunization for the pregnant woman recently exposed by close personal or sexual contact with a person with hepatitis A is provided by a 0.02 mL/kg dose of immune globulin (Centers for Disease Control and Prevention, 2006b). Recently, Victor and colleagues (2007) reported that HAV vaccine given in the usual dosage to exposed persons was equally as effective as immune serum globulin to prevent HAV. In both groups, HAV developed in 3 to 4 percent.

Hepatitis B (HBV)

This infection is found worldwide but is endemic in some regions, especially in Asia and Africa. As shown in Figure 50-2, its annual incidence has decreased in the United States by approximately 80 percent since vaccination was introduced in the 1980s (Centers for Disease Control and Prevention, 2008c; Hoffnagle, 2006). Despite this, there are an estimated 1.2 million chronic carriers in the United States and 400 million worldwide. Hepatitis B is caused by a hepadnavirus whose DNA codes for four viral products. Its serious sequelae include chronic hepatitis, cirrhosis, and hepatocellular carcinoma. *The World Health Organization considers hepatitis B to be second only to tobacco among human carcinogens.* Chronic infection follows in 5 to 10 percent of acutely infected adults and in 70 to 90 percent of infants.

According to the American College of Obstetricians and Gynecologists (2006), maternal-fetal transmission is the principal mode of transmission throughout the world. Other groups at high risk for hepatitis B infection are intravenous drug abusers, spouses of acutely infected individuals, sexually promiscuous persons—especially homosexual men, healthcare personnel, and patients who frequently receive blood products. HBV can be transmitted by any body fluid, but exposure to virus-laden serum is the most efficient mode of transmission. It is also sexually transmitted by saliva, vaginal secretions, and semen. Ye and co-workers (2006) have presented evidence that the virus infects the ova and may be transmitted to the fetus by that route. Because of similar modes of transmission, co-infection with human immunodeficiency virus type 1 (HIV-1) is common and has increased liver-related morbidity (Thio and colleagues, 2002).

At least half of initial HBV infections are asymptomatic. A variety of immunological serum markers have been identified in those with acute or chronic hepatitis B, in those previously infected but now immune, and in chronic carriers (see Table 50-3). The hepatitis B virus—the Dane particle, hepatitis B core antigen (HBcAg), hepatitis B surface antigen (HBsAg), hepatitis B e antigen (HBeAg), and their corresponding antibodies are all detectable by various techniques. Concentrations of viral antigen and particles in serum and other body fluids may reach 10^{12}/mL.

After infection, the first serological marker is HBsAg (Fig. 50-3). HBeAg signifies intact viral particles that invariably are present during early acute hepatitis. However, antigen persistence indicates chronic infection. After acute hepatitis, approximately 90 percent of persons recover completely. The

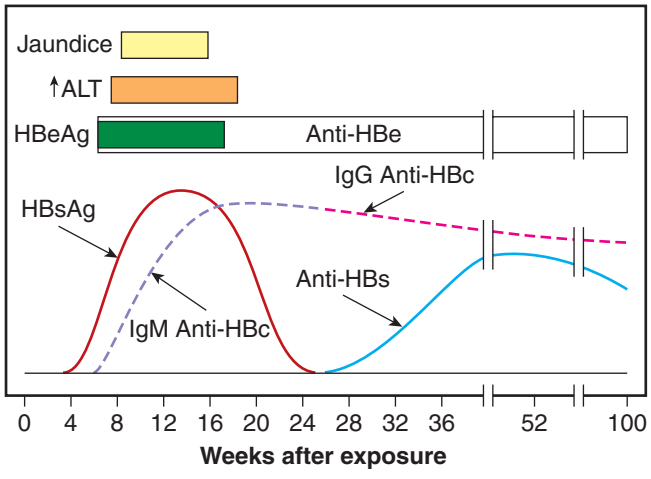

FIGURE 50-3 Sequence of appearance of various antigens and antibodies in acute hepatitis B. ALT = alanine aminotransferase; anti-HBc = antibody to hepatitis B core antigen; anti-HBe = antibody to hepatitis B e antigen; anti-HBs = antibody to hepatitis B surface antigen; HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen. (Redrawn from Dienstag, 2008a.)

10 percent who remain chronically infected are considered to have chronic hepatitis B. Approximately a fourth of these develop chronic liver disease as subsequently discussed. Those seropositive for HBeAg are at greatest risk for hepatocellular carcinoma (Yang and co-workers, 2002).

Pregnancy. The clinical course of acute HBV is similar to that of HAV and is not altered by pregnancy in developed countries. Treatment is supportive, and the likelihood of preterm delivery is increased. Most HBV infections identified during pregnancy are chronic, asymptomatic, and diagnosed by routine prenatal serological screening as recommended by the American College of Obstetricians and Gynecologists (2007) and discussed in Chapter 8 (p. 194). Although these women have chronic hepatitis, most are asymptomatic, and antiviral treatment is generally not given until after pregnancy. The prevalence of prenatal seropositivity in inner-city groups is approximately 1 percent. It is somewhat lower for military populations and private patients.

Transplacental viral infection is uncommon, and Towers and associates (2001) reported that viral DNA is rarely found in amnionic fluid or cord blood. Thus, most neonatal infection is vertically transmitted by peripartum exposure. There is no evidence, however, that cesarean delivery lowers the risk (American College of Obstetricians and Gynecologists, 2007). Although virus is present in breast milk, the incidence of transmission is not lowered by formula feeding. Mothers with hepatitis B surface and e antigens are more likely to transmit infection to their infants, whereas those positive for anti-HBe antibody are usually not infective. *Infants infected with hepatitis B are generally asymptomatic, but 85 percent become chronically infected.*

Prevention of Neonatal Infection. Along with successful vaccination programs that began in 1982, perinatal infection has declined dramatically. For example, from 1990 through 2005, the incidence of HBV in the United States in children younger than 15 years declined by 98 percent (Centers for Disease Control and Prevention, 2006a). Passive three-dose immunization with hepatitis immune globulin does not decrease this further (Yuan and associates, 2006). Neonatal infection can usually be prevented by prenatal screening, by passive and active immunization for newborns of seropositive mothers, and by active vaccination during pregnancy of seronegative women. Results of a study from China indicate that lamivudine added to neonatal immunoprophylaxis will decrease infection rates even more. Xu and colleagues (2009) decreased perinatal infection rates from 40 to 20 percent in highly viremic women by administering lamivudine from 32 weeks' gestation until 4 weeks postpartum.

Infants born to seropositive mothers are given hepatitis B immune globulin—HBIG—very soon after birth. This is accompanied by the first of a three-dose hepatitis B recombinant vaccine. Hill and colleagues (2002) applied this strategy in 369 infants and reported that the 2.4-percent transmission rate was not increased with breast feeding if vaccination was completed. As discussed in Chapter 8 (p. 208), concern over adverse vaccine effects is unfounded according to the Institute of Medicine and the Food and Drug Administration (Centers for Disease Control and Prevention, 2006a).

For high-risk mothers who are seronegative, vaccine can be given during pregnancy. Ingardia and colleagues (2004) reported that women immunized during one pregnancy had an 85-percent seropositivity rate in a subsequent pregnancy. After the first dose, vaccination is repeated at 1 and 6 months, at 1 and 4 months, or at 2 and 4 months (see Table 8-10, p. 208). Sheffield and colleagues (2006) reported that the three-dose regimen given prenatally—initially and at 1 and 4 months—resulted in seroconversion rates of 56, 77, and 90 percent, respectively. This compares with the 96-percent rate reported by Jurema and associates (2001) for postpartum women given all three doses.

Hepatitis D (HDV)

Also called *delta hepatitis*, this is a defective RNA virus that is a hybrid particle with an HBsAg coat and a delta core. The virus must co-infect with hepatitis B either simultaneously or secondarily. It cannot persist in serum longer than hepatitis B virus. Transmission is similar to hepatitis B. Chronic co-infection with B and D hepatitis is more severe and accelerated than HBV alone, and up to 75 percent of affected patients develop cirrhosis. Neonatal transmission is unusual because neonatal HBV vaccination usually prevents delta hepatitis.

Hepatitis C (HCV)

This is a single-stranded RNA virus of the family *Flaviviridae*. Transmission is similar to that of hepatitis B except that sexual transmission of the virus is less efficient. A third of anti-HCV–positive persons have no risk factors (Dienstag, 2008a). Acute HCV infection is usually asymptomatic or with mild symptoms, and chronic infection is identified through various screening programs. Prenatal screening has been recommended for women in high-risk categories by the American College of Obstetricians and Gynecologists (2007). As shown in Figure 50-2, the incidence of new cases decreased by 92 percent from 1992 to 2005, probably because of risk-reduction strategies in high-risk groups (Centers for Disease Control and Prevention, 2008c). Screening of blood donors for hepatitis C virus has markedly decreased the incidence of posttransfusion hepatitis (Lauer and Walker, 2001).

When there is acute or initial infection, anti-HCV antibody is not detected for an average of 15 weeks and in some cases as long as a year. Antibody usually does not prohibit transmission if viral RNA coexists as it does in 75 to 85 percent of anti-HCV–positive persons (Mast and associates, 2005). After initial infection, nearly 75 percent of patients have chronic viremia, and half of these have abnormal liver tests for more than a year (Lauer and Walker, 2001). In two thirds of these with transaminase elevations, liver biopsy shows chronic active hepatitis. Approximately a third of these progress to cirrhosis within 20 to 30 years. Despite this, long-term mortality rates are not appreciably increased (Dienstag, 2008b). Chronic hepatitis C does not worsen the prognosis of patients who have HIV co-infection (Sulkowski and colleagues, 2002).

Pregnancy. The incidence of anti-HCV seropositivity during pregnancy varies with the population studied. The American College of Obstetricians and Gynecologists (2006) cites a 0.14- to

2.4-percent pregnancy seroprevalence. It is higher in women who are HIV positive, and Santiago-Munoz and associates (2005) found that 6.3 percent of HIV-infected pregnant women at Parkland Hospital were co-infected with hepatitis B or C.

Almost 80 percent of seropositive women will have chronic hepatitis. Despite this, hepatitis C infection—acute or chronic—has no apparent adverse effects on pregnancy. For example, serum transaminase levels are not different from those in infected nonpregnant individuals. There are conflicting reports concerning changes in RNA viral load in pregnancy (Gervais and associates, 2000; Paternoster and co-workers, 2001). As discussed on page 1068, Locatelli and co-workers (1999) observed a 16-percent incidence of cholestatic jaundice in seropositive women compared with only 0.8 percent in controls. This is not surprising—recall that almost two thirds of anti-HCV–positive individuals have chronic liver disease. At this time, antiviral treatment is not advised during pregnancy (Hoffnagle and Seeff, 2006).

Perinatal Transmission. The primary adverse perinatal outcome is vertical transmission of HCV infection to the fetus-infant. Vertical transmission is higher in mothers with viremia. From their review, Airoldi and Berghella (2006) cited a rate of 1 to 3 percent in HCV-positive, RNA-negative women compared with 4 to 6 percent in those RNA-positive. In a more recent report from Dublin, McMenamin and colleagues (2008) described transmission rates in 545 HCV-positive women. They found a 7.1-percent vertical transmission rate in RNA-positive women compared with none in those who were RNA-negative. Some have found an even greater risk when the mother is co-infected with HIV (Ferrero and associates, 2003). Other outcomes are not usually affected even when the viral load exceeds 500,000 copies/mL (Laibl and associates, 2005). That said, Pergam and colleagues (2008) recently reported an association with HCV-infected women and low-birthweight infants who had increased risk for ventilation.

At this time, there are no methods to prevent perinatal transmission, including cesarean delivery (American College of Obstetricians and Gynecologists, 2006). Because of this, the Centers for Disease Control and Prevention (2008b) do not recommend routine prenatal screening. Infants delivered of known HCV-positive mothers should be tested and followed clinically.

Hepatitis E (HEV)

This water-borne RNA virus usually is enterically transmitted by contaminated water supplies. It causes epidemic outbreaks in third-world countries with substantive morbidity and mortality rates. Boccia and associates (2006) cited a case-fatality rate of 30 percent in 61 pregnant women refugees admitted to a hospital in Darfur, Sudan. Hepatitis E has features resembling those of hepatitis A, and it is not easily communicable by person-to-person contact. There are four HEV genotypes, and type 1 causes most human disease. Shrestha and co-workers (2007) recently reported 95-percent preventive efficacy with a recombinant HEV vaccine in Nepal, although there is currently no FDA-approved vaccine available.

Hepatitis G (HGV)

This blood-borne infection with flavivirus-like RNA virus does not actually cause hepatitis (Dienstag, 2008a). Its seroprevalence in a Scottish study was 0.08 percent (Jarvis and associates, 1996). Infant transmission has been described by Feucht (1996) and Inaba (1997) and all their colleagues.

Autoimmune Hepatitis

This is a generally progressive chronic hepatitis that is important to distinguish from chronic viral hepatitis because treatments are markedly different. According to Krawitt (2006), an environmental agent—a virus or drug—triggers events that mediate T-cells to destroy liver antigens in genetically susceptible patients. Type 1 hepatitis is more common and is characterized by multiple autoimmune antibodies such as antinuclear antibodies (ANA) as well as certain human leukocyte genes. Treatment employs corticosteroids, alone or combined with azathioprine. In some patients, cirrhosis or hepatocellular carcinoma develops.

In general, pregnancy outcomes of women with autoimmune hepatitis are poor, but the prognosis is good with well-controlled disease (Uribe and associates, 2006). In one study, Schramm and colleagues (2006) described 42 pregnancies in 22 German women with autoimmune hepatitis. A fifth had a flare antepartum and half had a flare postpartum. One woman underwent liver transplantation at 18 weeks, and another died of sepsis at 19 weeks. In their 38-year review, Candia and associates (2005) found 101 pregnancies in 58 women. They reported that preeclampsia developed in approximately a fourth, and there were two maternal deaths. As with other autoimmune disorders, chronic autoimmune hepatitis is more common in women and frequently co-exists with thyroiditis, ulcerative colitis, type 1 diabetes, and rheumatoid arthritis. Hepatitis is usually subclinical, but exacerbations can cause fatigue and malaise that can be debilitating.

Nonalcoholic Fatty Liver Disease

Steatohepatitis is an increasingly recognized condition that may occasionally progress to hepatic cirrhosis. As a macrovesicular fatty liver condition, it resembles alcohol-induced liver injury but is seen without alcohol abuse. Obesity, type 2 diabetes, and hyperlipidemia—*syndrome X*—frequently coexist and likely are etiological agents or "triggers" (McCullough, 2006). Fatty liver is common in obese persons and as many as 50 percent of the morbidly obese are affected (see Chap. 43, p. 948). Moreover, half of persons with type 2 diabetes have steatohepatitis. According to Bacon (2008a), there is a continuum or spectrum of liver damage in which *fatty liver progresses to nonalcoholic steatohepatitis—NASH,* and then *hepatic fibrosis* develops that may progress to cirrhosis.

In most persons, the disease is usually asymptomatic, and it is a common explanation for elevated transaminase levels found in blood donors and other routine screening testing. Indeed, it is the cause of elevated asymptomatic aminotransferase levels in up to 90 percent of cases in which other liver disease is excluded. It also is the most common cause of abnormal liver tests among adults in this country. Currently, weight loss along with diabetes and dyslipidemia control is the only recommended treatment.

Pregnancy

Fatty liver infiltration is probably much more common than realized in obese and diabetic pregnant women. We have encountered a number of cases in women in later pregnancy. Once severe liver injury, that is, acute fatty liver of pregnancy, was excluded, they were observed with no adverse outcomes relative to liver involvement. As the obesity endemic worsens, any adverse effects of pregnancy will eventually surface.

Cirrhosis

Irreversible chronic liver injury with extensive fibrosis and regenerative nodules is the final common pathway for several disorders. *Laënnec cirrhosis* from chronic alcohol exposure is the most common cause in the general population. But in young women—including pregnant women, most cases are caused by *postnecrotic cirrhosis* from chronic hepatitis B and C. Many cases of *cryptogenic cirrhosis* are now known to be caused by nonalcoholic fatty liver disease (Bacon, 2008b). Clinical manifestations of cirrhosis include jaundice, edema, coagulopathy, metabolic abnormalities, and portal hypertension with gastroesophageal varices and splenomegaly. The incidence of deep-venous thromboembolism is increased (Søgaard and colleagues, 2009). The prognosis is poor, and 75 percent have progressive disease leading to death in 1 to 5 years.

Cirrhosis and Pregnancy

Women with symptomatic cirrhosis frequently are infertile. Those who become pregnant generally have poor outcomes. Common complications include transient hepatic failure, variceal hemorrhage, preterm delivery, fetal-growth restriction, and maternal death (Aggarwal and associates, 1999; Tan and colleagues, 2008). In older studies, outcome generally was worse if there were coexisting esophageal varices. Schreyer and associates (1982) reviewed 69 pregnancies in 60 women with cirrhosis without hepatic shunts and 28 pregnancies in another 23 women who had undergone portal decompression shunting. Severe variceal hemorrhage was increased sevenfold in nonshunted women compared with that in those who had undergone such procedures—24 versus 3 percent.

Portal Hypertension and Esophageal Varices in Pregnancy

Hypertension of the hepatic portal system with resultant esophageal varices may result either from cirrhosis or from extrahepatic portal vein obstruction. Varices in pregnant women are caused by equal numbers of each cause. Some extrahepatic cases follow portal vein thrombosis associated with one of the *thrombophilia syndromes* (see Chap. 47, p. 1014). Others follow thrombosis from umbilical vein catheterization when the woman was a neonate, especially if preterm.

With either intrahepatic or extrahepatic resistance to flow, portal vein pressure rises from its normal range of 5 to 10 mm Hg, and values may exceed 30 mm Hg. Collateral circulation develops that carries portal blood to the systemic circulation. Drainage is via the gastric, intercostal, and other veins to the esophageal system, where varices develop. Bleeding is usually from varices near the gastroesophageal junction, and hemorrhage can be torrential. Bleeding during pregnancy from varices occurs in a third to half of affected women and is the major cause of maternal mortality (Aggarwal and colleagues, 2001; Britton, 1982).

Maternal prognosis is largely dependent on whether there is variceal hemorrhage. Mortality rates are higher if varices are associated with cirrhosis than for varices without cirrhosis—18 versus 2 percent, respectively. Perinatal mortality rates are high in women with esophageal varices. And like maternal outcomes, those of the neonate are worse if cirrhosis caused the varices.

Management

Treatment is the same as for nonpregnant patients. Preventatively, consideration should be given to determining the extent of variceal dilatation by endoscopy or multidector CT esophagography (Kim and colleagues, 2007). Beta-blocking drugs such as propranolol are given to reduce portal pressure and hence the risk of bleeding (Groszmann and co-workers, 2005).

For acute bleeding, endoscopic band ligation is preferred according to Bacon (2008b). Zeeman and Moise (1999) described a pregnant woman who underwent *prophylactic* banding at 15, 26, and 31 weeks' gestation to prevent bleeding. Sclerotherapy can also be used and in some cases may aid banding (Aggarwal and co-workers, 2001). Acute medical management for bleeding varices verified by endoscopy includes intravenous vasopressin or octreotide and somatostatin (Chung and Podolsky, 2005). *Balloon tamponade* of severe bleeding using a triple-lumen tube can be lifesaving if endoscopy is not available. Emergency shunting is used in 10 to 20 percent of patients in whom hemorrhage cannot be controlled by endoscopy. The interventional radiology procedure—*transjugular intrahepatic portosystemic stent shunting* (*TIPSS*)—can also control bleeding from gastric varices (Khan and associates, 2006; Sharara and Rockey, 2001). TIPSS can be done electively in patients with previous variceal hemorrhage.

Acute Acetaminophen Overdose

Nonsteroidal anti-inflammatory drugs (NSAIDs) are commonly used in suicide attempts. In a study from Denmark, Flint and associates (2002) reported that more than half of such attempts by 122 pregnant women were with either acetaminophen or aspirin. In the United States, acetaminophen is much more commonly used during pregnancy, and overdose may lead to hepatocellular necrosis and acute liver failure (Lee and colleagues, 2008). Massive necrosis causes a *cytokine storm* and multi-organ dysfunction. Early symptoms of overdose are nausea, vomiting, diaphoresis, malaise, and pallor. After a latent period of 24 to 48 hours, liver failure ensues and usually begins to resolve in 5 days. For patients with liver failure, mortality rates are 20 to 40 percent (Hay, 2008).

The antidote is *N-acetylcysteine,* which must be given promptly. The drug is thought to act by increasing glutathione levels, which aid metabolism of the toxic metabolite, *N*-acetyl-*para*-benzoquinoneimine. The need for treatment is based on projections of possible plasma hepatotoxic levels as a function of the

time from acute ingestion. Many poison control centers use the nomogram established by Rumack and Matthew (1975). A plasma level is measured 4 hours after ingestion, and if the level is greater than 120 μg/mL, treatment is given. If plasma determinations are not available, empirical treatment is given if the ingested amount exceeded 7.5 g. An oral loading dose of 140 mg/kg of *N*-acetylcysteine is followed by 17 maintenance doses of 70 mg/kg every 4 hours for 72 hours of total treatment time. The drug reaches therapeutic concentrations in the fetus, but its protective effects are unknown (Heard, 2008).

Effects on Pregnancy

After 14 weeks, the fetus has some cytochrome P_{450} activity necessary for metabolism of acetaminophen to the toxic metabolite. Riggs and colleagues (1989) reported follow-up data from the Rocky Mountain Poison and Drug Center in 60 such women. The likelihood of maternal and fetal survival was better if the antidote was given soon after overdose. At least one 33-week fetus appears to have died as a direct result of hepatotoxicity 2 days after ingestion. In another case, Wang and associates (1997) confirmed acetaminophen placental transfer with maternal and cord blood levels of 41 μg/mL. Both mother and infant died from hepatorenal failure.

Liver Transplantation

According to the Organ Procurement and Transplantation Network (OPTN), as of late 2008, liver transplant patients comprised 16 percent of all proposed waiting organ recipients. A fourth of these are childbearing-aged women. Almost 30 years after the first liver transplantation, McKay and Josephson (2006) reviewed experiences from the National Transplantation Pregnancy Registry and described 182 pregnancies in 106 liver recipients. Approximately a third of pregnancies were complicated by hypertension, a fourth had preeclampsia, and 5 percent had a rejection episode (**Table 50-4**). Live-birth rates for pregnancies in women who underwent liver transplantation approximate 70 percent (Dei Malatesta and associates, 2006; Sibanda and colleagues, 2007). Importantly, however, 5 percent of mothers had died within 28 months after delivery. This rate is comparable with nonpregnant liver transplantation patients, and pregnancy does not appear to worsen survival.

In pregnant women who have undergone transplantation, close surveillance is mandatory to detect hypertension, renal dysfunction, preeclampsia, and graft rejection. Management considerations, including immunosuppressive therapy, were recently reviewed by Mastrobattista and Gomez-Lobo (2008) and by McKay and Josephson (2006). Because of increased metabolic clearance, serum levels of some antirejection drugs should be determined. Ethical considerations of pregnancy in transplant recipients were reviewed by Ross (2006).

TABLE 50-4. Pregnancy Complications in More Than 400 Women with a Liver Transplant

Complication	Percent
Maternal	
Preeclampsia	13–33
Hypertension	20–40
Liver dysfunction	27
Rejection	0–17
Perinatal	
Preterm birth	31
Fetal-growth restriction	23

Data from Bonanno and Dove (2007), Christopher and associates (2006), Dei Malatesta and colleagues (2006), Mastrobattista and Gomez-Lobo (2008), and McKay and Josephson (2006).

GALLBLADDER DISORDERS

Cholelithiasis and Cholecystitis

In the United States, 20 percent of women older than 40 years have gallstones. Most stones contain cholesterol, and its oversecretion into bile is thought to be a major factor in stone formation. Biliary sludge, which may increase during pregnancy, is an important precursor to gallstone formation. The incidence of sonographically identified asymptomatic gallstones in more than 1500 pregnant or postpartum women was 2.5 to 10 percent (Maringhini and colleagues, 1987; Valdivieso and co-workers, 1993). Moreover, the cumulative risk of all patients with silent gallstones to require surgery for symptoms or complications is 10 percent at 5 years, 15 percent at 10 years, and 18 percent at 15 years (Greenberger and Paumgartner, 2008). For these reasons, prophylactic cholecystectomy is not warranted for *asymptomatic* stones.

For *symptomatic* gallstone disease, nonsurgical approaches have been used and include oral bile acid therapy with ursodeoxycholic acid and extracorporeal shock wave lithotripsy. There is no experience with these during pregnancy.

Acute cholecystitis usually develops when there is obstruction of the cystic duct. Bacterial infection plays a role in 50 to 85 percent of cases. In more than half of patients with acute cholecystitis, a history of previous right upper quadrant pain from cholelithiasis is elicited. With acute disease, pain is accompanied by anorexia, nausea and vomiting, low-grade fever, and mild leukocytosis. As shown in **Figure 50-4**, sonography can be used to see stones as small as 2 mm, and false-positive and false-negative rates are 2 to 4 percent (Greenberger and Paumgartner, 2008).

Symptomatic gallbladder diseases in young women include acute cholecystitis, biliary colic, and acute pancreatitis. Rarely, a gallbladder undergoes torsion or a neoplasm is found (Kleiss and co-workers, 2003; Wiseman and associates, 2008). In most symptomatic patients, cholecystectomy is warranted. Although acute cholecystitis responds to medical therapy, contemporary consensus is that early cholecystectomy is indicated (Greenberger and Paumgartner, 2008). In acute cases, medical therapy consisting of nasogastric suction, intravenous fluids, antimicrobials, and analgesics is instituted before surgical therapy. Laparoscopic cholecystectomy has become the treatment of choice for most patients.

Gallbladder Disease During Pregnancy

During pregnancy, approximately 1 in 1000 women develops cholecystitis. There is no doubt that pregnancy is "lithogenic." After the first trimester, both gallbladder volume during fasting

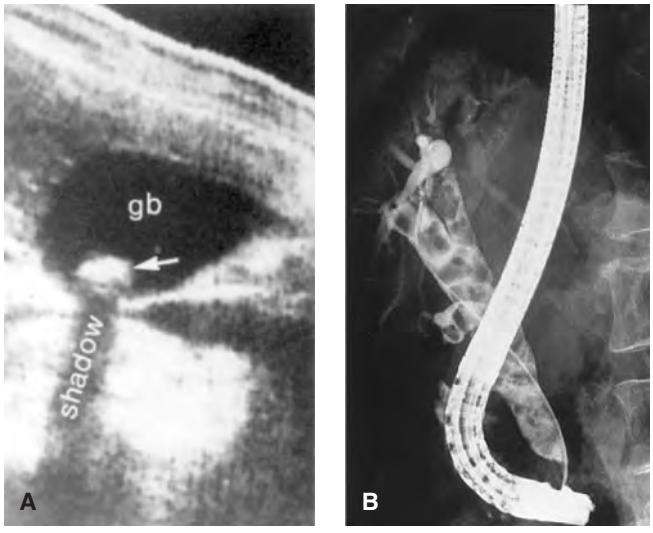

FIGURE 50-4 Gallstones. **A.** Visualization of a lone large gallstone by sonography. Note acoustic shadowing. **B.** Endoscopic retrograde cholangiopancreatogram (ERCP) showing multiple common-duct stones. (From Greenberger and Paumgartner, 2008, with permission.)

and residual volume after contracting in response to a test meal are doubled (Braverman and colleagues, 1980). Incomplete emptying may result in retention of cholesterol crystals, a prerequisite for cholesterol gallstones. Biliary sludge, which can be a forerunner to gallstones, develops in 30 percent of women during pregnancy (Maringhini and co-workers, 1987). After delivery, hospitalization for gallbladder disease within a year is relatively common. Ko (2006) studied Washington state discharge databases and documented that 0.5 percent of postpartum women were hospitalized within a year for a variety of conditions. Of these 6211 women, 76 had uncomplicated cholecystitis—55 underwent cholecystectomy.

Management

Acute cholecystitis during pregnancy or the puerperium is usually associated with gallstones or biliary sludge. Symptomatic cholecystitis is initially managed in a manner similar to that for nonpregnant women. In the past, most favored medical therapy, however, 25 to 50 percent of women ultimately require cholecystectomy for persistent symptoms (Cosenza and associates, 1999; Glasgow and co-workers, 1998). In an observational study of 44 pregnant women, Dixon and colleagues (1987) performed cholecystectomies in 18 with symptomatic acute cholecystitis or cholelithiasis. These women did well. Conversely, 15 of the 26 managed medically had recurrent symptoms during pregnancy. Similarly, Davis (1995) and Lee (2000) and their associates described a total of 77 cases of cholecystitis during pregnancy and cited better outcomes with primary surgical management.

These reports led to current management favoring surgical therapy during pregnancy. If treated conservatively, there is a high recurrence rate during the same pregnancy. Moreover, if cholecystitis recurs later in gestation, preterm labor is more likely and cholecystectomy technically more difficult. Management at Parkland Hospital has evolved to a more aggressive surgical approach, especially if there is concomitant biliary pancreatitis as subsequently discussed.

Laparoscopic Cholecystectomy. Reasonable experiences have been reported from several centers to indicate that laparoscopic surgery is as acceptable as open cholecystectomy in pregnant women (Barone, 1999; Cosenza, 1999; Glasgow, 1998, and all their colleagues). After their review of 213 cases, Lachman and co-workers (1999) concluded that laparoscopic cholecystectomy was safe throughout pregnancy. This procedure is discussed in Chapter 41 (p. 913).

Endoscopic Retrograde Cholangiopancreatography. Relief from symptomatic biliary duct gallstones during pregnancy has been greatly aided by use of endoscopic retrograde cholangiopancreatography—ERCP (Menees and Elta, 2006). The procedure is performed if there is suspected common duct obstruction, usually from stones (see Fig. 50-4). Approximately 10 percent of patients with symptomatic stone disease have common duct stones (Greenberger and Paumpartner, 2008). ERCP can be modified in many cases so that radiation exposure from fluoroscopy is avoided (Shelton and co-workers, 2008; Simmons and colleagues, 2004).

Results from 68 ERCP procedures performed in 65 pregnant women at Parkland Hospital were recently reported by Tang and associates (2009). All but two women had gallstones, and sphincterotomy was performed in all but one woman. Common-duct stones were identified in half of these 65 women, and in all but one, the stones were successfully removed. A biliary stent was placed in 22 percent and removed after delivery. Complications were minimized and post-ERCP pancreatitis developed in 16 percent. Pregnancy outcomes were not different than the general obstetrical population.

PANCREATIC DISORDERS

Pancreatitis

Pathogenesis and Incidence

Acute pancreatic inflammation is triggered by activation of pancreatic trypsinogen followed by autodigestion. It is characterized by cellular membrane disruption and proteolysis, edema, hemorrhage, and necrosis (Whitcomb, 2006). Approximately 20 percent have severe pancreatitis, and mortality rates in these patients reach up to 25 percent (Swaroop and associates, 2004).

In nonpregnant patients, acute pancreatitis is almost equally associated with gallstones and alcohol abuse. During pregnancy, however, cholelithiasis is almost always the predisposing condition. Other causes are hyperlipidemias, usually hypertriglyceridemia; hyperparathyroidism; congenital ductal anomalies; and rarely autoimmune pancreatitis (Crisan and colleagues, 2008; Finkelberg and associates, 2006). Nonbiliary pancreatitis occasionally develops postoperatively, or it is associated with trauma, drugs, or some viral infections. Certain metabolic conditions, including acute fatty liver of pregnancy and familial hypertriglyceridemia, also predispose to pancreatitis. Acute and chronic pancreatitis have been linked to the more than 1000

TABLE 50-5. Laboratory Values in 43 Pregnant Women with Pancreatitis

Test	Mean	Range	Normal
Serum amylase (IU/L)	1392	111–4560	30–110
Serum lipase (IU/L)	6929	36–41,824	23–208
Total bilirubin (mg/dL)	1.7	0.1–4.9	0.2–1.3
Aspartate transferase(U/L)	120	11–498	3–35
Leukocytes (per μL)	12,000	1000–14,600	4100–10,900

mutations of the cystic fibrosis transmembrane conductance regulator gene (Rowntree and Harris, 2003).

At Parkland Hospital, with a predominate Mexican-American population, acute pancreatitis complicated approximately 1 in 3300 pregnancies (Ramin and colleagues, 1995). At Brigham and Women's Hospital, with a more diversely ethnic population, Hernandez and co-workers (2007) reported an incidence of 1 in 4450. In a multi-institution Midwestern three-state review of more than 305,000 pregnancies, Eddy and associates (2008) found the incidence to be 1 in 3450 for acute pancreatitis.

Diagnosis

Acute pancreatitis is characterized by mild to incapacitating epigastric pain, nausea and vomiting, and abdominal distension. Patients are usually in distress and have low-grade fever, tachycardia, hypotension, and abdominal tenderness. As many as 10 percent have systemic inflammatory response syndrome, which causes endothelial activation and can lead to *acute respiratory distress syndrome* (see Chap. 42, p. 930).

Laboratory confirmation is from serum amylase levels three times upper normal values. As shown in **Table 50-5**, the mean amylase value in 43 pregnant women with pancreatitis was approximately 1400 IU/L, and the mean lipase value approximated 7000 IU/L. Importantly, there is no correlation between their degree of elevation and disease severity. Indeed, by 48 to 72 hours, amylase levels may return to normal despite other evidence for continuing pancreatitis. Serum lipase activity is also increased and usually remains elevated with continued inflammation. There is usually leukocytosis, and 25 percent of patients have hypocalcemia. Elevated serum bilirubin and aspartate aminotransferase levels usually signify gallstone disease.

A number of prognostic factors may be used to predict disease severity (Whitcomb, 2006). Some of these are respiratory failure, shock, need for massive colloid replacement, hypocalcemia of <8 mg/dL, and dark hemorrhagic fluid on paracentesis. If three of the first four features are documented, survival is only 30 percent.

Management

Medical treatment mirrors that for nonpregnant patients and includes analgesics, intravenous hydration, and measures to decrease pancreatic secretion by interdiction of oral intake. Other than supportive therapy, no particular treatment schemes have improved outcomes (Whitcomb, 2006). In the series by Ramin and colleagues (1995), all 43 affected pregnant women responded to conservative treatment and were hospitalized for a mean of 8.5 days. Nasogastric suction does not improve outcomes of mild to moderate disease, but enteral feeding may be helpful once pain improves and associated ileus resolves. Although we try to avoid parenteral nutrition, in 65 women with acute pancreatitis described by Eddy and co-workers (2008), a fourth had total parenteral nutrition. With bacterial superinfection of necrotizing pancreatitis, antimicrobials are indicated. For pregnant patients with gallstone pancreatitis, ERCP for removal of common duct stones and papillotomy has been used successfully (Simmons and co-workers, 2004; Tang and colleagues, 2009). Cholecystectomy should be considered after inflammation subsides if there is gallbladder disease. Hernandez and associates (2007) reported that half of such women who did not undergo cholecystectomy had recurrent pancreatitis during the same pregnancy. Severe necrotizing pancreatitis can be life threatening, and laparotomy for debridement and drainage may be required (Gosnell and colleagues, 2001; Robertson and associates, 2006).

Pregnancy outcomes appear to be related to the severity of acute pancreatitis. Eddy and associates (2008) reported a 30-percent preterm delivery rate—11 percent delivered before 35 weeks. There were only two pancreatitis-related deaths. Importantly, almost a third of 73 women had recurrent pancreatitis during pregnancy.

Pancreatic Transplantation

According to the United Network for Organ Sharing, the 5-year graft survival for pancreatic transplantation is 80 percent. Because there is improved survival when a combined pancreas and kidney are grafted for those with type 1 diabetes and renal failure, most operations include both organs.

Tydén and colleagues (1989) described four women in whom pancreas-kidney transplantation was followed in 1 to 2 years by pregnancy. Pelvic placement of the graft was not problematic. Glucose homeostasis was well maintained throughout pregnancy. Successful vaginal deliveries have been described by Allenby and

colleagues (1998). Mastrobattista and Gomez-Lobo (2008) reported results from the National Transplantation Pregnancy Registry. Of 44 pregnancies in 73 women following pancreas-kidney transplantation, outcomes have been encouraging. Although the incidence of hypertension, preeclampsia, preterm delivery, and fetal-growth restriction was high, there was only one perinatal death. There were four rejection episodes during pregnancy, which were treated successfully.

Pancreatic islet autotransplantation may be performed to prevent diabetes following pancreatectomy, and at least three successful pregnancies have been described (Jung, 2007; Teuscher, 1994; Wahoff, 1995, and all their colleagues).

CHAPTER 51

Hematological Disorders

ANEMIAS 1079
HEMOGLOBINOPATHIES 1085
PLATELET DISORDERS 1092
INHERITED COAGULATION DEFECTS 1096

Pregnancy induces physiological changes that often confuse the diagnosis of hematological disorders and assessment of their treatment. This is especially true for anemia. A number of pregnancy-induced hematological changes are discussed in detail in Chapter 5 (p. 114). One of the most significant changes is blood volume expansion with a disproportionate plasma volume increase, resulting in a normally decreased hematocrit.

Pregnant women are susceptible to hematological abnormalities that may affect any woman of childbearing age. These include chronic disorders such as hereditary anemias, immunological thrombocytopenia, and malignancies, including leukemias and lymphomas. Other disorders arise during pregnancy because of pregnancy-induced demands, two examples being iron-deficiency and megaloblastic anemias. Pregnancy may also unmask underlying hematological disorders such as compensated hemolytic anemias caused by hemoglobinopathies or red cell membrane defects. Finally, any hematological disease may first arise during pregnancy, such as autoimmune hemolysis or aplastic anemia.

ANEMIAS

Extensive hematological measurements have been made in healthy nonpregnant women. Concentrations of many cellular elements that are normal during pregnancy are listed in the Appendix. As shown in **Table 51-1**, anemia is defined as hemoglobin concentration less than 12 g/dL in nonpregnant women and less than 10 g/dL during pregnancy or the puerperium. The Centers for Disease Control and Prevention (1998) defined anemia in iron-supplemented pregnant women using a cutoff of the 5th percentile—11 g/dL in the first and third trimesters, and 10.5 g/dL in the second trimester.

The modest fall in hemoglobin levels during pregnancy is caused by a relatively greater expansion of plasma volume compared with the increase in red cell volume (**Fig. 51-1**). The disproportion between the rates at which plasma and erythrocytes are added to the maternal circulation is greatest during the second trimester. Late in pregnancy, plasma expansion essentially ceases, while hemoglobin mass continues to increase.

After delivery, the hemoglobin level fluctuates and then rises to and usually exceeds the nonpregnant level. The rate and magnitude of increase early in the puerperium result from the amount of hemoglobin added during pregnancy and the amount of blood loss at delivery modified by normally decreasing plasma volume postpartum.

Incidence and Causes of Anemia

The frequency of anemia during pregnancy depends primarily on preexisting iron states and prenatal supplementation. It is more common among indigent women and influenced by dietary customs (American College of Obstetricians and Gynecologists, 2008). For example, Ren and colleagues (2007) found that 22 percent of 88,149 Chinese women were anemic in the first trimester. In studies from the United States, Taylor and associates (1982) reported that hemoglobin levels at term averaged 12.7 g/dL among women who took supplemental iron compared with 11.2 g/dL for those who did not. Bodnar and associates (2001) studied a cohort of 59,248 pregnancies and found a prevalence of 27 percent for postpartum anemia. Although this was strongly correlated with prenatal anemia, 20 percent of women with normal prenatal hemoglobin levels had postpartum anemia that was caused by hemorrhage at delivery.

TABLE 51-1. Hemoglobin Concentrations in 85 Healthy Women with Proven Iron Stores

Hemoglobin (g/dL)	Nonpregnant	Midpregnancy	Late Pregnancy
Mean	13.7	11.5	12.3
Less than 12.0	1%	72%	36%
Less than 11.0	None	29%	6%
Less than 10.0	None	4%	1%
Lowest	11.7	9.7	9.8

From Scott and Pritchard (1967), with permission.

The etiology of the more common anemias encountered in pregnancy are listed in Table 51-2. The specific cause of anemia is important when evaluating effects on pregnancy outcome. For example, maternal and perinatal outcomes are seldom affected by moderate iron-deficiency anemia, yet they are altered markedly in women with sickle-cell anemia.

Effects of Anemia on Pregnancy

Most studies of the effects of anemia on pregnancy, such as those discussed in Chapter 8 (p. 202), describe large populations. As indicated, these likely deal with nutritional anemias and specifically those due to iron deficiency. Klebanoff and co-workers (1991) studied nearly 27,000 women and found a slightly increased risk of preterm birth with midtrimester anemia. Ren and colleagues (2007) found that a low first-trimester hemoglobin concentration increased the risk of low birthweight, preterm birth, and small-for-gestational age infants. In a study from Tanzania, Kidanto and co-workers (2009) reported that the incidence of preterm delivery and low birthweight was increased as the severity of anemia increased. They did not, however, take into account the cause(s) of anemia, which was diagnosed in almost 80 percent of their obstetrical population. Kadyrov and co-workers (1998) have provided evidence that maternal anemia influences placental vascularization by altering angiogenesis during early pregnancy.

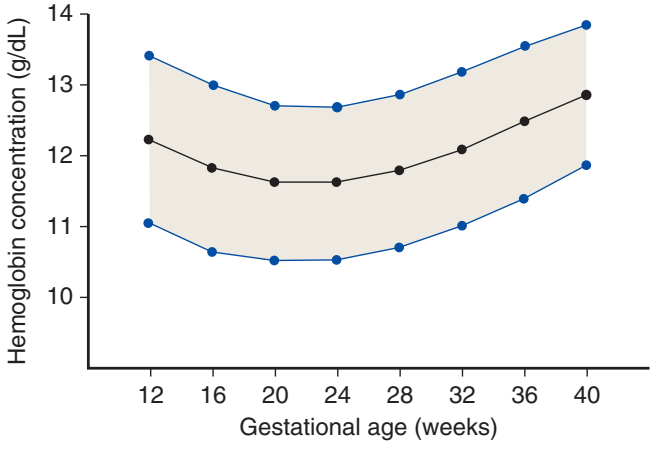

FIGURE 51-1 Mean hemoglobin concentrations (*black line*) and 5th and 95th percentiles (*blue lines*) for healthy pregnant women taking iron supplements. (Data from Centers for Disease Control and Prevention, 1989.)

A seemingly paradoxical finding is that healthy pregnant women with a higher hemoglobin concentration are also at increased risk for adverse perinatal outcomes (von Tempelhoff and colleagues, 2008). This may result from lower than average plasma volume expansion of pregnancy concurrent with normal red cell mass increase. Murphy and colleagues (1986) described more than 54,000 singleton pregnancies in the Cardiff Birth Survey and reported excessive perinatal morbidity with *high* maternal hemoglobin concentrations. Scanlon and associates (2000) studied the relationship between maternal hemoglobin levels and preterm or growth-restricted infants in 173,031 pregnancies. Women whose hemoglobin concentration was three standard deviations *above* the mean at 12 or 18 weeks had 1.3- to 1.8-fold increases in the incidence of fetal-growth restriction. These findings have led some to the illogical conclusion that withholding iron supplementation to cause iron-deficiency anemia will improve pregnancy outcomes (Ziaei and colleagues, 2007).

Iron-Deficiency Anemia

The two most common causes of anemia during pregnancy and the puerperium are iron deficiency and acute blood loss. The Centers for Disease Control and Prevention (1989) estimated that as many as 8 million American women of childbearing age were iron deficient. In a typical singleton gestation, the maternal need for iron averages close to 1000 mg. Of this, 300 mg is for the fetus and placenta; 500 mg for maternal hemoglobin mass expansion; and 200 mg that is shed normally through the gut, urine, and skin. The total amount of 1000 mg considerably exceeds the iron stores

TABLE 51-2. Causes of Anemia During Pregnancy

Acquired
- Iron-deficiency anemia
- Anemia caused by acute blood loss
- Anemia of inflammation or malignancy
- Megaloblastic anemia
- Acquired hemolytic anemia
- Aplastic or hypoplastic anemia

Hereditary
- Thalassemias
- Sickle-cell hemoglobinopathies
- Other hemoglobinopathies
- Hereditary hemolytic anemias

of most women and results in iron-deficiency anemia unless iron supplementation is given.

With the expansion of blood volume during the second trimester, iron deficiency is often manifested by an appreciable drop in hemoglobin concentration. In the third trimester, additional iron is needed to augment maternal hemoglobin and for transport to the fetus. Because the amount of iron diverted to the fetus is similar in a normal and in an iron-deficient mother, the newborn infant of a severely anemic mother does not suffer from iron-deficiency anemia. As discussed in Chapter 17 (p. 397), neonatal iron stores are related to maternal iron status and to timing of cord clamping.

Diagnosis

Classical morphological evidence of iron-deficiency anemia—erythrocyte hypochromia and microcytosis—is less prominent in the pregnant woman compared with that in the nonpregnant woman. Moderate iron-deficiency anemia during pregnancy usually is not accompanied by obvious morphological changes in erythrocytes. Serum ferritin levels, however, are lower than normal, and there is no stainable bone marrow iron. *Iron-deficiency anemia during pregnancy is the consequence primarily of expansion of plasma volume without normal expansion of maternal hemoglobin mass.*

The initial evaluation of a pregnant woman with moderate anemia should include measurements of hemoglobin, hematocrit, and red cell indices; careful examination of a peripheral blood smear; a sickle-cell preparation if the woman is of African origin; and measurement of serum iron, ferritin, or both. Expected values in pregnancy are found in the Appendix. Serum ferritin levels normally decline during pregnancy (Goldenberg and colleagues, 1996). Levels less than 10 to 15 mg/L confirm iron-deficiency anemia (American College of Obstetricians and Gynecologists, 2008). Ferritin concentrations across pregnancy, as well as other measurements used to assess this, are shown in the Appendix. Pragmatically, the diagnosis of iron deficiency in moderately anemic pregnant women usually is presumptive and based largely on exclusion.

When pregnant women with moderate iron-deficiency anemia are given adequate iron therapy, a hematological response is detected by an elevated reticulocyte count. The rate of increase of hemoglobin concentration or hematocrit is typically slower than in nonpregnant women due to the increasing and larger blood volumes during pregnancy.

Treatment

Correction of anemia and restitution of iron stores can be accomplished with simple iron compounds—ferrous sulfate, fumarate, or gluconate—that provide approximately 200 mg daily of *elemental iron*. If a woman cannot or will not take oral iron preparations, then parenteral therapy is given. Although both are administered intravenously, ferrous sucrose has been shown to be safer than iron-dextran (American College of Obstetricians and Gynecologists, 2008). There are equivalent increases in hemoglobin levels in women treated with either oral or parenteral iron therapy (Bayouneu and colleagues, 2002; Sharma and co-workers, 2004).

Transfusions of red cells or whole blood seldom are indicated unless hypovolemia from blood loss coexists or an emergency operative procedure must be performed on a *severely* anemic woman. To replenish iron stores, oral therapy should be continued for 3 months after anemia has been corrected.

Anemia from Acute Blood Loss

In early pregnancy, anemia caused by acute blood loss is common in instances of abortion, ectopic pregnancy, and hydatidiform mole. Anemia is much more common postpartum from obstetrical hemorrhage. Massive hemorrhage demands immediate treatment as described in Chapter 35 (p. 791). If a moderately anemic woman—defined by a hemoglobin value ≥ 7 g/dL—is hemodynamically stable, is able to ambulate without adverse symptoms, and is not septic, then blood transfusions are not indicated, and instead iron therapy is given for at least 3 months (Krafft and colleagues, 2005). In a randomized trial, Van Wyck and associates (2007) reported that intravenous ferric carboxymaltose given weekly was as effective as thrice-daily oral ferrous sulfate tablets for hemoglobin regeneration with postpartum anemia.

Anemia Associated with Chronic Disease

Weakness, weight loss, and pallor have been recognized since antiquity as characteristics of chronic disease. A wide variety of disorders, such as chronic renal failure, cancer and chemotherapy, human immunodeficiency virus (HIV) infection, and chronic inflammation, result in moderate and sometimes severe anemia, usually with slightly hypochromic and microcytic erythrocytes (Weiss and Goodnough, 2005).

In nonpregnant patients with chronic inflammatory diseases, the hemoglobin concentration is rarely less than 7 g/dL; bone marrow cellular morphology is not altered; and serum iron concentration is decreased, whereas ferritin levels usually are elevated. Thus, although slightly different from each other mechanistically, these anemias share similar features that include alterations in reticuloendothelial function, iron metabolism, and decreased erythropoiesis (Andrews, 1999).

During pregnancy, a number of chronic diseases may cause anemia, including renal insufficiency, suppuration, inflammatory bowel disease, systemic lupus erythematosus, granulomatous infections, malignant neoplasms, and rheumatoid arthritis. Chronic anemia is typically intensified as plasma volume expands disproportionately to red cell mass expansion.

Chronic Renal Disease

Chronic renal insufficiency may be accompanied by anemia, usually due to erythropoietin deficiency with an element of anemia of chronic disease. During pregnancy, the degree of red cell mass expansion is inversely related to renal impairment (see Fig. 48-4, p. 1039). Because plasma volume expansion usually is normal, however, anemia is intensified (Cunningham and associates, 1990).

Women who have acute *pyelonephritis* with sepsis often develop overt anemia. This is caused by acute red cell destruction from endotoxin-mediated sepsis, but with normal erythropoietin production (Cavenee and colleagues, 1994).

Treatment. Adequate iron stores must be ensured. Treatment with *recombinant erythropoietin* has been used successfully to treat chronic anemia (Weiss and Goodnough, 2005). In pregnancies complicated by chronic renal insufficiency, recombinant erythropoietin is usually considered when the hematocrit approximates 20 percent (Ramin and colleagues, 2006). One worrisome side effect is hypertension, which is already prevalent in women with renal disease. In addition, Casadevall and colleagues (2002) reported pure red cell aplasia and anti-erythropoietin antibodies in 13 nonpregnant patients given erythropoietin.

Megaloblastic Anemia

These anemias are characterized by blood and bone-marrow abnormalities from impaired DNA synthesis. Worldwide, the prevalence of megaloblastic anemia during pregnancy varies considerably, and in the United States, it is rare.

Folic Acid Deficiency

In the United States, megaloblastic anemia beginning during pregnancy almost always results from folic acid deficiency. In the past, this condition was referred to as *pernicious anemia of pregnancy*. It usually is found in women who do not consume fresh green leafy vegetables, legumes, or animal protein. As folate deficiency and anemia worsen, anorexia often becomes intense, further aggravating the dietary deficiency. In some instances, excessive ethanol ingestion either causes or contributes to folate deficiency.

In nonpregnant women, the folic acid requirement is 50 to 100 μg/day. During pregnancy, requirements are increased, and 400 μg/day is recommended (see Chap. 8, p. 204). The earliest biochemical evidence is low plasma folic acid concentrations. (see Appendix). Early morphological changes usually include neutrophils that are hypersegmented and newly formed erythrocytes that are macrocytic. With preexisting iron deficiency, macrocytic erythrocytes cannot be detected by measurement of the mean corpuscular volume. Careful examination of a peripheral blood smear, however, usually demonstrates some macrocytes. As the anemia becomes more intense, peripheral nucleated erythrocytes appear and examination of the bone marrow discloses megaloblastic erythropoiesis. Anemia may then become severe, and thrombocytopenia, leukopenia, or both may develop. The fetus and placenta extract folate from maternal circulation so effectively that the fetus is not anemic despite severe maternal anemia. There have been instances in which newborn hemoglobin levels were 18 g/dL or more whereas maternal values were as low as 3.6 g/dL (Pritchard and Scott, 1970).

Treatment. The treatment of pregnancy-induced megaloblastic anemia should include folic acid, a nutritious diet, and iron. As little as 1 mg of folic acid administered orally once daily produces a striking hematological response. By 4 to 7 days after the beginning of treatment, the reticulocyte count is increased, and leukopenia and thrombocytopenia are corrected.

Prevention. A diet sufficient in folic acid prevents megaloblastic anemia. A great deal of attention has been devoted to the role of folate deficiency in the genesis of neural-tube defects (see Chap. 8, p. 204, and Chap. 12, p. 281). Since the early 1990s, governmental nutrition experts, as well as the American College of Obstetricians and Gynecologists (2003), have recommended that all women of childbearing age consume at least 400 μg of folic acid daily. Additional folic acid is given in circumstances in which folate requirements are increased, such as in multifetal pregnancy, hemolytic anemia, Crohn disease, alcoholism, and inflammatory skin disorders. There is evidence that women who previously have had infants with neural-tube defects have a lower recurrence rate if daily 4-mg folic acid is given prior to and throughout early pregnancy.

Vitamin B_{12} Deficiency

Megaloblastic anemia during pregnancy caused by lack of vitamin B_{12}, that is, cyanocobalamin, is exceedingly rare. In *Addisonian pernicious anemia,* a lack of intrinsic factor results in failure to absorb vitamin B_{12}. It is an extremely uncommon autoimmune disease in women of reproductive age and typically has its onset after age 40 years. Unless treated with vitamin B_{12}, infertility may be a complication. In our limited experience, vitamin B_{12} deficiency in pregnant women is more likely encountered following partial or total gastric resection. Other causes are Crohn disease, ileal resection, and bacterial overgrowth in the small bowel.

During pregnancy, vitamin B_{12} levels are lower than nonpregnant values because of decreased levels of binding proteins that include haptocorrin (transcobalamins I and III) and transcobalamin II (Morkbak and colleagues, 2007). Women who have had a total gastrectomy require 1000 μg of vitamin B_{12} intramuscularly at monthly intervals. Those with a partial gastrectomy usually do not need such therapy, but vitamin B_{12} levels during pregnancy should be measured (see Appendix).

Acquired Hemolytic Anemias

Autoimmune Hemolytic Anemia

This is an uncommon condition, and the cause of aberrant antibody production is unknown. Typically, both the direct and indirect antiglobulin (Coombs) tests are positive. Anemias caused by these factors may be due to warm-active autoantibodies—80 to 90 percent, cold-active antibodies, or a combination. These syndromes also may be classified as primary (idiopathic) or secondary due to underlying diseases or other factors. Examples of the latter include lymphomas and leukemias, connective-tissue diseases, infections, chronic inflammatory diseases, and drug-induced antibodies (Provan and Weatherall, 2000). *Cold-agglutinin disease* may be induced by infectious etiologies like *Mycoplasma pneumoniae* or Epstein-Barr viral mononucleosis (Dhingra and colleagues, 2007).

Hemolysis and positive antiglobulin test results may be the consequence of either IgM or IgG anti-erythrocyte antibodies. Spherocytosis and reticulocytosis are characteristic of the peripheral blood smear. IgM antibodies do not cross the placenta, and thus, fetal red cells are not affected.

With autoimmune hemolytic anemia, there may be marked acceleration of hemolysis during pregnancy. Glucocorticoids

usually are effective, and treatment is with prednisone, 1 mg/kg orally per day, or its equivalent. Coincidental thrombocytopenia usually is corrected by therapy. Transfusion of red cells is complicated by the presence of circulating anti-erythrocyte antibodies. Warming the donor cells to body temperature, however, decreases their destruction by cold agglutinins.

Drug-Induced Hemolytic Anemia

This must be differentiated from other forms of autoimmune hemolytic anemia. Hemolysis typically is mild, resolves with drug withdrawal, and can be prevented by avoidance of the drug. Mechanisms of action generally are through drug-mediated immunological injury to red cells. The drug may act as a high-affinity hapten with a red cell protein to which antidrug antibodies attach—for example, IgM antipenicillin or anticephalosporin antibodies. Other drugs become low-affinity haptens and adhere to cell membrane proteins. Examples include probenecid, quinidine, rifampin, and thiopental.

The severity of symptoms depends on the degree of hemolysis. Usually there is mild to moderate chronic hemolysis, but some drugs that act as low-affinity haptens may precipitate severe acute hemolysis. Garratty and associates (1999) described seven cases of severe direct Coombs-positive hemolytic anemia caused by cefotetan prophylaxis for obstetrical procedures. In most cases, withdrawing the offending drug results in reversal of symptoms. Corticosteroids are of questionable efficacy. Drug-induced hemolysis is much more often related to a congenital erythrocyte enzymatic defect, such as *glucose-6-phosphate dehydrogenase (G6PD) deficiency,* especially in African-American women (see p. 1084).

Pregnancy-Induced Hemolytic Anemia

Unexplained hemolytic anemia during pregnancy is a rare but distinct entity in which severe hemolysis develops early in pregnancy and resolves within months after delivery. There is no evidence of an immune mechanism or intraerythrocytic or extraerythrocytic defects (Starksen and associates, 1983). Because the fetus-infant also may demonstrate transient hemolysis, an immunological cause is suspected. Maternal corticosteroid treatment is often but not always effective (Kumar and colleagues, 2001). We have observed one woman with recurrent hemolysis during several pregnancies. In each instance, intense severe hemolytic anemia was controlled by prednisone given until delivery.

Paroxysmal Nocturnal Hemoglobinuria

Although commonly regarded as a hemolytic anemia, this hemopoietic stem cell disorder is characterized by formation of defective platelets, granulocytes, and erythrocytes. Paroxysmal nocturnal hemoglobinuria is acquired and arises from one abnormal clone of cells, much like a neoplasm (Nguyen and associates, 2006). One mutated X-linked gene responsible for this condition is termed *PIG-A* because it codes for phosphatidylinositol glycan protein A. Resultant abnormal anchor proteins of the erythrocyte and granulocyte membrane make these cells unusually susceptible to lysis by complement (Provan and Weatherall, 2000).

Chronic hemolytic anemia has an insidious onset, and its severity ranges from mild to lethal. Hemoglobinuria develops at irregular intervals and is not necessarily nocturnal. Hemolysis may be initiated by transfusions, infections, or surgery. Almost 40 percent of patients suffer venous thromboses, as well as renal failure, hypertension, and Budd-Chiari syndrome. Because of the thrombotic risk, prophylactic anticoagulation is recommended (Parker and colleagues, 2005). Median survival after diagnosis is 10 years, and bone marrow transplantation is the definitive treatment. Successful treatment of nonpregnant patients has been reported with eculizumab, an antibody that inhibits complement activation (Hillmen and associates, 2006; Parker, 2009). There is no published experience with this drug in pregnant women.

Effects on Pregnancy. Paroxysmal nocturnal hemoglobinuria is a serious and unpredictable disease. During pregnancy, complications are reported in up to three fourths of affected women (De Gramont and colleagues, 1987). Maternal mortality is reported in 10 to 20 percent. Maternal complications are more common postpartum, and venous thrombosis is reported in 50 percent (Fieni, 2006; Greene, 1983; Ray, 2000, and all their colleagues).

Severe Preeclampsia and Eclampsia

Fragmentation or microangiopathic hemolysis with thrombocytopenia is relatively common with severe preeclampsia and eclampsia (Kenny and co-workers, 2009; Pritchard and associates, 1976). Mild degrees are likely present in most cases of severe disease and may be referred to as *HELLP syndrome*—hemolysis, elevated liver enzymes, and low platelet (see Chap. 34, p. 718).

Bacterial Toxins

The most fulminant acquired hemolytic anemia encountered during pregnancy is caused by the exotoxin of *Clostridium perfringens* (see Chap. 42, p. 932) or by group A β-hemolytic streptococcus (see Chap. 31, p. 662). Gram-negative bacterial endotoxin—lipopolysaccharide—especially with bacteremia from severe pyelonephritis may be accompanied by hemolysis and mild to moderate anemia (Cox and colleagues, 1991).

Hemolytic Anemias Caused by Inherited Erythrocyte Defects

The normal erythrocyte shape is a biconcave disc, and its membrane surface area is redundant relative to its volume. This allows numerous cycles of reversible deformations as the erythrocyte withstands shearing forces within arteries and negotiates through splenic slits half the width of its cross-sectional diameter. Several inherited red cell membrane defects or enzyme deficiencies result in destabilization of the membrane lipid bilayer. The loss of lipids from the erythrocyte membrane causes a surface area deficiency and poorly deformable cells that undergo hemolysis (**Fig. 51-2**). There are varying degrees of anemia that depend upon the degree of rigidity or decreased distensibility. Three examples of inherited membrane defects that cause accelerated destruction are *hereditary spherocytosis, pyropoikilocytosis,* and *ovalocytosis.*

Hereditary Spherocytosis. Several inherited molecular deficits in erythrocyte membrane proteins give rise to the syndrome of hereditary spherocytosis. Most are due to an autosomally

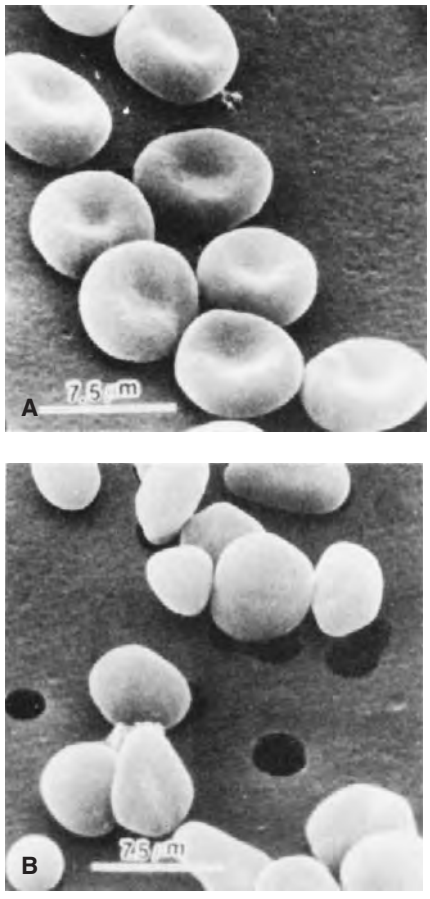

FIGURE 51-2 Scanning electron micrograph showing **(A)** normal-appearing erythrocytes from a heterozygous carrier of recessive spherocytosis, and **(B)** her daughter, a homozygote with severe anemia. (From Agre, 1989, with permission.)

dominant, variably penetrant *spectrin* deficiency. Others are autosomally recessive or de novo gene mutations and may be caused by deficiency of *ankyrin*, *protein 4.2, moderate band 3,* or combinations thereof (Bunn and Rosse, 2001; Yawata and colleagues, 2000). These disorders are characterized by varying degrees of anemia and jaundice as the consequence of hemolysis. The diagnosis is confirmed by identification of spherocytes on peripheral smear, reticulocytosis, and increased osmotic fragility.

So-called *crisis* is characterized by severe anemia from accelerated red cell destruction and develops in patients with a functioning spleen, which is usually enlarged. The balance between bone marrow production and hemolysis can be disrupted by infection, which may either increase hemolysis or suppress bone marrow production—one example is parvovirus B19 infection (see Chap. 58, p. 1215). For many patients, splenectomy reduces hemolysis, anemia, and jaundice.

Pregnancy. In general, women with hereditary spherocytosis do well during pregnancy. Folic acid supplementation is recommended. Maberry and associates (1992) reported the Parkland Hospital experience with 50 pregnancies in 23 women with spherocytosis. In late pregnancy, the mean hematocrit was 31 volumes percent and ranged from 23 to 41. Reticulocyte counts ranged from 1 to 23 percent. Eight women miscarried and four of 42 infants were born preterm, but none were growth restricted. Infection in four women intensified hemolysis, and three required transfusions. Similar results were reported by Pajor and colleagues (1993) in 19 pregnancies in eight women. The newborn who has inherited hereditary spherocytosis may have hyperbilirubinemia and anemia. We observed the hemoglobin level to fall to as low as 5.0 g/dL by 5 weeks of age in one infant.

Red Cell Enzyme Deficiencies. A deficiency of erythrocyte enzymes that permit anaerobic glucose use may cause *hereditary nonspherocytic anemia.* Most are inherited as autosomal recessive traits. *Glucose-6-phosphate dehydrogenase* (*G6PD) deficiency*, by far the most common, is a well-known exception that is X-linked. There are more than 400 variants of G6PD, predominantly due to a base substitution that leads to an amino acid replacement and to a broad range of clinical severity (Beutler, 1991). In the homozygous or A variant, both X chromosomes are affected, and erythrocytes are markedly deficient in normal enzyme activity. This condition is inherited by approximately 2 percent of African-American women. In the heterozygous variant, only one X chromosome is affected. This condition occurs in 10 to 15 percent of African-American women and may confer some degree of protection against malaria (Mockenhaupt and colleagues, 2003). Random X-chromosome inactivation, or *lyonization,* results in a variable deficiency of enzyme activity. Newborn screening for G6PD deficiency is not included in the American College of Medical Genetics (2006) recommendations for the United States (see Table 28-5, p. 599). That said, the World Health Organization (1989) recommends screening all newborns in countries with a high prevalence.

Infections or drugs may induce hemolysis in both heterozygous and homozygous women. Anemia is usually episodic, although some variants induce chronic nonspherocytic hemolysis. Because young erythrocytes contain more enzyme activity than older erythrocytes, in the absence of bone marrow depression, anemia ultimately stabilizes and is corrected soon after the drug is discontinued or the infection clears.

Pyruvate kinase deficiency, although uncommon, is probably the next most common enzyme deficiency. It is inherited as an autosomal recessive trait and is associated with variable anemia and hypertensive complications (Wax and associates, 2007). Due to recurrent transfusions in homozygous carriers, iron overload is common, and associated myocardial dysfunction should be monitored (Dolan and colleagues, 2002). Conservative management without transfusions can be accomplished (Ghidini and Korker, 1998). Recurrent hydrops fetalis due to homozygously affected fetuses has been described, and fetal anemia and pyruvate kinase deficiency were confirmed using funipuncture (Gilsanz and colleagues, 1993).

Other rare enzyme abnormalities may cause hemolysis. Although the degree of chronic hemolysis varies, most episodes of severe anemia with enzyme deficiencies are induced by drugs or infections. During pregnancy, iron and folic acid are given, oxidant drugs are avoided, and bacterial infections are treated promptly.

Aplastic and Hypoplastic Anemia

Although rarely encountered during pregnancy, aplastic anemia is a grave complication. It is characterized by pancytopenia and markedly hypocellular bone marrow (Young, 2008). There may be more than one form, and there is evidence that one is linked to persons with autoimmune diseases (Stalder and co-workers, 2009). The etiology can be identified in approximately a third of cases, and causes include drugs and other chemicals, infection, irradiation, leukemia, immunological disorders, and inherited conditions such as *Fanconi anemia* and *Diamond-Blackfan syndrome* (Green and Kupfer, 2009; Lipton and Ellis, 2009). The functional defect appears to be a marked decrease in committed marrow stem cells. The condition is likely immunologically mediated (Young and Maciejewski, 1997).

Hematopoietic stem-cell transplantation is optimal therapy in a young patient (Young, 2008). Immunosuppressive therapy is given with bone marrow transplantation, and approximately three fourths of patients have a good response and long-term survival when treated with antithymocyte globulin and cyclosporine (Rosenfeld and colleagues, 2003). There is a potential for transplantation with umbilical cord blood-derived stem cells (Moise, 2005; Pinto and Roberts, 2008). Previous blood transfusions and even pregnancy enhance the risk of graft rejection, which is the most common serious complication. It causes two thirds of deaths within the first 2 years (Socié and co-workers, 1999).

Aplastic Anemia During Pregnancy

In most cases, aplastic anemia and pregnancy simultaneously occur by chance. In a few women, hypoplastic anemia has been identified first during a pregnancy and then improved or even resolved when the pregnancy terminated, only to recur with a subsequent pregnancy (Bourantas and associates, 1997; Choudhry and colleagues, 2002).

Of 64 pregnancies with *Diamond-Blackfan anemia,* two thirds had complications that stemmed from placental vascular etiologies and that included abortion, preeclampsia, stillbirth, fetal-growth restriction, and preterm birth (Faivre and colleagues, 2006). This rare form of pure red cell aplasia may be inherited in an autosomal recessive pattern. Some patients respond to glucocorticoid therapy, but most are transfusion- dependent.

Gaucher disease is an autosomally recessive lysosomal enzyme deficiency that has multisystem involvement. When these women are pregnant, anemia and thrombocytopenia usually worsen (Granovsky-Grisaru and associates, 1995). In another report, *alglucerase* enzyme replacement improved pregnancy outcomes in six affected women (Elstein and colleagues, 1997).

The major risks to the pregnant woman with aplastic anemia are hemorrhage and infection. Overall mortality rates reported since 1960 during or after pregnancy have been 50 percent (Choudhry and co-workers, 2002). More recent case series report better outcomes (Kwon and associates, 2006). *Fanconi anemia* appears to be associated with a better prognosis (Alter and colleagues, 1991).

Management depends on gestational age, severity of disease, and whether treatment has been given. Supportive care includes continuous infection surveillance and prompt antimicrobial therapy. Granulocyte transfusions are given only during infections. Red cell transfusions are given to improve symptomatic anemia, and routinely to maintain the hematocrit at approximately 20 volumes percent. Platelet transfusions may be needed to control hemorrhage. Even when thrombocytopenia is intense, the risk of severe hemorrhage can be minimized by vaginal rather than cesarean delivery.

Bone Marrow Transplantation. There have been several case reports of successful pregnancies in women who had undergone bone marrow transplantation (Borgna-Pignatti and associates, 1996; Eliyahu and Shalev, 1994). Sanders and colleagues (1996) reviewed outcomes in 41 women with 72 pregnancies following bone marrow transplantation. Excluding spontaneous and induced abortions, 52 resulted in liveborn infants, however, almost half of these pregnancies were complicated by preterm delivery or hypertension. Our experiences with a few of these women indicate that they have normal pregnancy-augmented erythropoiesis and total blood volume expansion.

HEMOGLOBINOPATHIES

Sickle-Cell Hemoglobinopathies

Sickle hemoglobin (hemoglobin S) results from a single β-chain substitution of glutamic acid by valine because of an A for T substitution at codon 6 of the β-globin gene. Sickle-cell diseases include sickle-cell anemia—Hgb SS; sickle cell-hemoglobin C disease—Hgb SC; sickle cell-β-thalassemia disease—either Hb S/B^{o} or Hb S/B^{+}, and sickle-cell E disease—Hgb SE (Stuart and Nagel, 2004). All are also associated with increased rates of maternal and perinatal morbidity and mortality.

Pathophysiology

Red cells with hemoglobin S undergo sickling when they are deoxygenated and the hemoglobin aggregates. Constant sickling and de-sickling cause membrane damage, and the cell may become irreversibly sickled. Events that slow erythrocyte transit through the microcirculation contribute to vaso-occlusion. These include endothelial cell adhesion, erythrocytic dehydration, and vasomotor dysregulation. Clinically, the hallmark of sickling episodes are periods during which there is ischemia and infarction in various organs. These produce clinical symptoms, predominately pain, which is often severe—the *sickle-cell crises.* There may be aplastic, megaloblastic, sequestration, and hemolytic crises.

Chronic and acute changes from sickling include bony abnormalities such as osteonecrosis of femoral and humeral heads, renal medullary damage, autosplenectomy in homozygous SS patients and splenomegaly in other variants, hepatomegaly, ventricular hypertrophy, pulmonary infarctions, pulmonary hypertension, cerebrovascular accidents, leg ulcers, and a propensity to infection and sepsis (Driscoll and colleagues, 2003; Gladwin and associates, 2004; Stuart and Nagel, 2004). Of increasing importance is acquisition of pulmonary hypertension, which can be demonstrated in 20 percent of adults with SS hemoglobin (Gladwin and Vichinsky, 2008). Depending on its severity, it increases the relative risk for death from four- to 11-fold. The median age at death for women is 48 years. Even so, Serjeant and colleagues (2008) described a cohort of 102 patients followed since birth in which 40 were still alive at 60 to 87 years!

Inheritance

Sickle-cell anemia results from the inheritance of the gene for S hemoglobin from each parent. In the United States, 1 of 12 African Americans has the sickle-cell trait, which results from inheritance of one gene for hemoglobin S and one for normal hemoglobin A. The computed incidence of sickle-cell anemia among African Americans is 1 in 576 ($1/12 \times 1/12 \times 1/4 = 1/576$). But, the disease is less common in adults and therefore during pregnancy because of earlier mortality, especially during early childhood.

Approximately 1 in 40 African Americans has the gene for hemoglobin C. The theoretical incidence for co-inheritance of the gene for hemoglobin S and an allelic gene for hemoglobin C in an African-American child is about 1 in 2000 ($1/12 \times 1/40 \times 1/4$). Similarly, because the incidence of β-thalassemia minor is approximately 1 in 40, S-β-thalassemia also is found in about 1 in 2000 ($1/12 \times 1/40 \times 1/4$).

Pregnancy and Sickle-Cell Syndrome

Pregnancy is a serious burden to women with any of the major sickle hemoglobinopathies, particularly those with hemoglobin SS disease. Two large cohorts of pregnant women with sickle-cell syndromes were described recently using the Nationwide Inpatient Sample of the Healthcare Cost and Utilization Project of the Agency for Healthcare Research and Quality. The study by Villers and colleagues (2008) included 17,952 deliveries of women with sickle-cell syndromes from 2000 through 2003. The other reported by Chakravarty and associates (2008) was from 2002 through 2004 and included 4352 pregnancies. Common complications and their frequencies were compared with the cohort of more than 18 million pregnancies of women without sickle hemoglobin and their relative risks are shown in Table 51-3. In addition, Chakravarty and co-workers (2008) reported that sickle-cell disease was associated with significantly increased odds ratios for renal failure, various forms of gestational hypertension, and fetal-growth restriction. The risk of complications shown in Table 51-3 is increased in affected pregnant women compared with unaffected pregnant controls. Additionally, data from another four studies are compiled in Table 51-4.

Other morbidity includes ischemic necrosis of multiple organs, especially bone marrow, that causes episodes of severe pain, which usually becomes more frequent in pregnancy. Pyelonephritis and pneumonia are common, as are other pulmonary complications. The latter manifest by the *acute chest syndrome*—the radiological appearance of a new pulmonary infiltrate accompanied by fever and respiratory symptoms. There are four precipitants of this—infection, marrow emboli, thromboembolism, and atelectasis (Medoff and colleagues, 2005). Of these, infection stimulates about half of cases, with most caused by atypical bacteria and viruses. When the chest syndrome develops, the mean duration of hospitalization is 10.5 days, mortality rate is about 3 percent, and mechanical ventilation is required in about 15 percent (Gladwin and Vichinsky, 2008).

Pregnancy outcomes in women with the sickle syndromes have improved substantively in the past 25 to 30 years. Powars and colleagues (1986) reported a 6-percent maternal mortality rate before 1972 and only 1 percent after 1972. In the series shown in Table 51-4, there was only one pregnancy-related maternal death, and the average perinatal mortality rate was approximately 9 percent.

TABLE 51-3. Increased Rates for Maternal Complications in Pregnancies Complicated by Sickle-Cell Syndromes

Complications	OR[a]	*p* value
Preexisting Medical Disorders		
Cardiomyopathy	3.7	<.001
Pulmonary hypertension	6.3	<.001

[a]Excludes spontaneous and induced abortions.
[b]Study periods overlap and may contain some duplicated pregnancy outcomes.
ACS = acute chest syndrome; Pyelo = pyelonephritis; FGR = fetal-growth restriction; SB = stillborn; NND = neonatal death; NS = not stated; PMR = perinatal mortality rate.

Hemoglobin SC. In nonpregnant women, morbidity and mortality rates from SC disease are appreciably lower than those from sickle-cell anemia. Indeed, fewer than half of women with SC disease have symptoms prior to pregnancy. In our experiences, affected pregnant and puerperal women suffer attacks of severe bone pain and episodes of pulmonary infarction and embolization—acute chest syndrome—more commonly compared with when they are not pregnant (Cunningham and associates, 1983). It is arguable whether SC disease has an equivalent maternal mortality rate with hemoglobin SS disease (Pritchard and co-workers, 1973; Serjeant and associates, 2005). In the reports shown in Table 51-4, the perinatal mortality rate is somewhat greater than that of the general obstetrical population, but nowhere as great as with sickle-cell anemia (Tita and colleagues, 2007).

Management During Pregnancy

Adequate management of pregnant women with sickle-cell hemoglobinopathies necessitates close observation. These women maintain hemoglobin mass by intense hemopoiesis to compensate for the markedly shortened erythrocyte life span. Thus, any factor that impairs erythropoiesis or increases red cell destruction, or both, aggravates the anemia. Prenatal folic acid supplementation with 4 mg/day is needed to support the rapid turnover of red blood cells (American College of Obstetricians and Gynecologists, 2007).

One common danger is that a symptomatic woman may categorically be considered to be suffering from a sickle-cell crisis. As a result, serious obstetrical or medical problems that cause pain, anemia, or both may be overlooked. Some examples are ectopic pregnancy, placental abruption, pyelonephritis, or appendicitis. *The term "sickle-cell crisis" should be applied only after all other possible causes of pain or fever or worsening anemia have been excluded.*

Pain is from intense sequestration of sickled erythrocytes with infarction in various organs. These episodes may develop acutely, especially late in pregnancy, during labor and delivery, and early in the puerperium. Acute infarction is usually accompanied by severe pain, and because the bone marrow is frequently involved, intense bone pain is common. A system for care of these women has been appropriately stressed by Rees and colleagues (2003). Marti-Carvajal and co-workers (2009) performed a Cochrane Review and reported that there have been no randomized trials to evaluate treatments during pregnancy for these episodes. At the minimum, intravenous fluids are given and opioids administered promptly for severe pain. Oxygen via nasal cannula may decrease the intensity of sickling at the capillary level. We have found that red cell transfusions after the onset of severe pain do not dramatically improve the intensity of the current pain crisis and may not shorten its duration. Conversely, as discussed later, prophylactic transfusions almost always prevent further vaso-occlusive episodes and pain crises.

Rates of covert bacteriuria and acute pyelonephritis are increased substantively, and screening and treatment for bacteriuria are essential. If pyelonephritis develops, sickle cells are extremely susceptible to bacterial endotoxin, which can cause dramatic and rapid red cell destruction while simultaneously suppressing erythropoiesis. Pneumonia, especially due to *Streptococcus pneumoniae,* is common. The Centers for Disease Control and Prevention (2008 a, b, c) recommends the following vaccines for sickle cell—and all asplenic—patients: polyvalent pneumococcal, *Haemophilus influenzae* type B, and meningococcal vaccine.

As many as 40 percent of patients suffer from pulmonary complications—the acute chest syndrome. Described above, it is characterized by pleuritic chest pain, fever, cough, lung infiltrates, and hypoxia (Vichinsky and colleagues, 2000). And the spectrum of its pathology includes infection, infarction, pulmonary sequestration, and fat embolization from bone marrow (**Fig. 51-3**). At least for nonpregnant adults, some recommend rapid simple or exchange transfusions to remove the 'trigger' for acute chest syndromes (Gladwin and Vichinsky, 2009). In a

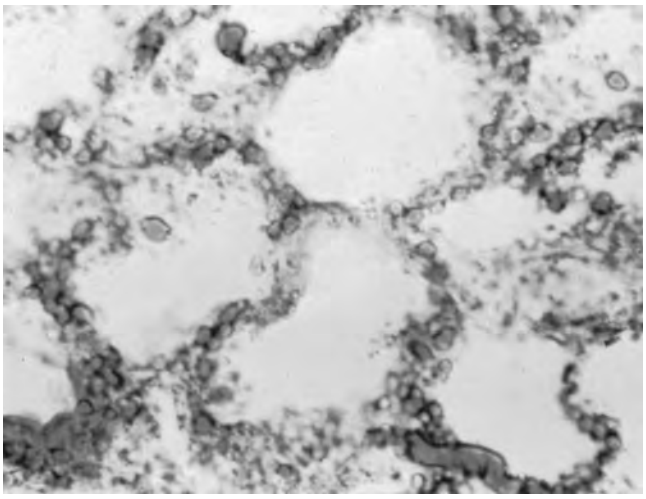

FIGURE 51-3 Photomicrograph of a section of lung from a 21-year-old primipara with hemoglobin SC who died 36 hours postpartum after developing acute dyspnea. Massive amounts of fat and bone marrow have embolized to both lungs. (From Maberry and Cunningham, 1993.)

cohort study of nonpregnant patients, Turner and colleagues (2009) reported that there were no increased benefits of exchange versus simple transfusions, and the former were associated with fourfold increased blood usage. Recurrent episodes may lead to restrictive chronic lung disease or arteriolar vasculopathy and pulmonary hypertension.

Pregnant women with sickle-cell anemia usually have some degree of *cardiac dysfunction* from ventricular hypertrophy. There is increased preload and decreased afterload with a normal ejection fraction and a high cardiac output. Chronic hypertension worsens this (Gandhi and colleagues, 2000). During pregnancy, the basal hemodynamic state characterized by high cardiac output and increased blood volume is augmented (Veille and Hanson, 1994). Although most women tolerate pregnancy without problems, complications such as severe preeclampsia or serious infections may result in ventricular failure (Cunningham and associates, 1986). As discussed in Chapter 44 (p. 970), heart failure caused by pulmonary hypertension must also be considered (Chakravarty and associates, 2008; Stuart and Nagel, 2004).

In a review of 4352 pregnancies in women with sickle-cell syndromes, Chakravarty and colleagues (2008) reported significantly increased pregnancy complications compared with the total population of 11.2 million women. Compared with controls, women with sickling disorders had a 63-percent rate of nondelivery-related admissions. They had a 1.8-fold increased incidence of hypertensive disorders—19 percent; a 2.9-fold increased rate of fetal-growth restriction—6 percent; and a 1.7-fold increased cesarean delivery rate—45 percent.

Assessment of Fetal Health. Because of the high incidence of fetal-growth restriction and perinatal mortality, serial fetal assessment is necessary. According to the American College of Obstetricians and Gynecologists (2007), a plan for serial sonographic examinations and antepartum fetal surveillance is reasonable. Anyaegbunam and colleagues (1991) evaluated fetal well-being during 39 sickling crises in 24 women. Almost 60 percent had nonreactive stress tests, which became reactive with crisis resolution, and all had an increased uterine artery systolic-diastolic (S/D) ratio. At the same time, there were no changes in umbilical artery S/D ratios (see Chap. 16, p. 362). These investigators concluded that transient effects of sickle-cell crisis do not compromise umbilical, and hence fetal, blood flow. At Parkland Hospital, we serially assess these women with sonography for fetal growth and amnionic fluid volume changes. Nonstress or contraction stress tests are not done routinely unless complications such as fetal-growth restriction develop or fetal movement is reported to be diminished.

Labor and Delivery. Management is essentially identical to that for women with cardiac disease (see Chap. 44, p. 961). Women should be kept comfortable but not oversedated. Labor epidural analgesia is ideal, and conduction analgesia seems preferable for operative delivery (Camous and associates, 2008). Compatible blood should be available. If a difficult vaginal or cesarean delivery is contemplated, and the hematocrit is less than 20 volumes percent, then packed erythrocyte transfusions are administered. Care must be taken to prevent circulatory overload and pulmonary edema from ventricular failure.

Prophylactic Red Cell Transfusions. These have been shown to decrease morbidity in sickle-cell syndromes when given perioperatively and during pregnancy or to prevent strokes in high-risk children. The use of routine prophylactic transfusions during pregnancy remains controversial (American College of Obstetricians and Gynecologists, 2007). Their most dramatic impact has been on maternal morbidity. In a 10-year prospective study at Parkland Hospital, we offered prophylactic transfusions to all pregnant women with sickle-cell syndromes. Red cell transfusions were given throughout pregnancy to maintain the hematocrit greater than 25 volumes percent and hemoglobin S no greater than 60 percent (Cunningham and Pritchard, 1979). There was minimal maternal morbidity such as pain, fever, and suppression of erythropoiesis. In a later study, these women were compared with historical controls not given blood, and there was a significant reduction in maternal morbidity and hospitalizations in the transfused groups (Cunningham and associates, 1983). A comparative study by Howard and colleagues (1995) produced similar data.

In a multicenter trial, Koshy and colleagues (1988) randomized 72 pregnant women with sickle-cell disease to prophylactic or indicated transfusions. They reported a significant decrease in the incidence of painful sickle-cell crises with prophylactic transfusions but no differences in perinatal outcomes. Because of risks inherent with blood administration, they concluded that prophylactic transfusions were not necessary.

Current consensus is that management should be individualized. Some clinicians choose prophylactic transfusions in women with a history of multiple vaso-occlusive episodes and poor obstetrical outcomes (Castro and colleagues, 2003).

Complications. Morbidity from multiple transfusions is significant. Delayed hemolytic transfusion reactions occur in as

many as 10 percent of patients (Garratty, 1997). Hepatitis is a major concern. At Parkland Hospital, the incidence of red cell isoimmunization was 3 percent per unit of blood transfused (Cox and associates, 1988). In 12 studies reviewed by Garratty (1997), a mean of 25 percent of chronically transfused sickle-cell patients had become isoimmunized. Although the specter of iron overload and transfusion hemochromatosis is worrisome, we found no evidence for this or for chronic hepatitis in liver biopsies from 40 women transfused during pregnancy (Yeomans and co-workers, 1990).

Other Therapy

There are several therapeutic schemes for sickle-cell patients, some of which are still experimental (Stuart and Nagel, 2004). Hemoglobin F induction has been studied for sickling and thalassemia syndromes. There are drugs that stimulate gamma-chain synthesis and thus hemoglobin F, which inhibits polymerization of hemoglobin S and resultant sickling. For patients with moderate to severe disease, *hydroxyurea* increases hemoglobin F production with fewer clinical sickling episodes (Platt, 2008). It may also reduce red cell membrane damage and decrease adherence to endothelium with less vascular damage. At this time, it is unknown if hydroxyurea increases long-term survival (Brawley and co-workers, 2008). Experience with hydroxyurea in pregnancy is limited, but it is teratogenic in animals (Briggs and colleagues, 2005).

Another cancer drug, *decitabine*, has been used in patients who are unresponsive to hydroxyurea (DeSimone and colleagues, 2002). Findings from a placebo-controlled trial of *inhaled nitric oxide* versus placebo suggested benefit for acute vaso-occlusive crises (Weiner and colleagues, 2003).

Hemopoietic cell transplantation as been used as a "cure" for patients with sickle-cell syndromes as well as with thalassemia major. Oringanje and co-workers (2009) performed a Cochrane Review and found that only observational studies have been reported. *Bone marrow transplantation*, as discussed on page 1085, has been used to provide normal hemoglobin A erythrocyte precursors in pediatric or adult patients with severe disease, and 5-year survival rates exceed 90 percent (Bhatia and Walters, 2008). *Cord blood stem cell transplantation* from related donors has shown great promise (Pinto and Roberts, 2008). Prenatal diagnosis of sickle-cell disease may allow for in utero *stem cell therapy* with hemoglobin A cells (Shaaban and Flake, 1999). Perhaps even more intriguing is the possibility that cells taken for prenatal diagnosis from a fetus destined to have sickle-cell anemia can be conditioned to produce hemoglobin A and used for replacement after birth (Ye and co-workers, 2009). Other experimental therapies include a gene therapy technique using a modified β-globin gene that encodes a sickling-resistant protein, which corrected the globin chain in transgenic hemoglobin SS knock-out mice (Pawliuk and colleagues, 2001).

Contraception and Sterilization

Because of chronic debility, complications caused by pregnancy, and the predictably shortened life span of women with sickle-cell anemia, contraception and possibly sterilization are important considerations. According to the American College of Obstetricians and Gynecologists (2000), estrogen-progesterone oral contraceptives have not been assessed well in women with sickle hemoglobinopathies. Many clinicians do not recommend their use because of potential adverse vascular and thrombotic effects (see Chap. 32, p. 679).

Progesterone has been long known to prevent painful sickle-cell crises. Because of this, low-dose oral progesterone, progesterone injections, or implants seem ideal. In one study, de Abood and associates (1997) reported significantly fewer and less intense pain crises in women given depot medroxyprogesterone intramuscularly. Some advise against the use of intrauterine contraceptive devices because of possibly increased risk of infection, but this has not been proven clinically. The safest contraceptives are unfortunately those with the highest failure rates—condoms with foam and diaphragms. Permanent sterilization is also an option (see Chap. 33, p 698).

Sickle-Cell Trait

The heterozygous inheritance of the gene for hemoglobin S results in sickle-cell trait, or AS hemoglobin. Hemoglobin A is most abundant, and the amount of hemoglobin S averages only approximately 30 percent in each red cell. The frequency of sickle-cell trait among African-Americans is approximately 8 percent. There is evidence that carriers have occasional hematuria, renal papillary necrosis, and hyposthenuria (Tsaras and co-workers, 2009). And although controversial, we are of the view that sickle trait is not associated with increased rates of abortion, perinatal mortality, low birthweight, or pregnancy-induced hypertension (Pritchard, 1973; Tita, 2007; Tuck, 1983, and all their associates). One unquestioned relationship is the twofold increased incidence of asymptomatic bacteriuria and urinary infection. ***Sickle-cell trait therefore should not be considered a deterrent to pregnancy on the basis of increased maternal risks.*** Finally, preliminary findings from a cohort study by Lally and colleagues (2009) suggested that African-American women with sickle trait may have a higher incidence of venous thromboembolism when using hormonal contraceptives compared with women without the trait. More data is needed before these effective contraceptive methods are withheld from trait-positive women.

Inheritance is a concern for the infant of a mother with sickle trait whenever the father carries a gene for abnormal hemoglobins that include S, C, and D or for β-thalassemia trait. Prenatal diagnosis through amniocentesis or chorionic villus sampling as well as preimplantation genetic screening is available (see Chap. 13, p. 299).

Other Hemoglobinopathies

Hemoglobin C and C-β-Thalassemia

The single β-chain substitution of glutamic acid by lysine at position 6 results in production of hemoglobin C. About 2 percent of African-Americans have C trait, which does not cause anemia or adverse pregnancy outcomes. However, when co-inherited with sickle-cell trait, hemoglobin SC causes the problems previously discussed.

Pregnancy and homozygous hemoglobin CC disease or hemoglobin C-β-thalassemia are relatively benign associations.

TABLE 51-5. Outcomes in 72 Pregnancies Complicated by Hemoglobin CC and C-β-Thalassemia

	Hemoglobin CC	C-β-Thalassemia
Women	15	5
Pregnancies	49	23
Hematocrit (range)	27 (21–23)	30 (28–33)
Birthweight (g)		
Mean	2990	2960
Range	1145–4770	2320–3980
Perinatal deaths	1	2
Surviving infants	42	20

Data from Maberry and colleagues (1990).

Maberry and colleagues (1990) reported our experiences from Parkland Hospital as shown in Table 51-5. Other than mild to moderate anemia, pregnancy outcomes were not different compared with those of the general obstetrical population. When severe anemia is identified, iron or folic acid deficiency or some other superimposed cause should be suspected. Supplementation with folic acid and iron is indicated.

Hemoglobin E

The second most common hemoglobin variant worldwide, is hemoglobin E, although it is uncommon in the United States. Hemoglobin E results from a single β-chain substitution of lysine for glutamic acid at codon 26. The hemoglobin is susceptible particularly to oxidative stress. The heterozygous E trait is common in Southeast Asia**.** Hurst and co-workers (1983) identified homozygous hemoglobin E, hemoglobin E plus β-thalassemia, or hemoglobin E trait in 36 percent of Cambodians and 25 percent of Laotians. In addition, α- and β-thalassemia traits were prevalent in all groups.

Homozygous hemoglobin EE is associated with little or no anemia, hypochromia, marked microcytosis, and erythrocyte targeting. In our limited experience, pregnant women do not appear to be at increased risk. Conversely, doubly heterozygous *hemoglobin E-β-thalassemia* is a common cause of childhood anemia in Southeast Asia (Fucharoen and Winichagoon, 2000). In a retrospective cohort study of 54 women with singleton pregnancies, Luewan and associates (2009) reported a threefold increased risk of preterm birth and fetal-growth restriction in affected women compared with normal controls. It is not clear if *hemoglobin SE* disease is as ominous during pregnancy as hemoglobin SC or S-β-thalassemia disease (Ramahi and colleagues, 1988).

Hemoglobinopathy in the Newborn

Infants with homozygous SS, SC, and CC disease can be identified accurately at birth by cord blood electrophoresis. The Maternal and Child Health Bureau (2005) recommends that all newborn infants be tested for sickle-cell disease. In most states, such screening is mandated by law and performed routinely on blood submitted for phenylketonuria and hypothyroidism testing (see Chap. 28, p. 599). Screening for sickle hemoglobinopathies leads to clearly decreased mortality rates in children with sickle-cell disease identified at birth.

Prenatal Diagnosis

There are many tests to detect sickle-cell disease prenatally. Most are DNA based and can be done using CVS samples or amniotic fluid specimens obtained by amniocentesis at 15 weeks (American College of Obstetricians and Gynecologists, 2007). A number of mutations that encode hemoglobin S as well as other abnormal hemoglobins can be detected by targeted mutation analysis as well as PCR-based techniques (see Chap. 12, p. 283).

Thalassemias

These genetically determined hemoglobinopathies are characterized by impaired production of one or more of the normal globin peptide chains. Abnormal synthesis rates may result in ineffective erythropoiesis, hemolysis, and varying degrees of anemia. Thalassemias are classified according to the globin chain that is deficient, and several hundred syndromes have been identified. The two major forms involve impaired production or instability either of α-peptide chains—causing α-thalassemia or of β-chains—causing β-thalassemia. The incidence of these traits during pregnancy for all races is 1 in 300 to 500 (Gehlbach and Morgenstern, 1988).

α-Thalassemias

Because there are four α-globin genes, the inheritance of α-thalassemia is more complicated than for β-thalassemia (Leung and associates, 2008). Possible genotypes and phenotypes arising from these mutations are shown in Table 51-6. For each, a close correlation has been established between clinical severity and the degree of α-globin chains synthesis impairment. In most populations, the α-globin chain "cluster" or gene loci are doubled on chromosome 16. Thus, the normal genotype for diploid cells can be expressed as αα/αα. There are two main groups of α-thalassemia determinants: α^{o}-thalassemia is characterized by the deletion of both loci from one chromosome (––/αα), whereas α^{+}-thalassemia is characterized by the loss of a single locus from one allele (–α/αα heterozygote) or a loss from each allele alleles (–α/–α homozygote).

There are two major phenotypes. The deletion of all four α-globin chain genes (––/––) characterizes *homozygous* α-thalassemia. Because α chains are contained in fetal hemoglobin, the fetus is affected. With none of the four genes expressed, there are no α-globin chains, and instead, hemoglobin Bart (γ_4) and hemoglobin H (β_4) are formed as abnormal tetramers (see Chap. 4, p. 92).

Hemoglobin Bart has an appreciably increased affinity for oxygen, and *hemoglobin Bart disease* is a common cause of stillbirths in Southeast Asia. Hsieh and associates (1989) studied 20 such hydropic fetuses by funipuncture and reported that blood contained 65 to 98 percent Bart hemoglobin. The fetus dies

TABLE 51-6. Genotypes and Phenotypes of α-Thalassemia Syndromes

Genotype	Genotype	Phenotype
Normal	αα/αα	−−
α^+-thalassemia heterozygote	−α/αα αα/−α	Silent carrier
α^+-thalassemia homozygote[a] α^o-thalassemia heterozygote[b]	−α/−α −−/αα	α-thalassemia minor—mild hypochromic microcytic anemia
Compound heterozygous α^o/α^+	−−/−α	Hgb H (β^4) with moderate to severe hemolytic anemia
Homozygous α-thalassemia	−−/−−	Hgb Bart (γ^4) disease, hydrops fetalis

[a]More common in African-Americans.
[b]More common in Asian-Americans.

either in utero or very soon after birth and demonstrates the typical features of nonimmune hydrops fetalis as shown in **Figure 51-4** (see also Chap. 29, p. 626). Lam and associates (1999) reported that sonography at 12 to 13 weeks was 100-percent sensitive and specific for identifying affected fetuses by measuring the cardiothoracic ratio. Carr and colleagues (1995) transfused a fetus with α-thalassemia at 25, 26, and 32 weeks and reversed its ascites. The transfusion-dependent infant was delivered at 34 weeks. Fetal anemia can be detected using Doppler flow measurement of middle cerebral artery velocity as described in Chapter 16 (p. 364).

The compound heterozygous state for α^o- and α^+-thalassemia results in the deletion of three of four genes (−−/−α). There is only one functional α-globin gene per diploid genome. This is referred to as *hemoglobin H disease* (β_4) and is compatible with extrauterine life. The abnormal red cells at birth contain a mixture of hemoglobin Bart (γ_4), hemoglobin H (β_4), and hemoglobin A. The neonate appears well at birth but soon develops hemolytic anemia. Most of the hemoglobin Bart present at birth is replaced postnatally by hemoglobin H. The disease is characterized by hemolytic anemia, which may be severe and similar to β-thalassemia major in children and adults. Anemia in these women usually is worsened during pregnancy.

A deletion of two genes results clinically in α-*thalassemia minor*, which is characterized by minimal to moderate hypochromic microcytic anemia. This may be due to α^o- or α^+-thalassemia traits. Thus, genotypes may be –α/–α or −−/αα, and differentiation can be made only by DNA analysis (Weatherall and Provan, 2000). Other than mild anemia, there are no associated clinical abnormalities with α-thalassemia minor, and it often goes unrecognized. Hemoglobin Bart is present at birth, but as its levels drop, it is not replaced by hemoglobin H. Red cells are hypochromic and microcytic, and the hemoglobin concentration is normal to slightly depressed. Women with α-thalassemia minor tolerate pregnancy well.

The single gene deletion (–α/αα) is the silent carrier state. No clinical abnormality is evident in the individual with a single gene deletion.

FIGURE 51-4 Stillborn hydropic fetus with extremely large placenta caused by homozygous α-thalassemia. (From Hsia, 1991, with permission.)

Frequency. The relative frequency of α-thalassemia minor, hemoglobin H disease, and hemoglobin Bart disease varies remarkably among racial groups. All of these variants are encountered in Asians. In individuals of African descent, however, even though α-thalassemia minor is demonstrated in approximately 2 percent, hemoglobin H disease is rare and hemoglobin Bart disease is unreported. This is because Asians usually have α^o-thalassemia minor with both gene deletions typically from the same chromosome (−−/αα), whereas in blacks with α^+-thalassemia minor, one gene is deleted from each chromosome (–α/–α). The α-thalassemia syndromes appear sporadically in other racial and ethnic groups. Diagnosis of α-thalassemia minor as well as α-thalassemia major in the fetus can be accomplished by

DNA analysis using molecular techniques (American College of Obstetricians and Gynecologists, 2007). Fetal diagnosis of hemoglobin Bart has been described using capillary electrophoresis or HPLC techniques (Sirichotiyakul, 2009; Srivorakun, 2009, and all their colleagues).

Beta-Thalassemias

These are the consequences of impaired production of β-globin chains or instability of α chains (Benz, 2008). More than 150 point mutations in the β-globin gene have been described (Weatherall, 2000). Most are single-nucleotide substitutions that produce transcription or translation defects, RNA splicing or modification, or frameshifts that result in highly unstable hemoglobins. Thus, deletional and nondeletional mutations affect β-globin RNA. The δγβ-gene "cluster" is on chromosome 11 (see Fig. 4-14, p. 92).

In β-thalassemia, there is decreased β-chain production, and excess α chains precipitate to cause cell membrane damage. In addition, β-thalassemia may be due to α-chain instability. Kihm and colleagues (2002) described a molecular chaperone that regulates α-globin subunit stability—*α-hemoglobin-stabilizing protein (AHSP)*—which forms a stable complex with free α-globin and prevents precipitation. Mutations in the AHSP gene may modify the clinical picture of β-thalassemia. For example, an overexpression of AHSP may convert β-thalassemia major to β-thalassemia intermedia. These basic defects lead to the panorama of pathology that characterizes homozygous β-thalassemia, so-called *β-thalassemia major* or *Cooley anemia*. With heterozygous β-thalassemia minor, hypochromia, microcytosis, and slight to moderate anemia develop without the intense hemolysis that characterizes the homozygous state. The hallmark of the common β-thalassemias is an elevated hemoglobin A_2 level.

In the typical case of thalassemia major, the neonate is healthy at birth, but as the hemoglobin F level falls, the infant becomes severely anemic and fails to thrive. A child who is entered into an adequate transfusion program develops normally until the end of the first decade. Then, effects of iron loading become apparent. Prognosis is improved by iron chelation therapy with deferoxamine (Olivieri and associates, 1998).

Prior to chelation and transfusions, pregnancy in women with severe thalassemia was rare. Aessopos (1999), Daskalakis (1998), and Kumar (1997) and their colleagues reported a total of 63 pregnancies without severe complications. Pregnancy is recommended only if there is normal maternal cardiac function and prolonged hypertransfusion to maintain the hemoglobin concentration at 10 g/dL. This is coupled with surveillance and monitoring of fetal growth (American College of Obstetricians and Gynecologists, 2007; Sheiner and colleagues, 2004).

With *β-thalassemia minor*, hemoglobin A_2, which is composed of two α- and two δ-globin chains, is increased to more than 3.5 percent. Simultaneously, hemoglobin F, which is composed of two α- and two γ-globin chains, is usually increased to more than 2 percent. Anemia is mild, and the red cells are hypochromic and microcytic. There is usually pregnancy-induced augmentation of erythropoiesis, and using erythrocytes tagged with chromium-51, we have documented normal blood volume expansion with slightly subnormal red cell mass expansion.

There is no specific therapy for β-thalassemia minor during pregnancy. Prophylactic iron and folic acid are given. Sheiner and associates (2004) reported that fetal-growth restriction and oligohydramnios were increased twofold in 261 affected women.

Prenatal diagnosis of β-thalassemia major is more difficult than detecting abnormal hemoglobins because of the large number of mutations. To diagnose a particular mutation, targeted mutation analysis is done that requires prior identification of the disease-causing mutation for that particular family (American College of Obstetricians and Gynecologists, 2007). Most of these are done using samples obtained by CVS. Preimplantation blastomere biopsy has been described by Galvani (2000) and Kanavakis (1999) and their associates. Isolation of single nucleated red blood cells from maternal circulation is being explored for prenatal diagnosis of β-thalassemia (Kolialexi and colleagues, 2007).

Polycythemia

Excessive erythrocytosis during pregnancy is usually related to chronic hypoxia due to maternal congenital cardiac disease or a pulmonary disorder. Occasionally, it is from heavy cigarette smoking. We have encountered otherwise healthy young pregnant women who were heavy smokers with chronic bronchitis and with a hematocrit from 55 to 60 volumes percent! Brewer and colleagues (1992) described a woman with persistent erythrocytosis associated with a placental site tumor. If polycythemia is severe, the probability of a successful pregnancy outcome is low.

Polycythemia vera is a myeloproliferative hemopoietic stem cell disorder characterized by excessive proliferation of erythroid, myeloid, and megakaryocytic precursors. It is uncommon and likely an acquired genetic disorder of stem cells (Spivak, 2008). Measurement of serum erythropoietin by radioimmunoassay differentiates polycythemia vera—low values—from secondary polycythemia—high values. Symptoms are related to increased blood viscosity, and thrombotic complications are common. Fetal loss has been reported to be high in women with polycythemia vera and pregnancy outcome may be improved with aspirin therapy (Deruelle, 2005; Griesshammer, 2006; Robinson, 2005; Tefferi, 2000, and all their associates).

PLATELET DISORDERS

Thrombocytopenia in pregnant women may be inherited or idiopathic. It is often associated with acquired hemolytic anemia, severe preeclampsia or eclampsia, severe hemorrhage with blood transfusions, consumptive coagulopathy from placental abruption or similar hypofibrinogenemic states, sepsis syndrome, systemic lupus erythematosus, antiphospholipid antibody syndrome, aplastic anemia, and megaloblastic anemia from severe folate deficiency. It also may result from viral infection, exposure to a variety of drugs, allergic reaction, and irradiation (Konkle, 2008). Drug-induced thrombocytopenia was reviewed by Aster and Bougie (2007).

Gestational Thrombocytopenia

Normal pregnancy may be accompanied by a physiological decrease in platelet concentration. This is usually evident in the third trimester and is thought to be predominantly due to hemodilution (see Appendix). Most evidence shows that platelet life span is unchanged in normal pregnancy (Kenny and colleagues, 2009).

Thus, some degree of *gestational thrombocytopenia* is considered normal. Obviously, the definition used for thrombocytopenia is important. In their review, Rouse and associates (1998) cite an incidence of 4 to 7 percent for gestational thrombocytopenia, defined by platelet counts $< 150{,}000/\mu L$. Burrows and Kelton (1993a) reported that 6.6 percent of 15,471 pregnant women had platelet counts $< 150{,}000/\mu L$, and in 1.2 percent, they were $< 100{,}000/\mu L$. They reported that almost 75 percent of 1027 women whose platelet counts were $< 150{,}000/\mu L$ were found to have normal-variant incidental thrombocytopenia. Of the remainder, 21 percent had a hypertensive disorder of pregnancy, and 4 percent had an immunological disorder. In another study, Boehlen and associates (2000) found that 11.6 percent of 6770 pregnant women had platelet counts $< 150{,}000/\mu L$. In this study, $116{,}000/\mu L$ was 2.5 standard deviations below the mean. Al-Kouatly and colleagues (2003) found a much higher rate of thrombocytopenia in triplet gestations, affecting nearly a third of cases. In contrast to thrombocytopenia in singletons, more than 70 percent of cases were due to hypertensive disorders.

Inherited Thrombocytopenias

The *Bernard-Soulier syndrome* is characterized by lack of platelet membrane glycoprotein (GPIb/IX), which causes severe dysfunction. Maternal antibodies against fetal GPIb/IX antigen can cause isoimmune fetal thrombocytopenia. Peng and colleagues (1991) described an affected woman who during four pregnancies had episodes of postpartum hemorrhage, gastrointestinal hemorrhage, and fetal thrombocytopenia. Fujimori and associates (1999) described a similarly affected woman whose neonate died from thrombocytopenic intracranial hemorrhage. Close monitoring through pregnancy and 6 weeks postpartum is critical due to the possibility of life-threatening hemorrhage (Prabu and Parapia, 2006).

Chatwani and associates (1992) reported a woman with autosomally dominant *May-Hegglin anomaly* whose infant was not affected. This condition is characterized by thrombocytopenia, giant platelets, and leukocyte inclusions. Urato and Repke (1998) also described such a woman who was delivered vaginally. Despite a platelet count of $16{,}000/\mu L$, she did not bleed excessively. The neonate inherited the anomaly, but also had no bleeding despite a platelet count of $35{,}000/\mu L$. Fayyad and colleagues (2002) managed three pregnancies in a woman with May-Hegglin anomaly. In the first, the mother had a term cesarean delivery of an unaffected infant; in the second, she had a fetal demise with multiple placental infarcts; and in the third, she received low-dose aspirin (75 mg/d) and gave birth to an unaffected infant.

Immune Thrombocytopenic Purpura

This is also called *idiopathic thrombocytopenic purpura (ITP)* and usually results from a cluster of IgG antibodies directed against one or more platelet glycoproteins (Schwartz, 2007). Antibody-coated platelets are destroyed prematurely in the reticuloendothelial system, especially the spleen. The mechanism of production of these platelet-associated immunoglobulins—PAIgG, PAIgM, and PAIgA—is not known, but most investigators consider them to be autoantibodies.

The American Society of Hematology formulated guidelines for the diagnosis and management of ITP, which are still in effect (George and colleagues, 1996). Acute ITP is most often a childhood disease that follows a viral infection. Most cases resolve spontaneously, although perhaps 10 percent become chronic. Conversely, in adults, immune thrombocytopenia is primarily a chronic disease of young women and rarely resolves spontaneously.

Secondary forms of chronic thrombocytopenia appear in association with systemic lupus erythematosus, lymphomas, leukemias, and a number of systemic diseases. For example, about 2 percent of thrombocytopenic patients have positive serological tests for lupus, and in some cases, there are high levels of anticardiolipin antibodies. As many as 10 percent of HIV-positive patients have associated thrombocytopenia (Konkle, 2008; Scaradavou, 2002).

Only a small number of adults with primary ITP recover spontaneously, and for those who do not, platelet counts usually range from 10,000 to $100{,}000/\mu L$ (George and associates, 1996). Those whose platelet counts remain less than $30{,}000/\mu L$ or those with significant bleeding at higher levels are treated. Prednisone, 1 to 2 mg/kg orally daily, raises the platelet count in approximately two thirds of cases. Unfortunately, relapse is common. Glucocorticoids suppress the phagocytic activity of the splenic monocyte-macrophage system. Also, intravenous immunoglobulin (IVIG) given in a total dose of 2 g/kg over 2 to 5 days is usually effective (Konkle, 2008). Godeau and colleagues (2002) reported results of a randomized trial of intravenous immunoglobulin or high-dose methylprednisolone given for 3 days. These were followed by either oral prednisone or placebo. Intravenous immunoglobulin plus oral prednisone was most effective, although methylprednisolone with prednisone was effective and well tolerated. Therapy is expensive, and IVIG currently costs $40 to $55 per gram with a typical course of therapy averaging 150 to 200 grams (Medical Letter, 2006).

For patients with no response to corticosteroid therapy in 2 to 3 weeks, those in whom massive doses are needed to sustain remission, or those with frequent recurrences, splenectomy is indicated. In approximately 60 percent, there is substantive improvement as the consequence of decreased removal of platelets and reduced antibody production. Massive doses described above of immunoglobulin given intravenously over 5 days result in satisfactory platelet count elevation in two thirds of patients. Such therapy may be useful for those with life-threatening thrombocytopenia refractive to other therapy or for patients preoperatively before splenectomy.

Therapy is problematic for the 30 percent of adults who do not respond to corticosteroids or splenectomy. Immunosuppressive drugs, including azathioprine, cyclophosphamide, and cyclosporine, have been used with some success. Danazol, vinca alkaloids, plasma exchange, and high-dose dexamethasone pulse therapy have also been described. Thrombopoietin agonists,

such as *eltrombopag,* have shown promise but are considered experimental (Bussel and co-workers, 2007).

Immune Thrombocytopenia and Pregnancy

There is no evidence that pregnancy increases the risk of relapse in women with previously diagnosed immune thrombocytopenia. Nor does it worsen thrombocytopenia in women with active disease. That said, it is certainly not unusual for women who have been in clinical remission for several years to have recurrent thrombocytopenia during pregnancy. Although this may be from closer surveillance, hyperestrogenemia has also been suggested as a cause.

Treatment is considered if the platelet count is less than 30,000 to 50,000/μL (George and associates, 1996; Konkle, 2008). Prednisone in a dose of 1 mg/kg orally per day may be required for improvement, and most likely treatment will have to be continued throughout pregnancy. Corticosteroid therapy usually produces amelioration. With steroid-refractory disease, high-dose immunoglobulin is given intravenously and may be considered as first-line therapy in the third trimester (Gernsheimer and McCrae, 2007). Clark and Gall (1997) reviewed 16 reports of 21 pregnancies in which ITP was treated with immunoglobulin. All but four responded with posttreatment platelet counts greater than 50,000/μL, and in 11 cases, counts exceeded 100,000/μL.

In pregnant women with no response to steroid or immunoglobulin therapy, open or laparoscopic splenectomy may be effective. In late pregnancy, surgery is technically more difficult, and cesarean delivery may be necessary for exposure. Intravenous anti-D IgG 50 to 75 μg/kg has been described for treatment of resistant ITP in D-positive patients with a spleen (Konkle, 2008). There usually is improvement by 1 to 3 days with a peak at approximately 8 days. Sieunarine and colleagues (2007) reported such therapy in a pregnant woman.

Fetal and Neonatal Effects

Platelet-associated IgG antibodies cross the placenta and may cause thrombocytopenia in the fetus-neonate. Fetal death from hemorrhage occurs occasionally (Webert and associates, 2003). The severely thrombocytopenic fetus is at increased risk for intracranial hemorrhage with labor and delivery. This fortunately is unusual. Payne and colleagues (1997) reviewed studies of maternal ITP published since 1973 and added their experiences with 55 cases. Of 601 newborns, 12 percent had severe thrombocytopenia defined as a platelet count $< 50{,}000/\mu L$. Six infants had intracranial hemorrhage, and in three, their initial platelet count was $> 50{,}000/\mu L$.

Considerable attention has been directed at identifying the fetus with potentially dangerous thrombocytopenia. All investigators have concurred that there is not a strong correlation between fetal and maternal platelet counts (George and associates, 1996; Payne and co-workers, 1997). Because of this, there have been attempts to quantify the relationships among maternal IgG free platelet antibody levels, platelet-associated antibody levels, and fetal platelet count. Again, there is little concurrence. Kaplan (1990) and Samuels (1990) and their colleagues reported conflicting results in using indirect platelet immunoglobulin for identification of high-risk neonates.

Investigators have also examined the association between the specific maternal cause of thrombocytopenia and the risk of a thrombocytopenic fetus. Four causes investigated include gestational thrombocytopenia, hypertension-associated thrombocytopenia, ITP, and isoimmune thrombocytopenia. Burrows and Kelton (1993a) reported neonatal umbilical cord platelet counts of $< 50{,}000/\mu L$ in 19 of 15,932 consecutive newborns (0.12 percent). Of all of these pregnancies, only one of 756 mothers with gestational thrombocytopenia had an affected infant. Of 1414 hypertensive women with thrombocytopenia, five infants had thrombocytopenia. In contrast, of 46 mothers with ITP, four infants had thrombocytopenia. Finally, isoimmune thrombocytopenia was associated with profound thrombocytopenia and cord platelet counts $< 20{,}000/\mu L$. One of these fetuses died, and two others had intracranial hemorrhage.

In a similar population study to the one above, Boehlen and associates (1999) determined antiplatelet antibody levels in 430 pregnant women whose platelet counts were $< 150{,}000/\mu L$. Antibodies were detected in 9 percent but had no predictive value. In another study, Sainio and co-workers (2000) performed cord platelet counts in almost 4500 neonates. Approximately 2 percent were $< 150{,}000/\mu L$, and only 0.2 percent (1 in 410) were $< 50{,}000/\mu L$. Once again, bleeding in all infants was due to isoimmune thrombocytopenia.

Detection of Fetal Thrombocytopenia

From the foregoing, it is apparent that there are no clinical characteristics or laboratory tests that accurately predict fetal platelet count. This led Scott and associates (1983) to recommend intrapartum fetal scalp platelet determinations once the cervix was 2 cm dilated and the membranes were ruptured. Cesarean delivery was performed for fetuses with platelet counts $< 50{,}000/\mu L$. Daffos and colleagues (1985) subsequently reported a high complication rate with percutaneous umbilical cord blood sampling—PUBS—for platelet quantification (see Chap. 13, p. 300). Berry and associates (1997) reported no complications but found a high negative-predictive value. Payne and colleagues (1997) summarized six such studies reported since 1988. Of 195 cases, severe neonatal thrombocytopenia of $< 50{,}000/\mu L$ was found in 7 percent, however, there were serious complications from cordocentesis in 4.6 percent of the fetuses.

Because of the low incidence of severe neonatal thrombocytopenia and morbidity, Burrows and Kelton (1993b), Silver and colleagues (1995), Payne and associates (1997), and the American Society of Hematology (George and co-workers, 1996) all concluded that fetal platelet determinations and cesarean delivery are not necessary.

Isoimmune Thrombocytopenia

Platelet isoimmunization can develop in a manner identical to erythrocyte antigen isoimmunization. This disorder is discussed in detail in Chapter 29 (p. 629).

Thrombocytosis

Also called *thrombocythemia*, thrombocytosis generally is defined as persistent platelet counts $> 450{,}000/\mu L$. Common

causes of *secondary* or *reactive thrombocytosis* are iron deficiency, infection, inflammatory diseases, and malignant tumors (Konkle, 2008). Platelet counts seldom exceed 800,000/μL in these secondary disorders, and prognosis depends on the underlying disease. On the other hand, *essential thrombocytosis* is a myeloproliferative disorder that accounts for most cases in which platelet counts exceed 1 million/μL. Thrombocytosis usually is asymptomatic, but arterial and venous thromboses may develop (Rabinerson and associates, 2007). In one study, Cortelazzo and colleagues (1995) reported that myelosuppression with hydroxyurea for nonpregnant patients with essential thrombocytosis decreased thrombotic episodes from 24 to 4 percent compared with those of untreated controls.

Thrombocytosis in Pregnancy

In 40 pregnancies of 16 women with essential thrombocythemia, 45 percent were complicated by spontaneous abortion, fetal demise, and preeclampsia (Niittyvuopio and colleagues, 2004). Experiences from the Mayo Clinic with 63 pregnancies in 36 women were described recently by Gangat and co-workers (2009). Again, abortion was common, and 35 percent of pregnancies miscarried, most in the first trimester. Aspirin therapy was associated with a significantly lower abortion rate than that in untreated women—1 vs. 75 percent. Other pregnancy complications were uncommon. Normal pregnancies have been described in women whose mean platelet counts were > 1.25 million/μL (Beard and co-workers, 1991; Randi and colleagues, 1994). Treatment that has been suggested during pregnancy includes aspirin, dipyridamole, heparin, platelet pheresis, or combinations thereof (Griesshammer and associates, 2003). Delage and coworkers (1996) reviewed 11 cases in which interferon-α was given during pregnancy with successful outcomes. They also described a woman at midpregnancy who had a platelet count of 2.3 million/μL and transient blindness. Thrombocytapheresis and interferon-α were used to keep the platelets at approximately 1 million/μL until delivery.

Thrombotic Microangiopathies

Although not proven a primary platelet disorder, there almost always is some degree of thrombocytopenia with the thrombotic microangiopathies. Their similarities to the preeclampsia syndrome underlie their obstetrical ramifications.

Moschcowitz (1925) originally described *thrombotic thrombocytopenic purpura* by the pentad of thrombocytopenia, fever, neurological abnormalities, renal impairment, and hemolytic anemia. Gasser and colleagues (1955) later described the similar *hemolytic uremic syndrome*, which had more profound renal involvement and fewer neurological aberrations. Allford and associates (2003) provided guidelines for the British Committee for Standards in Haematology for the diagnosis and management of thrombotic microangiopathic hemolytic anemias. The syndromes have an incidence of 2 to 6 per million persons per year (Miller and colleagues, 2004).

Although it is likely that different causes account for the variable findings within these syndromes, they frequently are clinically indistinguishable in adults. Thrombotic thrombocytopenic purpura—TTP—is thought to be caused by a plasma deficiency of a von Willebrand factor-clearing protease termed ADAMTS-13 (Crowther and George, 2008; Mayer and Aledort, 2005). Conversely, hemolytic uremic syndrome—HUS—is usually due to endothelial damage incited by viral or bacterial infections. There is no evidence that postpartum renal failure is a separate syndrome (Robson and associates, 1968).

Pathogenesis

Microthrombi of hyaline material consisting of platelets and small amounts of fibrin develop within arterioles and capillaries. These aggregates produce ischemia or infarctions in various organs. The general consensus is that intravascular platelet aggregation stimulates the cascade of events leading to end-organ failure. Although there is endothelial activation and damage, it is unclear whether this is a consequence or a cause. Elevated levels of unusually large multimers of von Willebrand factor are identified with active TTP. The endothelium-derived protease responsible for cleaving von Willebrand factor is neutralized by antibodies during an acute episode (Furlan and colleagues, 1998; Tsai and Lian, 1998). The *ADAMTS13 gene* encodes this protease (Levy and colleagues, 2001). Defects in this gene result in various clinical presentations of thrombotic microangiopathy (Camilleri and colleagues, 2007; Moake, 2002, 2004).

Clinical Presentation

Thrombotic microangiopathies are characterized by thrombocytopenia, fragmentation hemolysis, and variable organ dysfunction. A viral prodrome may precede up to 40 percent of cases. Neurological symptoms develop in up to 90 percent and include headache, altered consciousness, convulsions, fever, or stroke. Because renal involvement is common, the two syndromes are difficult to separate clinically. Renal failure is thought to be more severe with the hemolytic uremic syndrome, and in half of the cases, dialysis is required.

Hematological Abnormalities

Thrombocytopenia is usually severe. Fortunately, even with very low platelet counts, spontaneous severe hemorrhage is uncommon. Microangiopathic hemolysis is associated with moderate to marked anemia, and transfusions are frequently necessary. The blood smear is characterized by erythrocyte fragmentation with schizocytosis. The reticulocyte count is high, and nucleated red blood cells are numerous. Consumptive coagulopathy, although common, is usually subtle and clinically insignificant.

Treatment

Plasmapheresis with fresh-frozen plasma replacement has remarkably improved the outcome for patients with these formerly fatal diseases (Michael and co-workers, 2009). Red cell transfusions are imperative for life-threatening anemia. Rock and colleagues (1991) found plasma exchange to be superior to plasma infusion in nonpregnant patients, but mortality rates were still 30 percent. Bell and co-workers (1991) reported their experiences with 108 patients treated at Johns Hopkins Hospital, of which 10 percent were pregnant. Those with mild neurological symptoms were

given prednisone, 200 mg orally daily. If there were neurological abnormalities or rapid clinical deterioration, plasmapheresis and plasma exchange were performed daily. Approximately a fourth of patients with mild disease responded to prednisone alone. Of those requiring plasmapheresis, relapses were common, but the overall survival rate was 91 percent. According to Konkle (2008), 25 to 40 percent have a relapse within 30 days, whereas up to 40 percent have a later relapse. In addition, there may be long-term sequelae, such as renal impairment (Dashe and colleagues, 1998).

Pregnancy and Thrombotic Microangiopathy

It has been shown that ADAMTS-13 enzyme activity decreases almost 50 percent across pregnancy (Sanchez-Luceros and co-workers, 2004). At least intuitively, this is consonant with prevailing opinions that TTP is more common in pregnant women. We, however, are of the contrary view. This is because of observations over a 25-year period, during which Dashe and co-workers (1998) reported 11 pregnancies complicated by these syndromes among nearly 275,000 obstetrical patients within our well-defined catchment area for Parkland Hospital. This frequency of 1 in 25,000 approximates that in our general hospital population.

It is not surprising that severe preeclampsia and eclampsia complicated further by thrombocytopenia and overt hemolysis have been confused with thrombotic thrombocytopenic purpura and vice versa (Hsu and colleagues, 1995; Magann and co-workers, 1994). One constant feature of thrombotic microangiopathies is hemolytic anemia, which is rarely severe with preeclampsia, even with the *HELLP syndrome* (see Chap. 34, p. 718). Although deposition of hyaline microthrombi within the liver is seen with thrombotic microangiopathy, hepatocellular necrosis characteristic of preeclampsia has not been described. In addition, whereas delivery is imperative to treat preeclampsia in women with the HELLP syndrome, there is no evidence that thrombotic microangiopathy is improved by delivery (Letsky, 2000). Finally, microangiopathic syndromes are usually recurrent and unassociated with pregnancy. For example, 7 of 11 women described by Dashe and colleagues (1998) had recurrent disease either when not pregnant or within the first trimester of a subsequent pregnancy. George (2009) reported recurrent TTP in only five of 36 subsequent pregnancies.

Unless the diagnosis is unequivocally one of these thrombotic microangiopathies, rather than severe preeclampsia, the response to pregnancy termination should be evaluated before resorting to plasmapheresis and exchange transfusion, massive-dose glucocorticoid therapy, or other therapy. Measurement of ADAMTS-13 enzyme activity may not be helpful because it decreases with HELLP syndrome to levels lower that those for normal pregnancy (Franchini and co-workers, 2007). *Plasmapheresis is not indicated for preeclampsia-eclampsia complicated by hemolysis and thrombocytopenia.*

Paralleled with improved survival of nonpregnant patients treated with plasmapheresis and plasma exchange, maternal survival rates from thrombotic microangiopathy have increased appreciably with these treatments. Egerman and co-workers (1996) described 11 pregnant women so treated and noted two maternal and three fetal deaths. In our experiences at Parkland Hospital, five of eight women treated by plasmapheresis had a dramatic salutary response, although one woman died (Dashe and associates, 1998).

Long-Term Prognosis. Pregnant women with thrombotic microangiopathy have a number of long-term complications. In the study by Dashe and associates (1998), 9-year surveillance disclosed multiple recurrences; renal disease requiring dialysis, transplantation, or both; severe hypertension; and transfusion-acquired infectious diseases. Two women died remote from pregnancy—one from dialysis complications and one from HIV infection transmitted by blood or plasma transfusions. Egerman and colleagues (1996) reported similar observations. And for nonpregnant patients who have recovered from TTP, there are persistent cognitive defects as well as physical disabilities in most of those assessed at a median duration of 4 years (Kennedy and associates, 2009; Lewis and colleagues, 2009). These cognitive defects are intriguingly similar to those reported years later in eclamptic women as described by The Netherlands group (Aukes and co-workers, 2009) and discussed in further detail in Chapter 34 (p. 749).

INHERITED COAGULATION DEFECTS

Obstetrical hemorrhage is common, but it rarely is the consequence of an inherited defect in the coagulation mechanism. Several syndromes, however, are particularly important.

Hemophilias

There are two types of hemophilias, which are seen in varying degrees. They are considered mild, moderate, or severe, corresponding to plasma factor levels of 6 to 30, 2 to 5, or < 1 percent, respectively (Mannucci and Tuddenham, 2001).

Hemophilia A is an X-linked recessively transmitted disease characterized by a marked deficiency of *small component* antihemophilic factor (factor VIII:C). It is rare among women compared with men, in whom the heterozygous state is responsible for the disease. Although heterozygous women have diminished factor VIII levels, almost invariably the homozygous state is the requisite for hemophilia A. In a few instances, it appears in women spontaneously from a newly mutant gene.

The genetic and clinical features of severe deficiency of factor IX—*Christmas disease* or *hemophilia B*—are similar to those of hemophilia A. Guy and associates (1992) reviewed five cases in pregnancy, all with a favorable outcome. They recommended administration of factor IX when levels are below 10 percent.

Clinical Manifestations

The degree of risk for each hemophilia is influenced markedly by the level of circulating factor VIII:C or factor IX. If the level is at or very close to zero, the risk is major. In female carriers, activity is expected to average 50 percent, but there is a range due to lyonization (Letsky, 2000). If levels fall below 10 to 20 percent, hemorrhage may occur. Both of these clotting factors increase appreciably during normal pregnancy and in pregnant women who are carriers of hemophilia A and B (see Appendix).

Desmopressin may also stimulate factor VIII:C release. The risk of hemorrhage is reduced by avoiding lacerations, by minimizing episiotomy use and size, and by maximizing postpartum myometrial contractions and retraction. Kadir and co-workers (1997) reported that 20 percent of carriers had postpartum hemorrhage, and in two, it was massive.

An affected male fetus may develop hematomas with either vaginal or cesarean delivery (Kadir and associates, 1997). After delivery, the risk of hemorrhage in the neonate increases, especially if circumcision is attempted.

Inheritance

Whenever the mother has hemophilia A or B, all of her sons will have the disease, and all of her daughters will be carriers. If she is a carrier, half of her sons will inherit the disease and half of her daughters will be carriers. Prenatal diagnosis of hemophilia is possible in some families using chorionic villus biopsy (see Chap. 13, p. 300). Premiplantation genetic diagnosis for hemophilia was recently reviewed by Lavery (2009).

Factor VIII or IX Inhibitors

Rarely, antibodies directed against factor VIII or IX are acquired and may lead to life-threatening hemorrhage. Patients with hemophilia A or B, because of prior treatment with factor VIII or IX, more commonly develop such antibodies. In contrast, acquisition of these antibodies in nonhemophiliacs is rare. This phenomenon has also been identified rarely in women during the puerperium (Santoro and Prejano, 2009). In these cases, the prominent clinical feature is severe, protracted, repetitive hemorrhage from the reproductive tract starting a week or so after an apparently uncomplicated delivery (Reece and associates, 1988). The activated partial thromboplastin time is markedly prolonged. Treatment has included multiple transfusions of whole blood and plasma; huge doses of cryoprecipitate; large volumes of an admixture of activated coagulation factors, including porcine factor VIII; immunosuppressive therapy; and attempts at various surgical procedures, especially curettage and hysterectomy. Another treatment involves bypassing factor VIII or IX by the use of activated forms of factors VII, IX, and X. A recombinant activated factor VII (NovoSeven) stops bleeding in up to 75 percent of patients with inhibitors (Mannucci and Tuddenham, 2001). As discussed in Chapter 35 (p. 794), NovoSeven has also been used in nonhemophilic patients in cases of intractable obstetrical hemorrhage caused by uterine atony and by dilutional effects of multiple transfusions.

Von Willebrand Disease

Clinically, von Willebrand disease (vWD) is a heterogenous group of approximately 20 functional disorders involving aberrations of factor VIII complex and platelet dysfunction. These abnormalities are the most commonly inherited bleeding disorders, and their prevalence is as high as 1 to 2 percent (Mannucci, 2004). Most von Willebrand variants are inherited as autosomal dominant traits. Examples are types I and II, which are the most common variants. Type III, which is the most severe, is phenotypically recessive. These and other aspects of vWD were recently reviewed by an expert panel of the National Heart, Lung, and Blood Institute (Nichols and co-workers, 2008).

Fewer than 300 cases of *acquired vWD (AvWD)* have been reported in the literature. Most symptoms include rapid onset of subcutaneous bruising or mucous membrane bleeding in those with no prior personal or family history of clotting abnormalities. Etiologies include benign and malignant hematological conditions, solid tumors, autoimmune disorders, and medications. For example, autoantibodies against von Willebrand factor (vWF) lead to rapid clearance from the circulation or interference with its function. Alternatively, lymphoid or other tumors can express specific vWF receptors and selectively adsorb vWF onto their surfaces, thereby nullifying its function. Additionally, decreased synthesis of vWF has been found in those with hypothyroidism and valproate-induced vWD. Lastly, the vWF shows increased degradation in those with poorly controlled diabetes mellitus, congenital or acquired cardiac defects, and ciprofloxacin-induced vWD (Shau and colleagues, 2002). Although most cases of AvWD develop in those older than 50 years, management of AvWD in pregnancy has been described (Lipkind and colleagues, 2005).

Pathogenesis

The *von Willebrand factor* is a series of large plasma multimeric glycoproteins that form part of the factor VIII complex. It is essential for normal platelet adhesion to subendothelial collagen and formation of a primary hemostatic plug at the site of blood vessel injury. It also plays a major role in the stabilization of the coagulant properties of factor VIII. The procoagulant component is the antihemophilic factor or factor VIII:C, which is a glycoprotein synthesized by the liver. Conversely, von Willebrand precursor, which is present in platelets as well as plasma, is synthesized by endothelium and megakaryocytes under the control of autosomal genes on chromosome 12. The von Willebrand factor antigen (vWF:Ag) is the antigenic determinant measured by immunoassays.

Clinical Presentation

Symptomatic patients usually present with evidence of a platelet defect. The possibility of vWD is usually considered in women with bleeding suggestive of a chronic disorder of coagulation. The classical autosomal dominant form usually is symptomatic in the heterozygous state. The less common but clinically more severe autosomal recessive form is manifest when inherited from both parents, both of whom typically demonstrate little or no disease. Type I, which accounts for 75 percent of von Willebrand variants, is characterized clinically by easy bruising; epistaxis; mucosal hemorrhage; and excessive bleeding with trauma, including surgery. Its laboratory features are usually a prolonged bleeding time, prolonged partial thromboplastin time, decreased vWF antigen levels, decreased factor VIII immunological as well as coagulation-promoting activity, and inability of platelets in plasma from an affected person to react to a variety of stimuli.

Pregnancy and vWD

During normal pregnancy, maternal levels of both factor VIII as well as vWF antigen increase substantively (see Appendix).

Because of this, pregnant women with vWD often develop normal levels of factor VIII coagulant activity as well as vWF antigen, although the bleeding time still may be prolonged. If factor VIII activity is very low or if there is bleeding, treatment is recommended. Desmopressin by infusion may transiently increase factor VIII and vWF factor levels, especially in patients with type I disease (Kujovich, 2005; Mannucci, 2004). With significant bleeding, 15 or 20 units or "bags" of cryoprecipitate are given every 12 hours. Alternatively, factor VIII concentrates may be given that contain high-molecular-weight vWF multimers (Alfanate, Hemate-P). These concentrates are highly purified and are heat treated to destroy HIV. Lubetsky and associates (1999) have described continuous infusion with Hemate-P in nonpregnant patients during nine surgical procedures and in another woman during a vaginal delivery. According to Chi and associates (2009), conduction analgesia can be given safely if coagulation defects have normalized or if hemostatic agents are given prophylactically.

Pregnancy outcomes in women with von Willebrand disease are generally good, but postpartum hemorrhage is encountered in up to 50 percent of cases. Of 38 cases summarized by Conti and associates (1986), bleeding was reported with abortion, with delivery, or in the puerperium in a fourth. Greer and colleagues (1991) reported that 8 of 14 pregnancies were complicated by postpartum hemorrhage. Kadir and co-workers (1998) reported their experiences from the Royal Free Hospital in London with 84 pregnancies. They described a 20-percent incidence of immediate postpartum hemorrhage and another 20-percent incidence of late hemorrhage. Most cases were associated with low vWF levels in untreated women, and none given treatment peripartum had hemorrhage. In our experiences, levels of coagulant factors within the normal range do not always protect against such bleeding.

Inheritance

Although most patients with von Willebrand disease have heterozygous variants with a mild bleeding disorder, the disease can be severe. Certainly when both parents have the disorder, their homozygous offspring develop a serious bleeding disorder. Mullaart and colleagues (1991) reported periventricular hemorrhage in a 32-week fetus who inherited type IIa vWD from her father. Chorionic villus biopsy with DNA analysis to detect the missing genes has been described (see Chap. 13, p. 300). Some authorities recommend cesarean delivery to avoid trauma to a possibly affected fetus if the mother has severe disease.

Other Inherited Coagulation Factor Deficiencies

In general, the activity of most procoagulant factors in maternal plasma rise across pregnancy (see Appendix). A number of rare coagulopathies may be inherited in a manner similar to the hemophilias. *Factor VII deficiency* is a rare autosomal recessive disorder. The gene that codes for factor VII is on chromosome 13. Normally, factor VII increases during pregnancy, but it may do so only mildly in women with factor VII deficiency (Fadel and Krauss, 1989). Treatment with factor VIIa has been reported during labor, delivery, and the puerperium (Eskandari and associates, 2002).

Factor X or *Stuart-Prower factor* deficiency is rare and is inherited as an autosomal recessive trait. Factor X levels typically rise by 50 percent during normal pregnancy. Konje and colleagues (1994) described a woman with 2-percent activity who was given prophylactic treatment with plasma-derived factor X, which raised plasma levels to 37 percent. Despite this, she suffered an intrapartum placental abruption. Bofill and co-workers (1996) gave intrapartum fresh-frozen plasma to a woman with less than 1-percent factor X activity. She delivered spontaneously without incident. Beksac and associates (2009) described a woman with severe factor X deficiency who was successfully managed with prophylactic prothrombin complex concentrate.

Factor XI—plasma thromboplastin antecedent—deficiency is inherited as an autosomal trait that is manifest as severe disease in homozygotes but only as a minor defect in heterozygotes. It is most prevalent in Ashkenazi Jews, and it is rarely seen in pregnancy. Musclow and colleagues (1987) described 41 deliveries in 17 affected women with factor XI deficiency, none of whom required transfusions. They also described a woman who developed a spontaneous hemarthrosis at 39 weeks. Kadir and associates (1998) described 29 pregnancies in 11 affected women. In none of these did factor XI levels increase; 15 percent had immediate postpartum hemorrhage; and another 25 percent had delayed hemorrhage. Myers and colleagues (2007) reported 105 pregnancies in 33 affected women with uneventful pregnancy and delivery in 70 percent. They recommend peripartum treatment with factor XI concentrate if cesarean delivery is performed, and advise against epidural analgesia unless factor XI is given. From their review, Martin-Salces and associates (2008) found that there was poor correlation between factor XI levels and bleeding in women with severe deficiency.

Factor XII deficiency is another autosomal recessive disorder that rarely complicates pregnancy. An increased incidence of thromboembolism is encountered in nonpregnant patients with this deficiency. Lao and colleagues (1991) reported an affected pregnant woman in whom placental abruption developed at 26 weeks.

Factor XIII deficiency is autosomal recessive and may be associated with maternal intracranial hemorrhage (Letsky, 2000). According to their review, Kadir and co-workers (2009) cited an increased risk of recurrent miscarriage and placental abruption. Treatment is given with fresh frozen plasma.

Autosomally inherited abnormalities of fibrinogen usually involve the formation of a functionally defective fibrinogen and are commonly referred to as *dysfibrinogenemias* (Edwards and Rijhsinghani, 2000). Familial *hypofibrinogenemia,* and sometimes *afibrinogenemia*, are infrequent recessive disorders. In some cases, both are found—*hypodysfibrinogenemia* (Deering and colleagues, 2003). Our experience suggests that hypofibrinogenemia represents a heterozygous autosomal dominant state with 50 percent of the offspring affected. Typically, the thrombin-clottable protein level in these patients ranges from 80 to 110 mg/dL when nonpregnant, and this increases by 40 or 50 percent in normal pregnancy. Those pregnancy complications that give rise to acquired hypofibrinogenemia, for example, placental abruption, are more common with fibrinogen deficiency. Trehan and Fergusson (1991) and Funai and associates

(1997) described successful outcomes in two affected women in whom fibrinogen or plasma infusions were given weekly or biweekly throughout pregnancy.

Conduction Analgesia for Labor and Cesarean Delivery

Most serious bleeding disorders would logically preclude the use of epidural or subarachnoid space injections for obstetrical analgesia. If the bleeding disorder is controlled, either spontaneously or with therapy, then these methods may be considered. Chi and colleagues (2009) reviewed intrapartum outcomes in 80 pregnancies in 63 women with an inherited bleeding disorder. These included 19 with factor XI deficiency, 16 hemophilia carriers, 15 with von Willebrand disease, and the remainder with platelet disorders or a deficiency of factor VII, XI, and X. Regional block was used in 41, of whom 35 had spontaneously normalized hemostatic dysfunction and 10 were given prophylactic replacement therapy. They encountered no unusual complications and concluded that such practices were safe. Singh and associates (2009) reviewed 13 women with factor XI deficiency delivered at Brigham and Women's Hospital. Nine of the 11 women were given neuraxial analgesia without complications, but only after fresh-frozen plasma was given to most of them to correct the activated partial thromboplastin time.

Thrombophilias

Several important regulatory proteins inhibit clotting. There are physiological antithrombotic proteins that act as inhibitors at strategic sites in the coagulation cascade to maintain blood fluidity under normal circumstances. Inherited deficiencies of these inhibitory proteins are caused by mutations of genes influencing their control. Because they may be associated with recurrent thromboembolism, they are collectively referred to as *thrombophilias.* Examples include deficiencies of antithrombin III, protein C, or of its co-factor, protein S; activated protein C resistance from factor V single-gene mutations; a function-enhancing mutation in the prothrombin gene (G20210A); and hyperhomocystinemia. Because these deficiencies may be associated with thromboembolism, they are discussed in detail in Chapter 47 (p. 1014).

CHAPTER 52

Diabetes

CLASSIFICATION 1104
DIAGNOSIS OF DIABETES DURING PREGNANCY 1105
GESTATIONAL DIABETES 1108
PREGESTATIONAL DIABETES 1113
CONTRACEPTION 1121

The prevalence of diagnosed diabetes among American adults has increased by 40 percent in 10 years and rose from 4.9 percent in 1990 to 6.9 percent in 1999 (Narayon and colleagues, 2003). More worryingly, it is estimated that this incidence will increase another 165 percent by 2050. To put this into perspective, the lifetime risk of diabetes in individuals born in 2000 is 33 percent for males and 39 percent for females! This increase primarily is due to type 2 diabetes, which is also referred to as *diabesity*. As discussed in Chapter 43, this term reflects the strong relationship of diabetes with the current epidemic of obesity in the United States and other countries (Gale, 2003; Mokdad and associates, 2003).

The increasing prevalence of type 2 diabetes in general, and in younger people in particular, has led to an increasing number of pregnancies with this complication (Ferrara and co-workers, 2004). Many women found to have gestational diabetes are likely to have type 2 diabetes that has previously gone undiagnosed (Feig and Palda, 2002). Indeed, the incidence of diabetes complicating pregnancy has increased approximately 40 percent between 1989 and 2004 (Getahun and colleagues, 2008). In Los Angeles County, Baraban and co-workers (2008) reported that the age-adjusted prevalence tripled from 14.5 cases per 1000 women in 1991 to 47.9 cases per 1000 in 2003.

There is keen interest in events that precede diabetes, and this includes the *mini-environment of the uterus,* where it is believed that early imprinting can have effects later in life (Saudek, 2002). For example, in utero exposure to maternal hyperglycemia leads to fetal hyperinsulinemia, causing an increase in fetal fat cells, which leads to obesity and insulin resistance in childhood (Feig and Palda, 2002). This in turn leads to impaired glucose tolerance and diabetes in adulthood. Thus, a cycle of fetal exposure to diabetes leading to childhood obesity and glucose intolerance is set in motion. This sequence has been reported in Pima Indians as well as a heterogeneous Chicago population (Silverman and colleagues, 1995).

CLASSIFICATION

Diabetes is now classified based on the pathogenic processes involved (Powers, 2008). Absolute insulin deficiency characterizes *type 1 diabetes*, whereas defective insulin secretion or insulin resistance characterizes *type 2 diabetes* (Table 52-1). The terms insulin-dependent diabetes mellitus (IDDM) and noninsulin-dependent diabetes mellitus (NIDDM) are no longer used. Age is also no longer used in classification, because pancreatic β-cell destruction can begin at any age. Most commonly, its onset is before age 30, but in 5 to 10 percent of affected individuals, onset is after age 30 years. Type 2 diabetes, although most typical with increasing age, also develops in obese adolescents.

Classification During Pregnancy

Diabetes is the most common medical complication of pregnancy. Women can be separated into those who were known to have diabetes before pregnancy—*pregestational* or *overt*, and those diagnosed during pregnancy—*gestational*. In 2006, slightly more than 179,898 American women had pregnancies complicated by some form of diabetes, representing 4.2 percent of all live births (Martin and associates, 2009). In the United States, African-Americans, Native Americans, Asians, and Hispanic women are at higher risk for gestational diabetes compared

TABLE 52-1. Etiological Classification of Diabetes Mellitus

- **I. Type 1:** β-Cell destruction, usually absolute insulin deficiency
  - A. Immune-mediated
  - B. Idiopathic
- **II. Type 2:** Ranges from predominantly insulin resistance to predominantly an insulin secretory defect with insulin resistance
- **III. Other types**
  - A. Genetic mutations of β-cell function
  - B. Genetic defects in insulin action
  - C. Genetic syndromes—e.g., Down, Klinefelter, Turner
  - D. Diseases of the exocrine pancreas—e.g., pancreatitis, cystic fibrosis
  - E. Endocrinopathies—e.g., Cushing syndrome, pheochromocytoma, others
  - F. Drug or chemical induced—e.g., glucocorticosteroids, thiazides, β-adrenergic agonists, others
  - G. Infections—congenital rubella, cytomegalovirus, coxsackievirus
- **IV. Gestational diabetes (GDM)**

Adapted from Fauci AS, Braunwald E, Kasper DL, et al: *Harrison's Principles of Internal Medicine,* 17th ed., pp. 2275–2304. Copyright © 2008 The McGraw-Hill Companies, Inc.

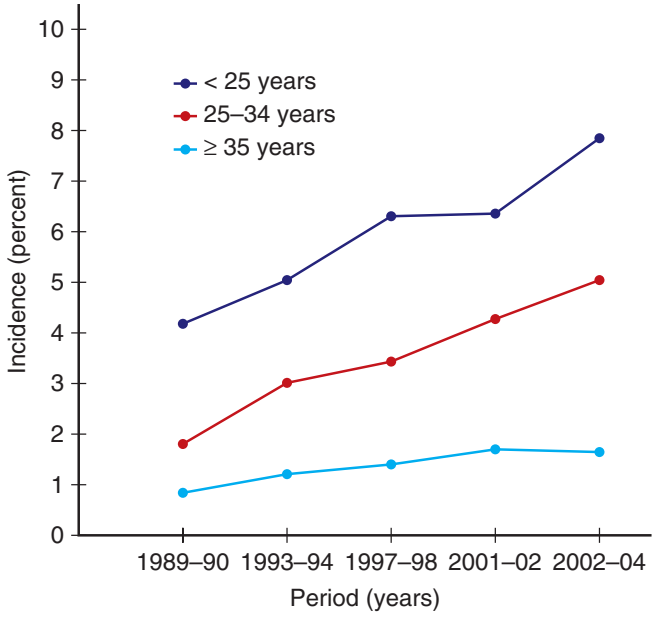

FIGURE 52-1 Age-specific incidence of gestational diabetes from National Hospital Discharge Survey Data (NHDS) of nearly 59 million births in the United States from 1989 to 2004. (Redrawn from *American Journal of Obstetrics & Gynecology,* Vol. 198, No. 5, D Getahun, C Nath, CV Ananth, et al., Gestational diabetes in the United States: temporal trends 1989 through 2004, pp. 525.e1–525.e5, Copyright 2008, with permission from Elsevier.)

with white women (Ferrara, 2007). The increasing incidence of gestational diabetes over the past 15 years shown in **Figure 52-1** is reminiscent of similar statistics for obesity discussed in Chapter 43 (p. 946).

White Classification in Pregnancy

It is important to describe the evolution of diabetes classification during pregnancy over the past 20 years because many older terms continue to be used. For example, frequent reference is made to the classification by White (1978). And because most literature currently cited contains data from these older classifications, the one recommended by the American College of Obstetricians and Gynecologists in 1986 is shown in **Table 52-2**. This was replaced in 1994 because, according to the College, "a single classification based on the presence or absence of good maternal metabolic control and the presence or absence of maternal diabetic vasculopathy is more helpful."

In the 1986 classification, women diagnosed with gestational diabetes were subdivided, and those with fasting hyperglycemia of 105 mg/dL or greater were placed into class A_2. Approximately 15 percent of women with gestational diabetes exhibit fasting hyperglycemia (Sheffield and co-workers, 1999). Women in classes B to H, corresponding to the White classification (1978), have overt diabetes antedating pregnancy. The White system emphasized that end-organ derangements, especially involving the eyes, kidneys, and heart, have significant effects on pregnancy outcome.

For several years now, the American College of Obstetricians and Gynecologists (2001, 2005) has no longer used a classification according to the White scheme. Instead, the focus is now on whether diabetes is first diagnosed during pregnancy or antedates pregnancy.

DIAGNOSIS OF DIABETES DURING PREGNANCY

Overt Diabetes

Women with high plasma glucose levels, glucosuria, and ketoacidosis present no problem in diagnosis. Similarly, women with a random plasma glucose level greater than 200 mg/dL plus classic signs and symptoms such as polydipsia, polyuria, and unexplained weight loss or a fasting glucose exceeding 125 mg/dL are considered by the American Diabetes Association (2004) to have overt diabetes. The diagnostic cutoff value for overt diabetes is a fasting plasma glucose of 126 mg/dL or higher. This is used because data indicate the risk of retinopathy rises dramatically at that fasting level. Women at the opposite end of the spectrum or those with only minimal metabolic derangement may be difficult to identify. The likelihood of impaired carbohydrate metabolism is increased appreciably in women who have a strong familial

TABLE 52-2. Classification Scheme Used from 1986 through 1994 for Diabetes Complicating Pregnancy

		Plasma Glucose Level		
Class	**Onset**	**Fasting**	**2-hour Postprandial**	**Therapy**
A_1	Gestational	<105 mg/dL	<120 mg/dL	Diet
A_2	Gestational	>105 mg/dL	>120 mg/dL	Insulin
Class	**Age of Onset (yr)**	**Duration (yr)**	**Vascular Disease**	**Therapy**
B	Over 20	<10	None	Insulin
C	10 to 19	10 to 19	None	Insulin
D	Before 10	>20	Benign retinopathy	Insulin
F	Any	Any	Nephropathy[a]	Insulin
R	Any	Any	Proliferative retinopathy	Insulin
H	Any	Any	Heart	Insulin

[a]When diagnosed during pregnancy: proteinuria ≥ 500 mg/24 h before 20 weeks' gestation.

history of diabetes, have given birth to large infants, demonstrate persistent glucosuria, or have unexplained fetal losses.

Reducing substances are commonly found in the urine of pregnant women. Commercially available dipsticks may be used to identify glucosuria while avoiding a positive reaction from lactose. Even then, glucosuria most often does not reflect impaired glucose tolerance, but rather augmented glomerular filtration (see Chap. 5, p. 123). Nonetheless, the detection of glucosuria during pregnancy warrants further investigation (Gribble and associates, 1995).

Gestational Diabetes

This is defined as carbohydrate intolerance of variable severity with onset or first recognition during pregnancy. This definition applies whether or not insulin is used for treatment. Undoubtedly, some women with gestational diabetes have previously unrecognized overt diabetes. Sheffield and coworkers (1999) studied outcomes in 1190 diabetic women delivered at Parkland Hospital between 1991 and 1995. They found that women with fasting hyperglycemia diagnosed before 24 weeks had pregnancy outcomes similar to those for women with overt diabetes. Bartha (2000) and Most (2009) with their colleagues reported similar results. Thus, fasting hyperglycemia early in pregnancy almost invariably represents overt diabetes.

Screening

Despite more than 40 years of research, there is no consensus regarding the optimal approach to screening for gestational diabetes (American College of Obstetricians and Gynecologists, 2001). The major issues include whether universal or selective screening should be used and which plasma glucose level after a 50-g glucose test threshold is best to identify women at risk for gestational diabetes (Bonomo and colleagues, 1998; Danilenko-Dixon and associates, 1999).

Since 1980, there have been five International Workshop Conferences on gestational diabetes, and participants have attempted to provide consensus statements on screening. Those at the Fifth Conference endorsed use of the definition, classification criteria, and strategies for detection and diagnosis of gestational diabetes recommended at the Fourth Workshop Conference in 1997 (Metzger and co-workers, 2007). Instead of *universal screening,* recommendations are now for *selective screening* using the guidelines shown in **Table 52-3**. Screening should be performed between 24 and 28 weeks in those women not known to have glucose intolerance earlier in pregnancy. This evaluation is usually done in two steps. In the two-step procedure, a 50-g oral glucose challenge test is followed by a diagnostic 100-g oral glucose tolerance test (OGTT) if initial results exceed a predetermined plasma glucose concentration.

Plasma glucose level is measured 1 hour after a 50-g glucose load without regard to the time of day or time of last meal. A value of ≥ 140 mg/dL (7.8 mmol/L) identifies 80 percent of all women with gestational diabetes. Using a value of ≥ 130 mg/dL (7.2 mmol/L) increases the yield to greater than 90 percent. However, 20 to 25 percent of women will have false positive test results compared with only 14 to 18 percent when the ≥ 140 mg/dL cutoff value is used.

The day-to-day reproducibility of the 50-g screening test has been evaluated by Espinosa de los Monteros and co-workers (1993). Although 90 percent of normal results were reproducible the next day, only 83 percent of abnormal test results were reproducible. Murphy and colleagues (1994) studied the accuracy and precision of reflectance photometers—*Accu-Check III*—for screening. Because this required redefining the circumstances for testing and threshold values for abnormal results, it seems best to avoid these devices for screening.

Gabbe and associates (2004) surveyed practicing obstetricians-gynecologists in 2003 and reported that 96 percent used universal screening for gestational diabetes. Integral to justifying this practice is the requirement to show that women who screen

TABLE 52-3. Fifth International Workshop-Conference on Gestational Diabetes: Recommended Screening Strategy Based on Risk Assessment for Detecting Gestational Diabetes (GDM)

GDM risk assessment: Should be ascertained at the first prenatal visit

- **Low Risk:** Blood glucose testing not routinely required if all the following are present:
  - Member of an ethnic group with a low prevalence of GDM
  - No known diabetes in first-degree relatives
  - Age < 25 years
  - Weight normal before pregnancy
  - Weight normal at birth
  - No history of abnormal glucose metabolism
  - No history of poor obstetrical outcome
- **Average Risk:** Perform blood glucose testing at 24 to 28 weeks using either:
  - Two-step procedure: 50-g oral glucose challenge test (GCT), followed by a diagnostic 100-g oral glucose tolerance test for those meeting the threshold value in the GCT.
  - One–step procedure: Diagnostic 100-g oral glucose tolerance test performed on all subjects.
- **High Risk:** Perform blood glucose testing as soon as feasible, using the procedures described above if one or more of these are present:
  - Severe obesity
  - Strong family history of type 2 diabetes
  - Previous history of GDM, impaired glucose metabolism, or glucosuria. If GDM is not diagnosed, blood glucose testing should be repeated at 24 to 28 weeks or at any time there are symptoms or signs suggestive of hyperglycemia.

positive are benefited by the treatment. The justification for screening, and by extension, treatment of women with gestational diabetes, was given considerable impetus by a study reported by Crowther and colleagues (2005). They assigned 1000 women with gestational diabetes between 24 and 34 weeks' gestation to receive dietary advice with blood glucose monitoring plus insulin therapy—intervention group—versus routine prenatal care. Women were diagnosed to have gestational diabetes if their blood glucose was < 100 mg/dL after an overnight fast and between 140 and 198 mg/dL 2 hours after ingesting a 75-g glucose solution. Women in the intervention group had a significantly reduced risk of a composite adverse outcome that included one or more of perinatal death, shoulder dystocia, bone fracture, and nerve palsy. Macrosomia defined by birthweight ≥ 4000 g complicated 10 percent of deliveries in the intervention group compared with 21 percent in the routine prenatal care group ($p <$ .001). Cesarean delivery rates were almost identical in the two study groups. In an editorial accompanying this report, Greene and Solomon (2005) concluded that the study provided important evidence that identifying and treating gestational diabetes can substantially reduce the risk of adverse perinatal outcomes.

Slightly different results were recently reported by the Maternal Fetal Medicine Units Network randomized trial of 958 women (Landon and colleagues, 2009). This study was designed to compare whether dietary counseling and glucose monitoring in women with mild gestational diabetes would reduce the incidence of perinatal morbidity compared with standard obstetrical care. Mild gestational diabetes was identified in women with fasting glucose < 95 mg/dL. They reported no differences in rates of composite morbidity that included stillbirth; neonatal hypoglycemia, hyperinsulinemia, and hyperbilirubinemia; and birth trauma. Importantly, though, secondary analyses did reveal a 50-percent reduction in macrosomia, fewer cesarean deliveries, and a significant decrease in shoulder dystocia—1.5 versus 4 percent—in treated versus control women.

From the foregoing, it is easy to understand why some of these issues are often contentious. Indeed, the U.S. Preventive Services Task Force (2008) recently again concluded that evidence is insufficient to assess the balance of benefits versus harms of screening, either before or after 24 weeks.

Diagnosis

There is not international agreement as to the optimal glucose tolerance test to identify gestational diabetes. The World Health Organization (1985) has recommended the 75-g 2-hour oral glucose tolerance test, which is often used in Europe (Weiss and colleagues, 1998). In the United States, the *100-g 3-hour oral glucose tolerance test* performed after an overnight fast remains the standard recommended by the American College of Obstetricians and Gynecologists (2001). Even so, Catalano and coworkers (1993) found that the 100-g 3-hour test was not reproducible in 25 percent of women when repeated 1 week after the initial test. They attributed this to increased norepinephrine-mediated gluconeogenesis from maternal stress at initial testing.

Recommended criteria for interpretation of the 100-g diagnostic glucose tolerance test are shown in Table 52-4. Also shown are the criteria for the 75-g test most often used outside the United States, but increasingly used in this country.

TABLE 52-4. Fifth International Workshop Conference on Gestational Diabetes: Diagnosis of Gestational Diabetes by Oral Glucose Tolerance Testing[a]

	Oral Glucose Load			
Time	100-g Glucose[b]		75-g Glucose[b]	
Fasting	95 mg/dL	5.3 mmol/L	95 mg/dL	5.3 mmol/L
1-h	180 mg/dL	10.0 mmol/L	180 mg/dL	10.0 mmol/L
2-h	155 mg/dL	8.6 mmol/L	155 mg/dL	8.6 mmol/L
3-h	140 mg/dL	7.8 mmol/L	—	—

[a]The test should be performed in the morning after an overnight fast of at least 8 h but not more than 14 h and after at least 3 days of unrestricted diet (≥ 150 g carbohydrate/d) and physical activity. The subject should remain seated and should not smoke during the test.
[b]Two or more of the venous plasma glucose concentrations indicated below must be met or exceeded for a positive diagnosis.

The Hyperglycemia and Adverse Pregnancy Outcome (HAPO) Study

This was a seven-year international epidemiological study of 23,325 pregnant women at 15 centers in nine countries that comprised the HAPO Study Cooperative Research Group (2008). The investigation was designed to determine the association of various levels of glucose intolerance during the third trimester with adverse infant outcomes in women with gestational diabetes. Between 24 and 32 weeks, the general population of pregnant women underwent 75-g oral glucose tolerance testing after overnight fasting. Blood glucose levels were measured pretest fasting and again, 1 and 2 hours after glucose ingestion. Caregivers were blinded to results except for women whose glucose levels exceeded values that required treatment and removal from the study. Values at each of three time posts were stratified into seven categories and analyzed for birthweight > 90th percentile (LGA), primary cesarean delivery, clinical neonatal hypoglycemia, and cord-serum C-peptide levels > 90th percentile. Odds of each outcome were calculated using the lowest category—for example, fasting plasma glucose < 75 mg/dL—as the referent group. Their findings in general supported the supposition that increasing plasma glucose levels at each epoch were associated with increasing adverse outcomes. One example is shown in Figure 52-2.

In an editorial accompanying publication of the HAPO trial, Ecker and Greene (2008) posed the question: "Given the results of the HAPO study, should we lower our threshold for the diagnosis and treatment of gestational diabetes?" It was concluded that it will be difficult to show that treating lesser degrees of carbohydrate intolerance—as suggested in the HAPO study—would provide any meaningful improvements in clinical outcomes. Ecker and Greene (2008) concluded, and we agree, that changes of criteria are not justified until clinical trials prove benefits.

GESTATIONAL DIABETES

The word *gestational* implies that diabetes is induced by pregnancy—ostensibly because of exaggerated physiological changes in glucose metabolism (see Chap. 5, p. 113). Another explanation is that gestational diabetes is type 2 diabetes unmasked or discovered during pregnancy. As the incidence of type 2

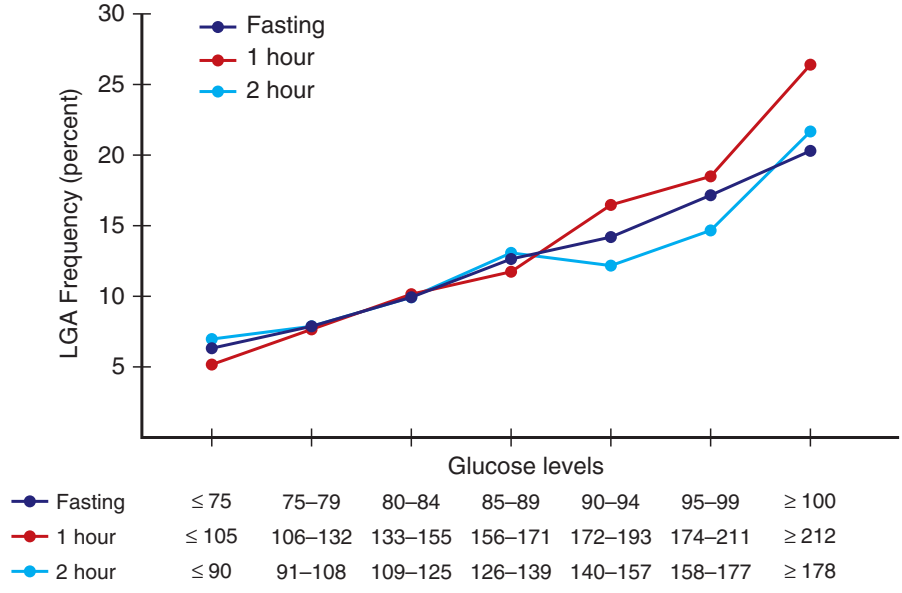

FIGURE 52-2 Hyperglycemia and Adverse Pregnancy Outcome (HAPO) Study. The frequency of infant birthweight ≥ 90th percentile for gestational age plotted against glucose levels fasting and at 1- and 2-hr intervals following a 75-g oral glucose load. LGA = large for gestational age. (Adapted from The HAPO Study Cooperative Research Group: Hyperglycemia and adverse pregnancy outcomes. *N Engl J Med* 358(19):1991–2002, with permission. Copyright © 2008 Massachusetts Medical Society. All rights reserved.)

diabetes accrues with age and is unmasked by other diabetogenic factors, that is, obesity, it is likely that *both* pregnancy aggravation and impending insulinopenia are involved. For example, Harris (1988) found that the prevalence of undiagnosed glucose intolerance in nonpregnant women between ages 20 and 44 years was virtually identical to the prevalence of gestational diabetes. Catalano and associates (1999) compared longitudinal changes in insulin sensitivity, insulin response, and endogenous glucose production in women who had normal glucose tolerance with changes identified in women with gestational diabetes. The latter women had abnormalities in glucose metabolism that are hallmarks of type 2 diabetes.

Use of the diagnostic term *gestational diabetes* has been encouraged to communicate the need for increased surveillance and to stimulate women to seek care for further testing postpartum. The likelihood of fetal death with appropriately treated gestational diabetes is not different than in the general population (Metzger and Coustan, 1998). The most important perinatal concern is excessive fetal growth, which may result in both maternal and fetal birth trauma. *More than half of women with gestational diabetes ultimately develop overt diabetes in the ensuing 20 years, and there is mounting evidence for long-range complications that include obesity and diabetes in their offspring.*

Maternal and Fetal Effects

There is an important difference concerning adverse fetal consequences of gestational diabetes. Unlike in women with overt diabetes, fetal anomalies are not increased (Sheffield and colleagues, 2002). Similarly, whereas pregnancies in women with overt diabetes are at greater risk for fetal death, this danger is not apparent for those who have diet-treated postprandial hyperglycemia (Lucas and co-workers, 1993; Sheffield and associates, 2002).

In contrast, women with *elevated* fasting glucose levels have increased rates of unexplained stillbirths similar to women with pregestational diabetes (Johnstone and colleagues, 1990). Specifically, the American Diabetes Association (1999a) has concluded that fasting hyperglycemia $>$ 105 mg/dL may be associated with an increased risk of fetal death during the last 4 to 8 weeks of gestation. Adverse maternal effects include an increased frequency of hypertension and cesarean delivery.

Macrosomia

Excessive fetal size can be problematic, and macrosomia is defined variably by different authors. The American College of Obstetricians and Gynecologists (2000) defines macrosomic infants as those whose birthweight exceeds 4500 g. Approximately a third of women delivered of such infants give birth to another in their next pregnancy (Mahony and associates, 2006). The perinatal goal is avoidance of difficult delivery due to macrosomia, with concomitant birth trauma associated with shoulder dystocia. Except for the brain, most fetal organs are affected by the macrosomia that commonly characterizes the fetus of a diabetic woman.

Macrosomic infants of diabetic mothers are described as anthropometrically different from other large-for-gestational age infants (Durnwald and colleagues, 2004; McFarland and associates, 2000). Specifically, those whose mothers are diabetic have excessive fat deposition on the shoulders and trunk, which predisposes them to shoulder dystocia or cesarean delivery (Fig. 52-3). Fortunately, shoulder dystocia is uncommon, even in women with gestational diabetes. For example, Magee and coworkers (1993) diagnosed shoulder dystocia in 3 percent of women with class A_1 diabetes. None of these infants sustained brachial plexus injuries.

FIGURE 52-3 This 6050-g macrosomic infant was born to a woman with gestational diabetes.

Maternal hyperglycemia prompts fetal hyperinsulinemia particularly during the second half of gestation, which in turn stimulates excessive somatic growth. Macrosomia results. Similarly, neonatal hyperinsulinemia may provoke hypoglycemia within minutes of birth. The incidence varies greatly depending on the threshold used to define significant neonatal hypoglycemia. For example, the American Diabetes Association (1995) defines values $<$ 35 mg/dL as abnormal in a term infant and lower values for preterm infants because glycogen stores are less. Infants described by the HAPO Study Cooperative Research Group (2008) had an incidence of clinical neonatal hypoglycemia that increased with increasing maternal OGTT values defined in Figure 52-2. The frequency varied from 1 to 2 percent, but was as high as 4.6 percent in women with fasting glucose levels $\geq$ 100 mg/dL. Likewise, cord-blood insulin levels are related to maternal glucose control (Leipold and colleagues, 2004).

There is extensive evidence that insulin-like growth factors I (IGF-I) and II (IGF-II) also play a role in the regulation of fetal growth (see Chap. 38, p. 842). These growth factors, which structurally are proinsulin-like polypeptides, are produced by virtually all fetal organs and are potent stimulators of cell differentiation and division. Verhaeghe and co-workers (1993) measured cord IGFs and insulin (C-peptide) concentrations throughout gestation in women without diabetes and found that levels correlated with birthweight. Large-for-gestational age infants had significantly increased levels of these factors. The HAPO investigators also reported dramatic increases of cord serum C-peptide levels with increasing maternal glucose levels following a 75-g OGTT. Levels > 90th percentile were found in almost a third of newborns in the highest glucose categories. Other factors implicated in macrosomia include epidermal growth factor, leptin, and adiponectin (Loukovaara, 2004; Mazaki-Tovi, 2005; Okereke, 2002, and all their colleagues).

Maternal obesity is an independent and more important risk factor for large infants in women with gestational diabetes than is glucose intolerance (Ehrenberg and colleagues, 2004; Lucas and associates, 1993). Moreover, maternal obesity is an important confounding factor in the diagnosis of gestational diabetes. Johnson and co-workers (1987) reported that 8 percent of 588 women who weighed more than 250 pounds had gestational diabetes compared with less than 1 percent of women who weighed less than 200 pounds. Weight distribution also seems to play a role because Landon (1994) and Zhang (1995) and their colleagues found that the risk of gestational diabetes was increased with truncal obesity.

Management

Women with gestational diabetes can be divided into two functional classes using fasting glucose levels. Insulin therapy is usually recommended when standard dietary management does not consistently maintain the fasting plasma glucose at < 95 mg/dL or the 2-hour postprandial plasma glucose < 120 mg/dL (American College of Obstetricians and Gynecologists, 2001). Whether insulin should be used in women with lesser degrees of fasting hyperglycemia—105 mg/dL or less before dietary intervention—is unclear because there have been no controlled trials to identify ideal glycemia targets for prevention of fetal risks. The Fifth International Workshop Conference on Gestational Diabetes, however, recommended that maternal capillary glucose levels be kept ≤ 95 mg/dL in the fasting state (Metzger and colleagues, 2007).

Diet. As discussed previously, recent reports by Crowther and colleagues (2005) and Landon and associates (2009) describe the benefits of dietary counseling and monitoring in women with gestational diabetes. The American Diabetes Association (ADA) (2000) has recommended nutritional counseling with individualization based on height and weight and a diet that provides an average of 30 kcal/kg/d based on prepregnant body weight for nonobese women. Although the most appropriate diet for women with gestational diabetes has not been established, the ADA has suggested that obese women with a body mass index (BMI) > 30 kg/m^2 may benefit from a 30-percent caloric restriction. This should be monitored with weekly tests for ketonuria, because maternal ketonemia has been linked with impaired psychomotor development in offspring (Rizzo and co-workers, 1995). That said, Langer and colleagues (2005a, b) found that insulin was necessary to achieve glucose control in obese women.

Exercise. Because exercise is known to be important in nonpregnant patients, the American College of Obstetricians and Gynecologists (2001) reviewed three randomized trials of exercise in women with gestational diabetes (Avery, 1997; Bung, 1993; Jovanovic-Peterson, 1989, and all their colleagues). The results suggested that exercise improved cardiorespiratory fitness without improving pregnancy outcome. Dempsey and co-workers (2004) found that physical activity during pregnancy reduced the risk of gestational diabetes. Brankston and associates (2004) reported that resistance exercise diminished the need for insulin therapy in overweight women with gestational diabetes.

Glucose Monitoring. Hawkins and colleagues (2009) compared outcomes in 315 women with diet-treated gestational diabetes who used personal glucose monitors with those of 615 gestational diabetics who were also diet-treated but who underwent intermittent fasting glucose evaluation during semiweekly obstetrical visits. Women using daily self blood-glucose monitoring had fewer macrosomic infants and gained less weight after diagnosis—median 0.56 compared with 0.74 pounds per week—than women evaluated during clinic visits only. These researchers' findings support the common practice of self blood-glucose monitors for women with gestational diabetes who are treated with diet alone.

Postprandial surveillance for gestational diabetes has been shown to be superior to preprandial surveillance. DeVeciana and colleagues (1995) studied 66 pregnant women with class A_2 diabetes in whom insulin was initiated for fasting hyperglycemia. The women were randomized to glucose surveillance using either preprandial or 1-hour postprandial capillary blood-glucose concentrations measured by glucometer. Postprandial surveillance was shown to be superior in that blood-glucose control was significantly improved and was associated with fewer cases of neonatal hypoglycemia—3 versus 21 percent, less macrosomia—12 versus 42 percent, and fewer cesarean deliveries for dystocia—24 versus 39 percent.

Insulin. Insulin given to decrease complications related to macrosomia in women with gestational diabetes and fasting euglycemia has long been controversial. Langer and co-workers (1994) reviewed 23 reports from 1979 through 1993 and found that none demonstrated improved perinatal outcomes related to any management approach, including prophylactic insulin treatment. Four randomized studies reported between 1989 and 2001 showed that intensive therapy had little effect on birthweight, birth trauma, operative delivery, or neonatal complications (Garner, 1997; Kjos, 2001; Nordlander, 1989; Thompson, 1990, and all their associates).

Most practitioners—93 percent according to Owen and colleagues (1995)—initiate insulin therapy in women with gestational diabetes if fasting glucose levels exceeding 105 mg/dL persist despite diet therapy. At Parkland Hospital, this is accomplished in a specialized outpatient clinic, but occasionally

hospitalization is necessary. Experts differ in their approach to insulin therapy in gestational diabetes. A total dose of 20 to 30 units given once daily, before breakfast, is commonly used to initiate therapy. The total dose is usually divided into two-thirds intermediate-acting insulin and a third short-acting insulin. Alternatively, weight-based split-dose insulin is administered twice daily. Once therapy has been initiated, it must be recognized that the level of glycemic control to reduce fetal and neonatal complications has not been established.

Oral Hypoglycemic Agents. The American College of Obstetricians and Gynecologists (2001) has not recommended these agents during pregnancy. Langer and colleagues (2000, 2005a) randomized 404 women with gestational diabetes to *insulin versus glyburide* therapy. Near normoglycemic levels were achieved equally well with either regimen, and there were no apparent neonatal complications attributable to glyburide. In a follow-up study, Conway and co-workers (2004) reported that women with fasting glucose levels > 110 mg/dL did not adequately respond to glyburide therapy. Similar results were reported by Chmait (2004) and Kahn (2006) and their associates. Until recently, glyburide was thought not to cross the placenta. Hebert and colleagues (2008), however, sampled 20 paired maternal and umbilical specimens and found umbilical cord concentrations were half that of maternal concentrations in women treated with glyburide.

There is increasing support for the use of glyburide as an alternative to insulin in the management of gestational diabetes (Durnwald and Landon, 2005; Saade, 2005). A survey of almost 1400 fellows of the American College of Obstetricians and Gynecologists found that 13 percent of respondents were using glyburide as first-line therapy for diet failure with gestational diabetes (Gabbe and co-workers, 2004). Further evidence of expanding use of glyburide was provided by Kremer (2004) and Jacobson (2005) and their colleagues. They reported retrospective studies of glyburide as an alternative to insulin in a combined total of 309 women who failed diet therapy. Most of these women required daily glyburide doses < 7.5 mg to achieve glucose control (**Table 52-5**). Hypoglycemia was reported to be less frequent when glyburide was compared with insulin (Yogev and co-workers, 2004). In a recent meta-analysis, Moretti and associates (2008) reported no increased perinatal risks with glyburide therapy and recommended further randomized trials.

TABLE 52-5. Glyburide Treatment Regimen for Women with Gestational Diabetes Who Fail Diet Therapy

1. Glucometer blood glucose measurements fasting and 1 or 2 hours following breakfast, lunch, and dinner.
2. Glucose level goals (mg/dL): Fasting < 100, 1-h < 155, and 2-h < 130.
3. Glyburide starting dose 2.5 mg orally with morning meal.
4. If necessary, increase daily glyburide dose by 2.5-mg/wk increments until 10 mg/d, then switch to twice-daily dosing until maximum of 20 mg/d reached. Switch to insulin if 20 mg/d does not achieve glucose goals.

Adapted from Jacobson and colleagues (2005).

Metformin has been used as treatment for polycystic ovarian disease and has been reported to reduce the incidence of gestational diabetes in women who use the drug throughout pregnancy (Glueck and colleagues, 2004). Even so, it is usually recommended that metformin be discontinued once pregnancy is diagnosed because it is long known to reach the fetus (Harborne and associates, 2003). The Fifth International Workshop Conference recommended that metformin treatment for gestational diabetes be limited to clinical trials with long-term infant follow-up (Metzger and co-workers, 2007).

Subsequently, Rowan and colleagues (2008) reported results of a study in which they randomized 751 women with gestational diabetes to metformin or insulin treatment. The primary outcome was a composite of one or more of neonatal hypoglycemia, respiratory distress, phototherapy, birth trauma, 5-minute Apgar score of 7 or less, and preterm birth. Similarities in the composite outcome between metformin and insulin led the investigators to conclude that metformin was not associated with increased perinatal complications. As expected, women preferred metformin to insulin treatment. It is noteworthy that 46 percent of women in the metformin trial required supplemental insulin compared with only 4 percent of women treated with glyburide by Langer and colleagues (2000).

Obstetrical Management

In general, women with gestational diabetes who do not require insulin seldom require early delivery or other interventions. Elective cesarean delivery to avoid brachial plexus injuries in macrosomic infants is an important issue. The American College of Obstetricians and Gynecologists (2001) has suggested that cesarean delivery should be considered in women with a sonographically estimated fetal weight ≥ 4500 g. Effects of such a policy were retrospectively analyzed by Gonen and colleagues (2000) in a general obstetrical population of more than 16,000 women. *Elective cesarean delivery had no significant effect on the incidence of brachial plexus injury.*

Elective induction to prevent shoulder dystocia in women with sonographically diagnosed fetal macrosomia, compared with spontaneous labor, is also controversial. Conway and Langer (1996) found that elective delivery reduced the rate of shoulder dystocia from 2.2 to 0.7 percent. In contrast, Combs and colleagues (1993b) and Adasheck (1996) and their associates reported no advantages. Chauhan and co-workers (2005) reviewed the literature and concluded that sonographic suspicion of macrosomia was too inaccurate to recommend induction or primary cesarean delivery without a trial of labor.

There is no consensus regarding whether antepartum fetal testing is necessary, and if so, when to begin such testing in women without severe hyperglycemia (American College of Obstetricians and Gynecologists, 2001; Metzger and associates,

TABLE 52-6. Fifth International Workshop-Conference: Metabolic Assessments Recommended after Pregnancy with Gestational Diabetes

Time	Test	Purpose
Postdelivery (1–3 d)	Fasting or random plasma glucose	Detect persistent, overt diabetes
Early postpartum (6–12 wks)	75-g 2-h OGTT	Postpartum classification of glucose metabolism
1 yr postpartum	75-g 2-h OGTT	Assess glucose metabolism
Annually	Fasting plasma glucose	Assess glucose metabolism
Tri-annually	75-g 2-h OGTT	Assess glucose metabolism
Prepregnancy	75-g 2-h OGTT	Classify glucose metabolism

Classification of the American Diabetes Association (2003)

Normal	Impaired Fasting Glucose or Impaired Glucose Tolerance	Diabetes Mellitus
Fasting < 110 mg/dL	110–125 mg/dL	≥ 126 mg/dL
2 hr < 140 mg/dL	2 hr ≥ 140–199 mg/dL	2 hr ≥ 200 mg/dL

Copyright © 2007 American Diabetes Association. From Diabetes Care®, Vol. 30; 2007, S251–S260. Reprinted with permission from The American Diabetes Association.

2007). This is because of the low risk of fetal death with gestational diabetes. Those women who require insulin therapy for fasting hyperglycemia, however, typically undergo fetal testing and are managed as if they had overt diabetes.

Postpartum Evaluation

The Fifth International Workshop Conference on Gestational Diabetes recommended that women diagnosed with gestational diabetes undergo evaluation with a 75-g oral glucose tolerance test at 6 to 12 weeks postpartum and other intervals thereafter (Metzger and associates, 2007). These recommendations are shown in Table 52-6 along with the classification scheme of the American Diabetes Association (2003).

Although postpartum follow-up of women diagnosed with gestational diabetes was recommended throughout the 1990s, reports on compliance have only recently become available. Smirnakis and co-workers (2005) reviewed electronic medical records in 197 women diagnosed with gestational diabetes in 2000 and 2001 and found that only 37 percent underwent postpartum screening tests. In a more recent study, Almario and colleagues (2008) reported a 33-percent compliance rate at an academic medical center. At Parkland Hospital, after discharge, women with insulin-treated gestational diabetes undergo evaluation of fasting plasma glucose at 2 and 6 weeks postpartum.

Recommendations for postpartum follow-up are based on the 50-percent likelihood of women with gestational diabetes developing overt diabetes within 20 years (O'Sullivan, 1982). If fasting hyperglycemia develops during pregnancy, then diabetes is more likely to persist postpartum. For example, in women with fasting glucose levels of 105 to 130 mg/dL, 43 percent were found to be overtly diabetic (Metzger and associates, 1985). When fasting glucose exceeded 130 mg/dL during pregnancy, 86 percent became overtly diabetic. Likewise, insulin therapy during pregnancy, and especially before 24 weeks, is a powerful predictor of persistent diabetes (Dacus and co-workers, 1994; Greenberg and colleagues, 1995).

Women with a history of gestational diabetes are also at risk for cardiovascular complications associated with dyslipidemia, hypertension, and abdominal obesity—the *metabolic syndrome* (see Chap. 43, p. 947). Pallardo and colleagues (1999) evaluated cardiovascular disease risk factors 3 to 6 months' postpartum in 788 women with gestational diabetes. They found that the degree of postpartum glucose intolerance was significantly associated with these risk factors. A recent Canadian study by Shah and co-workers (2008) documented excessive cardiovascular disease even by 10 years in these women compared with nondiabetic controls. Finally, Akinci and associates (2009) reported that a fasting glucose level ≥ 100 mg/dL with the index OGTT was an independent predictor of the metabolic syndrome.

Recurrence of gestational diabetes in subsequent pregnancies was documented in 40 percent of 344 primiparous women analyzed by Holmes and colleagues (2003). Obese women were more likely to have impaired glucose tolerance in subsequent pregnancies. Thus, lifestyle behavioral changes, including weight control and exercise between pregnancies, likely would prevent recurrence of gestational diabetes as well as modify onset and severity of type 2 diabetes later in life (Kim and co-workers, 2008; Pan and associates, 1997). Interestingly, perinatal outcomes in women with previous gestational diabetes but with normal glucose tolerance tests during a subsequent pregnancy were not improved with regard to birthweight, macrosomia, route of delivery, and neonatal complications (Danilenko-Dixon and colleagues, 2000). Finally, Lu and co-workers (2002) found that women *without* gestational diabetes in their first pregnancy were unlikely to have gestational diabetes when screened in a second pregnancy.

Contraception

Low-dose hormonal contraceptives may be used safely by women with recent gestational diabetes (see Chap. 32, p. 678). The rate of subsequent diabetes in oral contraceptive users is not significantly different from that in those who did not use hormonal contraception (Kjos and colleagues, 1990a).

TABLE 52-7. Pregnancy Outcomes of Births in Nova Scotia from 1988 to 2002 in Women with and without Pregestational Diabetes

Factor	Diabetic (n = 516) Percent	Nondiabetic (n = 150,589) Percent	*p* value
Gestational hypertension	28	9	< .001
Preterm birth	28	5	< .001
Macrosomia	45	13	< .001
Fetal-growth restriction	5	10	< .001
Stillbirths	1.0	0.4	.06
Perinatal deaths	1.7	0.6	.004

Adapted from Yang and colleagues (2006).

Gestational Diabetes at Parkland Hospital

Prior to 1997, selective glucose screening was employed. For women with risk factors, a standard 50-g oral glucose tolerance test was performed between 24 and 28 weeks without regard to recent meal status. For screen-positive women, the standard 100-g 3-hour OGTT was used. Women identified with diet-treated gestational diabetes were seen weekly in a specific clinic designed to provide dietary counseling. Fasting plasma-glucose measurements were obtained at each visit. Women without other complications such as hypertension or postterm gestation were permitted to enter spontaneous labor, and antepartum testing was not used. Women identified with insulin-treated gestational diabetes were managed as overt diabetics, as described later.

Beginning in 1997, women at high risk for gestational diabetes underwent immediate glucose screening at their first prenatal clinic visit. All other women without risk factors underwent universal screening at 24 to 28 weeks using a standard 1-hour, 50-g oral glucose challenge test. Obstetrical management practices previously used during selective screening were continued. Casey and colleagues (1999) found that obstetrical outcomes attributable to the diagnosis of gestational diabetes were not different after the change in screening. In a subsequent analysis, Hawkins and associates (2008) found that women with diet-treated gestational diabetes identified during early pregnancy with risk-based screening had an increased risk for preeclampsia, shoulder dystocia, and macrosomic infants compared with women identified using universal screening at 24 to 28 weeks' gestation.

PREGESTATIONAL DIABETES

It is unquestioned that pregestational—or overt—diabetes has a significant impact on pregnancy outcome. The embryo, the fetus, and the mother commonly experience serious complications directly attributable to diabetes. The likelihood of successful outcomes with overt diabetes is related somewhat to the degree of glycemic control, but more importantly, to the degree of underlying cardiovascular or renal disease. Therefore, as the alphabetical classification shown in Table 52-2 worsens, the likelihood of good pregnancy outcomes lessens.

Yang and associates (2006) chronicled the effects of overt diabetes on pregnancy outcomes in Nova Scotia from 1998 through 2002. They compared outcomes in 516 overtly diabetic women with those of 150,589 pregnancies in nondiabetic women. As shown in Table 52-7, women with diabetes experienced significantly worse pregnancy outcomes. The incidence of chronic and gestational hypertension—and especially preeclampsia—are remarkably increased. As shown in Figure 52-4, women with type 1 diabetes who are in the more advanced white classes of overt diabetes increasingly developed preeclampsia. Similar results have been reported for the United Kingdom and Australia (MacIntosh and colleagues, 2006; Shand and co-workers, 2008).

Fetal Effects

Improved fetal surveillance, neonatal intensive care, and maternal metabolic control have reduced perinatal losses with overt diabetes to 2 to 4 percent. From Edinburgh, Johnstone and colleagues (2006) assessed pregnancy outcomes in women with type 1 diabetes and reported a dramatic reduction in perinatal mortality rates—from 22 percent in the 1960s to 1 percent in the 1990s—but no change in fetal overgrowth. One reason that perinatal mortality rates have seemingly plateaued is that the two major causes of fetal death—congenital malformations and

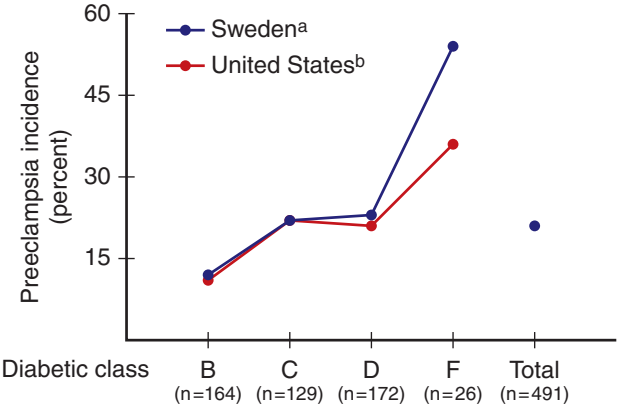

FIGURE 52-4 Incidence of preeclampsia in 491 type 1 diabetic women in Sweden and the United States reported by the National Institute of Child Health and Human Development Maternal-Fetal Medicine Units Network. (Data from Hanson and Persson, 1993; Sibai and colleagues, 2000.)

unexplained fetal death—remain unchanged by medical intervention (Garner, 1995a).

Miscarriage

Several studies have shown that early abortion is associated with poor glycemic control (Greene and co-workers, 1989; Mills and associates, 1988a). In 215 women with type 1 diabetes enrolled for prenatal care before 9 weeks, 24 percent had a miscarriage (Rosenn and colleagues, 1994). Only those whose initial glycohemoglobin A1c concentrations were > 12 percent or whose persistent preprandial glucose concentrations were > 120 mg/dL were at increased risk (see also Chap. 9, p. 226).

Preterm Delivery

Overt diabetes is an undisputed risk factor for preterm birth. The Maternal-Fetal Medicine Units Network analyzed pregnancy outcomes in 461 such women (Sibai and associates, 2000). Almost 9 percent of these women spontaneously delivered before 35 weeks compared with 4.5 percent of nondiabetic women. Moreover, another 7 percent of diabetic women underwent indicated preterm delivery compared with 2 percent of nondiabetic women. In the Canadian study shown in Table 52-7, the incidence of preterm birth was 28 percent—a fivefold increase compared with that of their normal population.

Malformations

The incidence of major malformations in women with type 1 diabetes is approximately 5 percent (Sheffield and co-workers, 2002). These account for almost half of perinatal deaths in diabetic pregnancies. Specific types of anomalies linked to maternal diabetes and their relative incidence are summarized in Table 52-8. *Diabetes is not associated with increased risk for fetal chromosomal abnormalities.*

TABLE 52-8. Congenital Malformations in Infants of Women with Overt Diabetes

Anomaly	Ratios of Incidence[a]
Caudal regression	252
Situs inversus	84
Spina bifida, hydrocephaly, or other central nervous system defects	2
Anencephaly	3
Cardiac anomalies	4
Anal/rectal atresia	3
Renal anomalies	5
Agenesis	4
Cystic kidney	4
Duplex ureter	23

[a]Ratio of incidence is in comparison with the general population. Cardiac anomalies include transposition of the great vessels and ventricular or atrial septal defects. Adapted from Mills and colleagues (1979) and the American Diabetes Association (1995).

It is generally believed that the increased risk of severe malformations is the consequence of poorly controlled diabetes, both preconceptionally and early in pregnancy. Eriksson (2009) concluded that the etiology was multifactorial. One proposed mechanism for cardiac defects is that of hyperglycemia-induced oxidative stress that inhibits expression of cardiac neural crest migration (Morgan and associates, 2008). Miller and co-workers (1981) suggested that women with lower glycosylated hemoglobin values at the time of conception had fewer fetuses with anomalies compared with women with abnormally high values. The Diabetes in Early Pregnancy Study did not totally corroborate these findings. Specifically, Mills and colleagues (1988b) enrolled more than 600 diabetic women in this investigation, and they concluded that a normal glycosylated hemoglobin distribution did not guarantee avoidance of all diabetes-associated anomalies. Conversely, not all women with elevated levels had poor outcomes. It appeared, however, that women in whom periconceptional glucose control was optimized had a 5-percent fetal malformation rate compared with a 9-percent rate in the group who presented after organogenesis was completed. Ray and co-workers (2001) performed a meta-analysis of seven studies addressing preconceptional care published between 1970 and 2000. They concluded that such care was associated with a lower risk of congenital anomalies, and this was further linked to lower glycosylated hemoglobin values (see Chap. 7, p. 175).

Altered Fetal Growth

The incidence of macrosomia rises significantly when mean maternal blood glucose concentrations exceed 130 mg/dL (Willman and co-workers, 1986). Some authors have objected to classification of these infants as either "macrosomic" or "nonmacrosomic," because this ignores the observation that virtually all are *growth promoted* (Bradley and associates, 1988). This is discussed further in Chapter 38 (p. 853). As shown in Figure 52-5, the birthweight distribution of infants of diabetic mothers is skewed toward consistently heavier birthweights compared with that of normal pregnancies. In contrast, fetal-growth restriction in women with diabetes may be seen and may be related to substrate deprivation from advanced maternal vascular disease or to congenital malformations.

Landon and co-workers (1989) performed serial sonographic examinations during the third trimester in 79 women with diabetes and observed that excessive fetal abdominal circumference growth was detectable by 32 weeks (Fig. 52-6). Ben-Haroush and colleagues (2007) analyzed fetal sonographic measurements between 29 and 34 weeks in 423 diabetic pregnancies and found that accelerated fetal growth was particularly evident in women with poor glycemic control.

Unexplained Fetal Demise

Stillbirths without identifiable causes are a phenomenon relatively unique to pregnancies complicated by overt diabetes. They are "unexplained" because factors such as obvious placental insufficiency, abruption, fetal-growth restriction, or oligohydramnios are not apparent. These infants are typically large-for-gestational age and die before labor, usually at 35 weeks or later (Garner, 1995b). Studies employing cordocentesis have

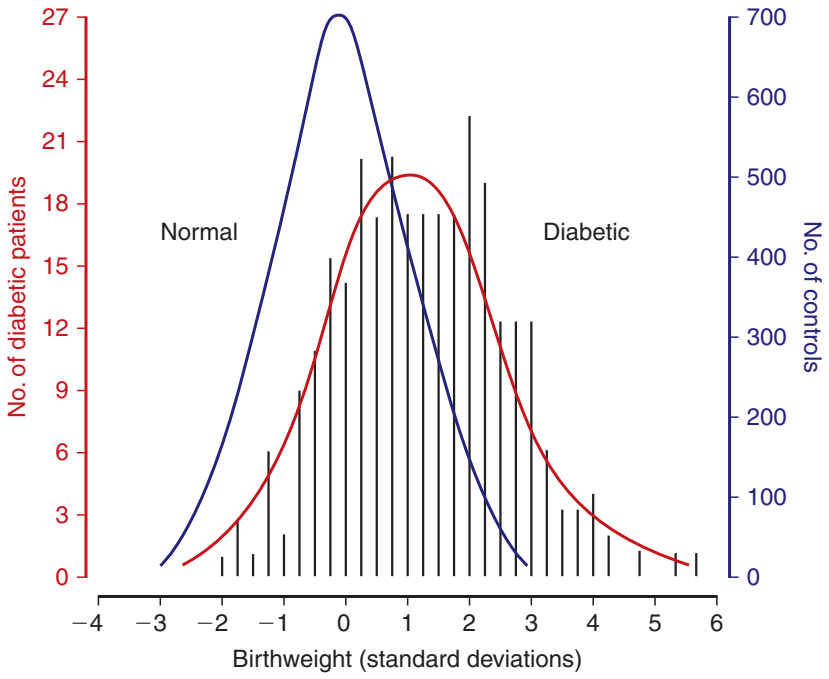

FIGURE 52-5 Distribution of birthweights—standard deviation from the normal mean for gestational age—for 280 infants of diabetic mothers and 3959 infants of nondiabetic mothers. (From Bradley and co-workers, 1988; redrawn from *British Medical Journal*, 1988, Vol. 297, No. 6663, pp. 1583–1584, with permission from the BMJ Publishing Group.)

provided some insights into acid-base metabolism in fetuses of diabetic women. Salvesen and colleagues (1992, 1993) reported decreased pH and increased P_{CO_2}, lactate, and erythropoietin levels in some of these fetuses. Such findings lend credence to the long-held hypothesis that hyperglycemia-mediated chronic aberrations in transport of oxygen and fetal metabolites may account for unexplained fetal deaths (Pedersen, 1977).

Two observations also lend some insight into these deaths. Richey and co-workers (1995) at Parkland Hospital were at the bedsides of two diabetic women whose pregnancies were complicated by a macrosomic fetus and hydramnios. Otherwise unexplained fetal deaths were seemingly in progress. In both of these rare clinical instances, both fetuses were acidemic before labor, and both placentas were hydropic due to edema of the chorionic villi. These features were linked to maternal hyperglycemia, and it was hypothesized that osmotically induced villous edema led to impaired fetal oxygen transport. The observations of Daskalakis and associates (2008), who found microscopic evidence of placental dysfunction in 40 consecutive placentas from pregnancies in women with gestational diabetes, also corroborate this hypothesis.

Explicable stillbirths due to placental insufficiency also occur with increased frequency in women with overt diabetes, usually in association with severe preeclampsia. This, in turn, is increased in women with advanced diabetes and vascular complications. Similarly, ketoacidosis can cause fetal death.

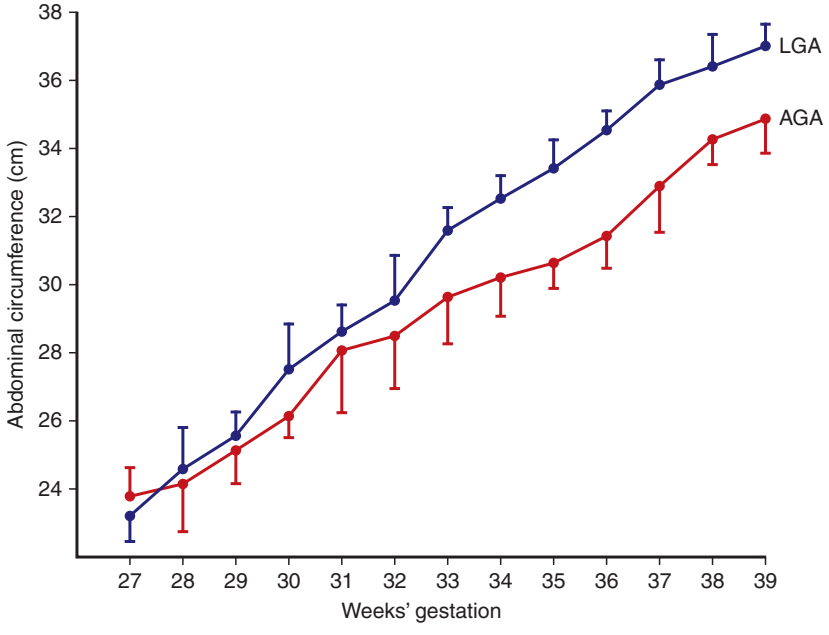

FIGURE 52-6 Comparison of abdominal circumference growth curve for appropriate-for-gestational age (AGA) and large-for-gestational age (LGA) fetuses of diabetic mothers. Growth is accelerated at 32 weeks in the LGA group. (This figure was published in *American Journal of Obstetrics & Gynecology*, Vol. 160, No. 1, MB Landon, MC Mintz, and SG Gabbe, Sonographic evaluation of fetal abdominal growth: Predictor of the large-for-gestational-age infant in pregnancies complicated by diabetes mellitus, pp. 115–121, Copyright Elsevier 1989.)

Hydramnios

Although diabetic pregnancies are often complicated by hydramnios, the cause is unclear. A likely—albeit unproven—explanation is that fetal hyperglycemia causes polyuria (see Chap. 21, p. 493). In a study from Parkland Hospital, Dashe and co-workers (2000) found that the amnionic fluid index parallels the amnionic fluid glucose level among women with diabetes. This finding suggests that the hydramnios associated with diabetes is a result of increased amnionic fluid glucose concentration. Further support for this hypothesis was provided by Vink and colleagues (2006), who linked poor maternal glucose control to macrosomia and hydramnios.

Neonatal Mortality and Morbidity

Before tests of fetal health and maturity became available, preterm delivery was deliberately effected to avoid unexplained fetal deaths. Although this practice has been abandoned, there is still an increased frequency of preterm delivery in women with diabetes (see Table 52-7). Most preterm

births are associated with advanced diabetes and superimposed preeclampsia.

Modern neonatal care has largely eliminated neonatal deaths due to immaturity. More than 15 years ago, Cnattingius and colleagues (1994) reported only one neonatal death due to immaturity in 914 singleton births to overtly diabetic women. Conversely, neonatal *morbidity* due to preterm birth continues to be a serious consequence. Indeed, some of the morbidities in these infants are considered to be uniquely related to aberrations in maternal glucose metabolism.

Respiratory Distress Syndrome

Conventional obstetrical teaching through the late 1980s generally held that fetal lung maturation was delayed in diabetic pregnancies (see Chap. 29, p. 607). Thus, it was taught that these infants were at increased risk for respiratory distress (Gluck and Kulovich, 1973). Subsequent observations have challenged this concept, and gestational age rather than overt diabetes is likely the most significant associated factor with respiratory distress (Berkowitz and colleagues, 1996; Kjos and associates, 1990b).

Hypoglycemia

A rapid decrease in plasma glucose concentration after delivery is characteristic of the infant of a diabetic mother. This is attributed to hyperplasia of the fetal β-islet cells induced by chronic maternal hyperglycemia. Taylor and associates (2002) found that neonatal hypoglycemia—blood glucose levels < 45 mg/dL before the second feeding—was related to maternal blood glucose levels > 145 mg/dL during labor. Prompt recognition and treatment of the hypoglycemic infant has minimized adverse sequelae.

Hypocalcemia

Defined as a total serum calcium concentration < 8 mg/dL in term infants, hypocalcemia is one of the major metabolic derangements in infants of diabetic mothers. Its cause has not been explained. Theories include aberrations in magnesium– calcium economy, asphyxia, and preterm birth (Cruikshank and co-workers, 1980). In the randomized study by DeMarini and colleagues (1994), 137 pregnant women with type 1 diabetes were managed with strict versus customary glucose control. Almost a third of infants in the customary control group developed hypocalcemia compared with only 18 percent of those in the strict control group. Gestational age and preeclampsia were also implicated.

Hyperbilirubinemia and Polycythemia

The pathogenesis of hyperbilirubinemia in infants of diabetic mothers is uncertain. Factors implicated have included preterm birth and polycythemia with hemolysis (see Chap. 29, p. 625). Venous hematocrits of 65 to 70 volume percent have been observed in up to 40 percent of these infants (Salvesen and associates, 1992). Renal vein thrombosis is also reported to result from polycythemia.

Cardiomyopathy

Infants of diabetic pregnancies may have hypertrophic cardiomyopathy that occasionally progresses to congestive heart failure (Gandhi and co-workers, 1995; Reller and Kaplan, 1988). These infants typically have macrosomia, and fetal hyperinsulinemia has been implicated in the pathogenesis of heart disease. Girsen and colleagues (2008) reported that 32 neonates born to women with type 1 diabetes had higher mean cord-blood levels of N-terminal proatrial natriuretic peptide (NT-proANP) and probrain natriuretic peptide (proBNP) compared with those of control infants. They also found that NT-proANP levels were higher in those fetuses of diabetic mothers whose glycemic control was poor. Way (1979) reported that the cardiomyopathy generally disappears by 6 months of age.

Long-Term Cognitive Development

Rizzo and colleagues (1995) used multiple tests of intelligence and psychomotor development to assess 196 children of diabetic women up to age 9 years. They concluded that maternal diabetes had a negligible impact on cognitive development.

Inheritance of Diabetes

Offspring born to women with overt diabetes have a 1- to 3-percent risk of developing type 1 diabetes (Garner, 1995a). The risk is 6 percent if only the father has diabetes. If both parents have type 1 diabetes, the risk is 20 percent. McKinney and associates (1999) studied 196 children with type 1 diabetes and found that older maternal age and maternal type 1 diabetes are important risk factors. Plagemann and colleagues (2002) have implicated breast feeding by diabetic mothers in the genesis of childhood diabetes.

Maternal Effects

Diabetes and pregnancy interact significantly such that maternal welfare can be seriously jeopardized. With the possible exception of diabetic retinopathy, however, the long-term course of diabetes is not affected by pregnancy.

Although maternal death is uncommon, rates in women with diabetes are still increased tenfold (Cousins, 1987). Deaths most often result from ketoacidosis, hypertension, preeclampsia, and pyelonephritis. Especially ominous is ischemic heart disease. Pombar and colleagues (1995) reviewed 17 women with coronary artery disease—class H diabetes—and reported that only half survived pregnancy.

Diabetic Nephropathy

Diabetes is the leading cause of end-stage renal disease in the United States (see Chap. 48, p. 1039). The incidence of renal failure is nearly 30 percent in individuals with type 1 diabetes and ranges from 4 to 20 percent in those with type 2 diabetes. Importantly, the incidence of nephropathy in individuals with type 1 diabetes declined during the 1980s, presumably from improved glucose control. Investigators for the Diabetes Control and Complications Trial (2002) reported that there was a 25-percent decrease in the rate of nephropathy for each 10-percent decrease in hemoglobin A1c levels.

Clinically detectable nephropathy in type 1 disease begins with microalbuminuria—30 to 300 mg/24 h of albumin. This may manifest as early as 5 years after the onset of diabetes

(Nathan, 1993). After another 5 to 10 years, overt proteinuria—more than 300 mg/24 h—develops in patients destined to have end-stage renal disease. Hypertension almost invariably develops during this period, and renal failure ensues typically in the next 5 to 10 years.

Approximately 5 percent of pregnant women with diabetes already have renal involvement—White class F (Hanson and Persson, 1993; Siddiqi and associates, 1991). Recall that as shown in Figure 52-4, these women are at significantly increased risk for preeclampsia and for indicated preterm delivery. Combs and co-workers (1993a) reported that 38 percent of 311 women with proteinuria > 500 mg/day before 20 weeks developed preeclampsia. They also found that women with microproteinuria—190 to 500 mg/d—had an increased risk of preeclampsia. Conversely, in an analysis of 460 women with classes B through F-R diabetes, How and colleagues (2004) found no association between preeclampsia and microproteinuria. However, chronic hypertension with diabetic nephropathy increased the risk of preeclampsia to 60 percent. Gordon and associates (1996) reported that chronic renal insufficiency and heavy proteinuria before 20 weeks were predictive of preeclampsia.

There appear to be no long-term sequelae of pregnancy on diabetic nephropathy. Chaturvedi and associates (1995) provided long-term follow-up studies in 1358 European women with type 1 diabetes, of whom 582 had been pregnant. The incidence of either micro- or macroalbuminuria was not increased in women with prior pregnancies compared with that of nulliparas. That said, renal involvement carries a guarded long-term prognosis for these women. Miodovnik and colleagues (1996) found that a fourth of 46 women with class F diabetes developed end-stage renal failure at a mean of 6 years after pregnancy. This is similar to pregnant women with nondiabetic glomerulopathies reported by Stettler and Cunningham (1992) and discussed in Chapter 48 (p. 1043).

Diabetic Retinopathy

Retinal vasculopathy is a highly specific complication of both type 1 and type 2 diabetes. Its prevalence is related to duration of diabetes. Almost 8 percent of persons with impaired glucose tolerance already have retinopathy, and 13 percent of those newly identified with diabetes in the Diabetes Prevention Project (2007) were already affected. In the United States, diabetic retinopathy is the most important cause of visual impairment in persons younger than age 60 years (Frank, 2004).

The first and most common visible lesions are small microaneurysms followed by blot hemorrhages that form when erythrocytes escape from the aneurysms. These areas leak serous fluid that creates hard exudates. Such features are termed *benign* or *background* or *nonproliferative retinopathy*. With increasingly severe retinopathy, the abnormal vessels of background eye disease become occluded, leading to retinal ischemia and infarctions that appear as *cotton wool exudates*. These are considered *preproliferative retinopathy*. In response to ischemia, there is neovascularization on the retinal surface and out into the vitreous cavity. Vision is obscured when there is hemorrhage. Laser photo coagulation before hemorrhage, as shown in **Figure 52-7**, reduces the rate of visual loss progression and blindness by half. The procedure is performed during pregnancy when indicated.

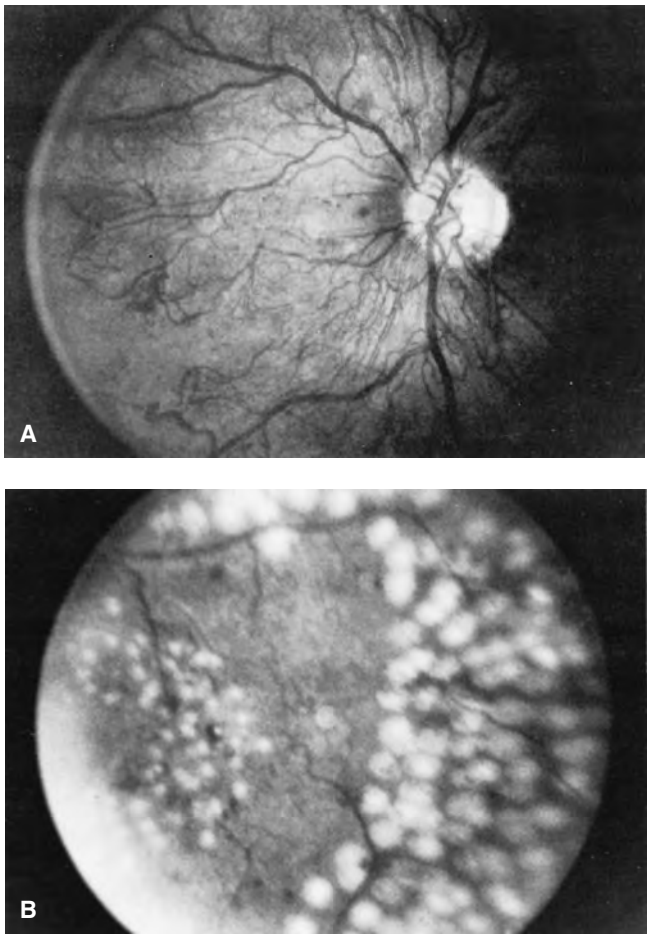

FIGURE 52-7 Retinal photographs from a 30-year-old diabetic woman. **A.** Optic nerve head showing severe proliferative retinopathy characterized by extensive networks of new vessels surrounding the optic disc. **B.** A portion of the acute photocoagulation full "scatter" pattern following argon laser treatment. (From Elman and colleagues, 1990, with permission.)

Siddiqi and colleagues (1991) reported that almost a third of 175 insulin-dependent pregnant women examined by 10 weeks had background retinal changes—class D, or proliferative retinopathy—class R. The effects of pregnancy on proliferative retinopathy are controversial (Garner, 1995a). It has been long taught that this complication is a rare example of a long-term adverse effect of pregnancy. Whereas Klein and co-workers (1990) concluded that pregnancy worsened proliferative retinopathy, Chaturvedi and associates (1995) found an equivalent prevalence of retinopathy in multiparous and nulliparous women. In a prospective postpartum 5-year follow-up of 59 type 1 diabetic women, Arun and Taylor (2008) confirmed that baseline retinopathy was the only independent risk factor for progression. Currently, most agree that laser photocoagulation and good glycemic control during pregnancy minimize the potential for deleterious effects of pregnancy.

Ironically, there are case reports that link "acute" rigorous metabolic control during pregnancy to acute worsening of retinopathy (Dahl-Jørgensen and co-workers, 1985; Van Ballegooie and associates, 1984). In a study of 201 women with retinopathy, McElvy and associates (2001) found that almost 30 percent suffered

progression of eye disease during pregnancy despite intensive glucose control. That said, Wang and co-workers (1993) have observed that retinopathy worsened during the critical months of rigorous glucose control, but in the longer term, deterioration of eye disease slowed. In the report by McElvy and co-workers (2001), progression of retinopathy was associated with reduced fetal growth. Lauszus and colleagues (1998), however, reported that proliferative retinopathy, per se, did not worsen perinatal outcome.

In a preliminary report, Kitzmiller and colleagues (1999) implicated insulin lispro, that is, short-acting insulin, in the development of proliferative retinopathy during pregnancy. Conversely, Buchbinder and associates (2000) found no evidence that such therapy was linked to the development or progression of diabetic retinopathy. Also, Durnwald and Landon (2008) reported no such complications with lispro insulin.

Diabetic Neuropathy

Peripheral symmetrical sensorimotor diabetic neuropathy is uncommon in pregnant women. But a form of this, known as *diabetic gastropathy*, is troublesome in pregnancy because it causes nausea and vomiting, nutritional problems, and difficulty with glucose control. Treatment with metoclopramide and H_2-receptor antagonists is sometimes successful. *Hyperemesis gravidarum* is further discussed in Chapter 49 (p. 1050).

Preeclampsia

Hypertension that is induced or exacerbated by pregnancy is the major complication that most often forces preterm delivery in diabetic women. According to Garner (1995a), the perinatal mortality rate is increased 20-fold for preeclamptic women with diabetes compared with that for those who remain normotensive. Special risk factors for preeclampsia include any vascular complications and preexisting proteinuria, with or without chronic hypertension. Referring back to Figure 52-4, the risk of preeclampsia is 11 to 12 percent in class B, 21 to 22 percent in class C, 21 to 23 percent in class D, and 36 to 54 percent in classes F-R. Savvidou and colleagues (2002) described impaired vascular reactivity in pregnant women with type 1 diabetes. Temple and co-workers (2006) prospectively studied HbA1c levels at 24 weeks in 290 women with type 1 diabetes and found that preeclampsia was related to glucose control. Management of preeclampsia is discussed in Chapter 34 (p. 728).

Diabetic Ketoacidosis

Although it affects only approximately 1 percent of diabetic pregnancies, ketoacidosis remains one of the most serious complications (Garner, 1995a). It is unique to type 1 diabetes, and it may develop with hyperemesis gravidarum, β-mimetic drugs given for tocolysis, infection, and corticosteroids given to induce fetal lung maturation. Kent and colleagues (1994) found that only half of young women with recurrent ketoacidosis had successful pregnancies compared with 95 percent of women without ketoacidosis.

The incidence of fetal loss is about 20 percent with ketoacidosis. Noncompliance is a prominent factor, and this and ketoacidosis have long been considered prognostically bad signs in pregnancy (Pedersen and co-workers, 1974). Pregnant women usually have ketoacidosis with lower blood glucose levels than when nonpregnant. In a study from China, the mean glucose level for pregnant women with DKA was 293 mg/dL compared with 495 mg/dL for nonpregnant women (Guo and co-workers, 2008). These investigators described one woman whose plasma glucose was only 124 mg/dL. Chico and associates (2008) reported ketoacidosis in a pregnant woman whose plasma glucose was only 87 mg/dL! A management protocol is shown in Table 52-9.

TABLE 52-9. Protocol Recommended by the American College of Obstetricians and Gynecologists (2005) for Management of Diabetic Ketoacidosis During Pregnancy

Laboratory assessment
Obtain arterial blood gases to document degree of acidosis present; measure glucose, ketones, and electrolyte levels at 1- to 2-hour intervals

Insulin
Low-dose, intravenous
Loading dose: 0.2–0.4 U/kg
Maintenance: 2–10 U/h

Fluids
Isotonic sodium chloride
Total replacement in first 12 hours of 4–6 L
1 L in first hour
500–1000 mL/h for 2–4 hours
250 mL/h until 80 percent replaced

Glucose
Begin 5-percent dextrose in normal saline when glucose plasma level reaches 250 mg/dL (14 mmol/L)

Potassium
If initially normal or reduced, an infusion rate up to 15–20 mEq/h may be required; if elevated, wait until levels decrease into the normal range, then add to intravenous solution in a concentration of 20–30 mEq/L

Bicarbonate
Add one ampule (44 mEq) to 1 L of 0.45 normal saline if pH is < 7.1

This table was published in Landon MB, Catalano PM, and Gabbe SG, Diabetes mellitus complicating pregnancy, in *Obstetrics: Normal and Problem Pregnancies*, 5th ed., SG Gabbe, JR Niebyl, and JL Simpson (eds.), pp. 977–1011, Copyright Elsevier/Saunders 2007, with permission.

Infections

Almost all types of infections are increased in diabetic pregnancies. Stamler and associates (1990) reported that almost 80 percent of women with type 1 diabetes develop at least one infection during pregnancy compared with only 25 percent in those without diabetes. Takoudes and colleagues (2004) found that pregestational diabetes is associated with a two- to threefold increase in wound complications after cesarean delivery. Common infections include candida vulvovaginitis, urinary infections, respiratory tract infections, and puerperal pelvic infections. Cousins (1987) observed that antepartum pyelonephritis developed in

TABLE 52-10. Action Profiles of Commonly Used Insulins

Insulin Type	Onset	Peak (hours)	Duration (hours)
Short-acting, SC			
Lispro	<15 min	0.5–1.5	3–4
Aspart	<15 min	0.5–1.5	3–4
Regular	30–60 min	2–3	4–6
Long-acting			
Isophane insulin suspension	1–3 hr	5–7	13–18
Insulin zinc suspension	1–3 hr	4–8	13–20
Extended insulin zinc suspension	2–4 hr	8–14	18–30
Insulin glargine	1–4 hr	Minimal peak activity	24

SC = subcutaneous.

4 percent of women with type 1 diabetes compared with 1 percent in those without diabetes. Importantly, renal infection was associated with increased preterm delivery. Fortunately, these latter infections can be minimized by screening and eradication of asymptomatic bacteriuria (see Chap. 48, p. 1035).

Management of Diabetes in Pregnancy

The goals of management are tailored somewhat uniquely for pregnant women. Management preferably should begin before pregnancy and include specific goals during each trimester.

Preconceptional Care

To minimize early pregnancy loss and congenital malformations in infants of diabetic mothers, optimal medical care and education are recommended before conception (see Chap. 7, p. 175). Unfortunately, up to 60 percent of pregnancies in these women are unplanned (Holing and co-workers, 1998). Thus, diabetic women frequently begin pregnancy with suboptimal glucose control (Casele and Laifer, 1998; Kim and colleagues, 2005).

The American Diabetes Association (1999a) has defined optimal preconceptional glucose control using insulin to include self-monitored preprandial glucose levels of 70 to 100 mg/dL and postprandial values < 140 mg/dL and < 120 mg/dL at 1 and 2 hours, respectively. Glycosylated hemoglobin measurement, which expresses an average of circulating glucose for the past 4 to 8 weeks, is useful to assess early metabolic control. The Association further defines optimal preconceptional glycosylated hemoglobin values as those within or near the upper limit of normal for a specific laboratory or within three standard deviations of the normal mean. The most significant risk for malformations is with levels exceeding 10 percent (American College of Obstetricians and Gynecologists, 1994). Finally, folate, 400 μg/d, is given periconceptionally and during early pregnancy to decrease the risk of neural-tube defects.

First Trimester

Careful monitoring of glucose control is essential. For this reason, many clinicians hospitalize overtly diabetic women during early pregnancy to institute an individualized glucose control program and to provide education concerning the ensuing months of pregnancy. It also provides an opportunity to assess the extent of vascular complications of diabetes and to precisely establish gestational age.

Insulin Treatment

Insulin is used for overtly diabetic pregnant women. Although oral hypoglycemic agents have been used successfully for gestational diabetes (p. 1111), these agents are not currently recommended for overt diabetes except on an investigational basis (American College of Obstetricians and Gynecologists, 2005). Maternal glycemic control can usually be achieved with *multiple daily insulin injections* and adjustment of dietary intake. The action profiles of commonly used insulins are shown in Table 52-10.

Subcutaneous insulin infusion by a calibrated pump may be used during pregnancy. It has both advantages and disadvantages, but, as demonstrated in a Cochrane Database review by Farrar and associates (2007), there is scarce robust evidence for any salutary pregnancy effects. Kernaghan and co-workers (2007) in a retrospective study of 42 pregnant women failed to show improved glycemic control or reduced infant birthweight comparing those using a pump with those treated with conventional insulin therapy. Women who use an insulin pump must be highly motivated and compliant to minimize the risk of nocturnal hypoglycemia (Gabbe and Graves, 2003).

Self-monitoring of capillary glucose levels using a glucometer is recommended because this involves the woman in her own care. The goals of glucose control recommended during pregnancy are shown in Table 52-11. Parretti and colleagues (2001) measured maternal capillary glucose responses to meals throughout 51 normal pregnancies to better characterize glucose goals for management of diabetic women (Table 52-12).

Noninvasive Monitoring. Technology under development may provide methods for noninvasive glucose monitoring. Such an automatic and painless means to obtain blood glucose information would undoubtedly greatly aid patient compliance. Tamada and colleagues (1999) reported clinical results in

TABLE 52-11. Self-Monitored Capillary Blood Glucose Goals

Specimen	Level (mg/dL)
Fasting	≤95
Premeal	≤100
1-hr postprandial	≤140
2-hr postprandial	≤120
0200–0600	≥60
Mean (average)	100
Hb A1c	≤6

nonpregnant diabetics with such a monitoring device (Cygnus, Inc., Redwood City, California). It extracts glucose through the skin by iontophoresis, which uses electrical potentials. It then measures glucose concentrations in the extracted sample. The device provides up to three glucose readings per hour and causes only transient mild skin irritation at the sensor site. These investigators found close agreement between noninvasive glucose measurements and those obtained by standard fingersticks.

Diet

For women of normal weight, the American Diabetes Association (1999b) recommends a caloric intake of 30 to 35 kcal/kg, taken as three meals and three snacks daily (Franz and colleagues, 2004; Garner, 1995a). For underweight women, this is increased to 40 kcal/kg/d. For those more than 120 percent above ideal weight, it is decreased to 24 kcal/kg/d. An ideal dietary composition is 55 percent carbohydrate, 20 percent protein, and 25 percent fat with less than 10 percent as saturated fat.

TABLE 52-12. Average Diurnal Capillary Blood Glucose Levels in 51 Normal Pregnant Women During the Third Trimester

Time of Day	Blood Glucose Range of Values, mg/dL
0800 hr	51–65
← Breakfast	
0900 hr	87–112
1000 hr	73–100
1200 hr	58–75
← Lunch	
1400 hr	77–102
2000 hr	59–73
← Dinner	
0400 hr	57–70

Hypoglycemia

Diabetes tends to be unstable in the first trimester. Rosenn and colleagues (1995) assessed the impact of maternal hypoglycemia in 84 pregnant women with overt diabetes. Clinically significant hypoglycemia with glucometer values less than 35 mg/dL was documented in 70 percent of the women, with a peak incidence between 10 and 15 weeks. Almost 25 percent of these 84 women experienced unconsciousness, and 15 percent developed seizures as a result of hypoglycemia. These investigators recommended caution in attempting euglycemia in women with recurrent episodes of hypoglycemia.

We have reported that good pregnancy outcomes can be achieved in women with mean preprandial plasma glucose values up to 143 mg/dL (Leveno and associates, 1979). In women with diabetes who are not pregnant, the Diabetes Control and Complications Trial Research Group (1993) found that similar glucose values—intensive control was defined as mean values < 155 mg/dL—delayed and slowed diabetic retinopathy, nephropathy, and neuropathy. Thus, women with overt diabetes who have glucose values considerably above those defined as normal both during and after pregnancy can expect good outcomes.

Second Trimester

Maternal serum alpha-fetoprotein determination at 16 to 20 weeks is used in association with targeted sonographic examination at 18 to 20 weeks in an attempt to detect neural-tube defects and other anomalies (see Chap. 13, p. 288). Maternal alpha-fetoprotein levels may be lower in diabetic pregnancies, and interpretation is altered accordingly. Targeted sonography is important, and Albert and co-workers (1996) identified 72 percent of 29 fetal anomalies in 289 diabetic pregnancies. That said, Dashe and colleagues (2009) cautioned that detection of fetal anomalies in obese diabetic women is more difficult than in similarly sized women without diabetes.

Euglycemia with self-monitoring continues to be the goal in management. Individualized programs are necessary to avoid both excessive hyperglycemia and frequent episodes of hypoglycemia. After the first-trimester instability, a stable period ensues. This is followed by an increased insulin requirement after approximately 24 weeks (Steel and co-workers, 1994). This rise results from the increased production of pregnancy hormones, which are insulin antagonists (see Chap. 3, p. 65, and Chap. 5, p. 113). These investigators reported the absolute increase in mean insulin requirement to be 52 units in 237 women with type 1 diabetes—importantly, however, there was wide variation. The magnitude of increase was directly related to maternal weight and inversely related to the duration of diabetes.

Third Trimester and Delivery

In a woman with White class B or C diabetes, cesarean delivery has commonly been used to avoid traumatic birth of a large infant at or near term. In women with more advanced diabetes, especially those with vascular disease, the reduced likelihood of

TABLE 52-13. Insulin Management During Labor and Delivery Recommended by the American College of Obstetricians and Gynecologists (2005)

- Usual dose of intermediate-acting insulin is given at bedtime.
- Morning dose of insulin is withheld.
- Intravenous infusion of normal saline is begun.
- Once active labor begins or glucose levels decrease to < 70 mg/dL, the infusion is changed from saline to 5-percent dextrose and delivered at a rate of 100–150 mL/hr (2.5 mg/kg/min) to achieve a glucose level of approximately 100 mg/dL.
- Glucose levels are checked hourly using a bedside meter allowing for adjustment in the insulin or glucose infusion rate.
- Regular (short-acting) insulin is administered by intravenous infusion at a rate of 1.25 U/hr if glucose levels exceed 100 mg/dL.

successfully inducing labor remote from term has also contributed appreciably to an increased cesarean delivery rate. Labor induction may be attempted when the fetus is not excessively large and the cervix is considered favorable (see Chap. 22, p. 500). Cesarean delivery rates range from 50 to 80 percent (Gabbe, 1977; Kitzmiller, 1978; Leveno, 1979; Martin, 1987; Schneider, 1980, and all their associates). The rate for women with overt diabetes has remained at approximately 80 percent for the past 30 years at Parkland Hospital.

It is important to considerably reduce or delete the dose of long-acting insulin given on the day of delivery. Regular insulin should be used to meet most or all of the insulin needs of the mother at this time, because insulin requirements typically drop markedly after delivery. We have found that continuous insulin infusion by calibrated pump is most satisfactory (**Table 52–13**). During labor and after delivery, the woman should be adequately hydrated intravenously and given glucose in sufficient amounts to maintain normoglycemia. Capillary or plasma glucose levels should be checked frequently, and regular insulin should be administered accordingly. It is not unusual for a woman to require virtually no insulin for the first 24 hours or so postpartum and then for insulin requirements to fluctuate markedly during the next few days. Infection must be promptly detected and treated.

CONTRACEPTION

There is no single contraceptive method appropriate for all women with diabetes. Because of the risk of vascular disease, hormonal contraceptives may be problematic. Many clinicians are reluctant to recommend intrauterine devices in women with diabetes, primarily because of a possible increased risk of pelvic infections. All of these concerns, along with available options, are discussed in Chapter 32 (p. 673). For many of these reasons, and because of frequent associated morbidity with chronic diseases, many overtly diabetic women elect puerperal sterilization as discussed in Chapter 33 (p. 698). This option should be made readily available. Schwarz and colleagues (2006) compared counseling provided to nonpregnant, diabetic and nondiabetic, women during 40,304 ambulatory visits. Only 4 percent of diabetic women received contraception counseling. They concluded that this was inevitably implicated in diabetic women conceiving before optimal periconceptional glucose control was obtained.

CHAPTER 53

Thyroid and Other Endocrine Disorders

THYROID DISORDERS 1126
PARATHYROID DISEASES 1135
ADRENAL GLAND DISORDERS 1136
PITUITARY DISEASES 1139

A variety of endocrine disorders can complicate pregnancy and vice versa. Diabetes mellitus is the most prevalent and is discussed in Chapter 52 (p. 1104). Thyroid disorders are also common, and a number of less common endocrinopathies—for example, pheochromocytoma—can have devastating effects on pregnancy outcome. The pathogenesis of many endocrinopathies is disordered autoimmunity. And as with most organ-specific autoimmune disorders, clinical manifestations of endocrinopathies result from a complex interplay among genetic, environmental, and endogenous factors that activate the immune system against target cells (Weetman, 2004). In many cases, a nonspecific event such as a viral infection initiates an organ-specific response with subsequent immune-mediated glandular destruction. Also, studies implicating cells transferred between mother and fetus during pregnancy in development of autoimmune disease decades later represent a new investigative frontier (Muraji and associates, 2008; Rust and Bianchi, 2009).

THYROID DISORDERS

Taken in aggregate, thyroid disorders are common in young women. There is an intimate relationship between maternal and fetal thyroid function, and drugs that affect the maternal thyroid also affect the fetal gland. Thyroid autoantibodies have been associated with increased early pregnancy wastage, and uncontrolled thyrotoxicosis and untreated hypothyroidism are both associated with adverse pregnancy outcomes (Männistö and colleagues, 2009). Finally, there is evidence that the severity of autoimmune thyroid disorders is ameliorated during pregnancy, only to be exacerbated postpartum.

Thyroid Physiology and Pregnancy

The impact of pregnancy on maternal thyroid physiology is substantial. Changes in the structure and function of the gland sometimes cause confusion in the diagnosis of thyroid abnormalities. These are discussed in greater detail in Chapter 5 (p. 126), and normal hormone level changes are found in the Appendix. Maternal serum concentration of thyroid-binding globulin is increased concomitantly with total or bound thyroid hormone levels (Fig. 5-16). *Thyrotropin,* or *thyroid-stimulating hormone (TSH),* currently plays a central role in screening and diagnosis of many thyroid disorders. Serum thyrotropin levels in early pregnancy decrease because of thyroid stimulation from the weak TSH effects of human chorionic gonadotropin (hCG) (Grossman and associates, 1997). TSH does not cross the placenta. At the same time, hCG serum levels are maximal for the first 12 weeks, free thyroxine levels increase to suppress pituitary thyrotropin secretion (**Fig. 53-1**). Accordingly, *thyrotropin-releasing hormone (TRH)* is undetectable in maternal serum. Fetal serum TRH is detectable beginning at midpregnancy, but does not increase.

Throughout pregnancy, maternal thyroxine is transferred to the fetus (Calvo and associates, 2002; Vulsma and colleagues, 1989). Maternal thyroxine is important for normal fetal brain development, especially prior to development of fetal thyroid gland function (Bernal, 2007). And even though the fetal gland begins concentrating iodine and synthesizing thyroid hormone after 12 weeks, maternal thyroxine contribution remains important. In fact, maternal thyroxine accounts for 30 percent of thyroxine in fetal serum at term (Thorpe-Beeston and colleagues, 1991; Vulsma and co-workers, 1989). Developmental risks associated with maternal hypothyroidism after midpregnancy remain poorly understood (Morreale de Escobar and colleagues, 2004).

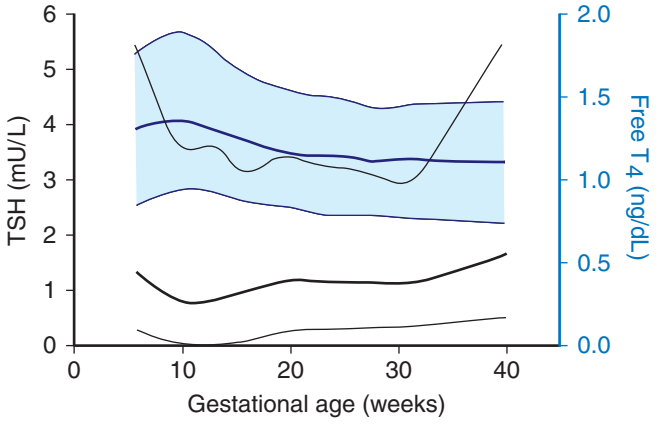

FIGURE 53-1 Gestational age-specific values for serum thyroid-stimulating hormone (TSH) levels (*black lines*) and free thyroxine (T_4) levels (*blue lines*). Data were derived from 17,298 women tested during pregnancy. For each color, the dark solid lines represent the 50th percentile, whereas the upper and lower light lines represent the 2.5th and 97.5th percentiles, respectively. (Data from Casey and colleagues, 2005; Dashe and co-workers, 2005.)

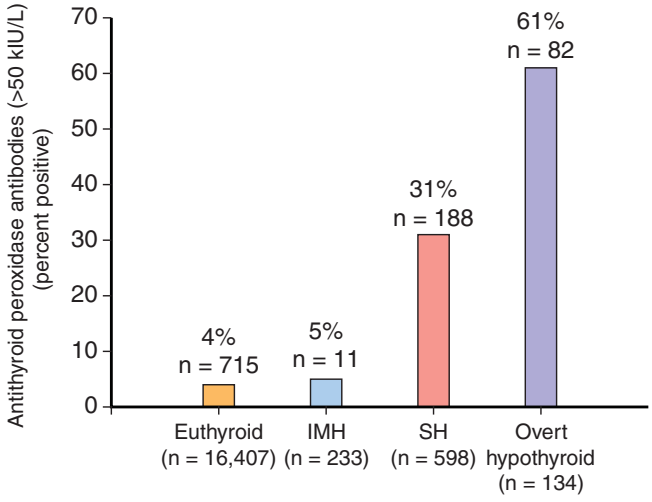

FIGURE 53-2 Incidence of antithyroid peroxidase antibodies in women who are euthyroid; in those with isolated maternal hypothyroxinemia (IMH), defined by a normal serum thyroid-stimulating hormone (TSH) value and serum free thyroxine (T_4) level < 0.86 ng/dL; in those with subclinical hypothyroidism (SH), defined as serum TSH value ≥ 3.0 mU/L with a normal reference range serum free T_4 level; and in those with overt hypothyroidism defined by an abnormally high serum TSH value with an abnormally low serum free T_4 level. (Data from Casey and associates, 2007.)

Autoimmunity and Thyroid Disease

Most thyroid disorders are inextricably linked to the presence of autoantibodies to various cell components. A number of these antibodies variably stimulate thyroid function, block function, or cause thyroid inflammation that may lead to follicular cell destruction. Oftentimes, these effects overlap or even coexist.

Thyroid-stimulating autoantibodies, also called *thyroid-stimulating immunoglobulins (TSI)*, bind to the thyrotropin receptor and activate it, causing thyroid hyperfunction and growth. Although these antibodies are identified in most patients with classic Graves disease, simultaneous production of *thyroid-stimulating blocking antibodies* may blunt this effect (Weetman, 2000). *Thyroid peroxidase antibodies*, previously called thyroid *microsomal autoantibodies*, have been identified in 5 to 15 percent of all pregnant women as shown in **Figure 53-2** (Casey and colleagues, 2007; Kuijpens and co-workers, 2001). These antibodies have been associated with early pregnancy loss (Abramson and Stagnaro-Green, 2001). Conversely, women with antibodies identified in the first half of pregnancy did not have increased rates of poor pregnancy outcomes (Casey and colleagues, 2008). These women are, however, at high risk for postpartum thyroid dysfunction and at lifelong risk for permanent thyroid failure (Hidaka and associates, 1994; Premawardhana and co-workers, 2000).

Autoimmune thyroid disease is much more common in women than in men. One intriguing explanation for this disparity is fetal-to-maternal cell trafficking. When fetal lymphocytes enter the maternal circulation, they can live for more than 20 years. Stem cell interchange also seems likely with engraftment in a number of maternal tissues to include the thyroid (Bianchi and Romero, 2003; Khosrotehrani and associates, 2004). Such maternal *microchimerism* with male fetuses has been identified in some women who have the *SRY* sex-determining gene. Up to a third of women who have borne a male fetus have *SRY*-positive lymphocytes in their peripheral blood. Specimens from women with thyroiditis or Graves disease also have *SRY*-positive thyrocyte microchimerism with a greater frequency and intensity than euthyroid controls (Ando and associates, 2002; Klintschar and colleagues, 2001). A high prevalence of Y-chromosome-positive cells has also been identified using fluorescent in situ hybridization in thyroid glands of women with Hashimoto thyroiditis—60 percent, or Graves disease—40 percent (Renné and co-workers, 2004). These are presumed to have arisen from stem cells acquired from a male fetus.

Hyperthyroidism

Symptomatic thyrotoxicosis or hyperthyroidism complicates 1 in 1000 to 2000 pregnancies as shown in **Table 53-1** (Casey and Leveno, 2006; Mestman and colleagues, 1995). Because normal pregnancy simulates some clinical findings similar to thyroxine (T_4) excess, mild thyrotoxicosis may be difficult to diagnose. Suggestive findings include tachycardia that exceeds that usually seen with normal pregnancy, thyromegaly, exophthalmos, and failure to gain weight despite adequate food intake. Laboratory confirmation is by a markedly depressed thyrotropin (TSH) level along with an elevated serum free T_4 (fT_4) level. Rarely, hyperthyroidism is caused by abnormally high serum triiodothyronine (T_3) levels—so-called *T_3-toxicosis.*

Thyrotoxicosis and Pregnancy

The overwhelming cause of thyrotoxicosis in pregnancy is *Graves disease*, an organ-specific autoimmune process usually associated with thyroid-stimulating antibodies as previously discussed. Such antibody activity declines during pregnancy, and it

TABLE 53-1. Incidence of Hyper- and Hypothyroidism in Two Large Cohorts of Pregnant Women Undergoing Serum Thyrotropin Screening

Thyroid Activity	Casey et al (2005, 2007) (n = 17,298)[a]	Cleary-Goldman et al (2008) (n = 10,990)[b]
Hyperthyroidism	1.7%	
Overt	0.5/1000	
Subclinical	1.7%	
Hypothyroidism	2.5%	2.5%
Overt	2/1000	3/1000
Subclinical	2.3%	2.2%

[a]Before 20 weeks.
[b]First trimester.

may become undetectable in the third trimester (Kung and Jones, 1998; Smyth and co-workers, 2005). Amino and colleagues (2003) have found that levels of blocking antibodies are also decreased during pregnancy.

Treatment. Thyrotoxicosis during pregnancy can nearly always be controlled by thionamide drugs. Some clinicians prefer *propylthiouracil (PTU)* because it partially inhibits the conversion of T_4 to T_3 and crosses the placenta less readily than *methimazole.* Although not definitely proven, methimazole use in early pregnancy has been associated with a rare methimazole embryopathy characterized by *esophageal* or *choanal atresia* as well as *aplasia cutis*, which is a congenital skin defect (Diav-Citrin and Ornoy, 2002; Di Gianantonio and colleagues, 2001). Although these malformations are uncommon in women treated with methimazole, and despite the lack of epidemiological studies that PTU is safer, PTU still is the preferred thionamide in the United States (Brent, 2008).

Transient leukopenia can be documented in up to 10 percent of women taking antithyroid drugs but does not require cessation of therapy. In 0.3 to 0.4 percent, *agranulocytosis* develops suddenly and mandates discontinuance of the drug. It is not dose related, and because of its acute onset, serial leukocyte counts during therapy are not helpful. Thus, if fever or sore throat develop, women are instructed to discontinue medication immediately and report for a complete blood count (Brent, 2008). Hepatotoxicity is another potentially serious side effect that occurs in 0.1 to 0.2 percent. Approximately 20 percent of patients treated with PTU develop *antineutrophil cytoplasmic antibodies* (*ANCA*), but only a small percentage of these go on to develop serious vasculitis (Helfgott, 2002). Finally, although thionamides have the potential to cause fetal complications, these are uncommon. In some cases, thionamides may even be therapeutic, because thyrotropin receptor antibodies cross the placenta and can stimulate the fetal thyroid gland to cause thyrotoxicosis and goiter.

The initial propylthiouracil dose is empirical. For nonpregnant patients, the American Thyroid Association recommends an initial daily dose of 100 to 600 mg for PTU or 10 to 40 mg for methimazole (Singer and colleagues, 1995). At Parkland Hospital, we usually start with 300 or 450 mg of PTU daily for our pregnant patients. In our experience, overt thyrotoxicosis in pregnant women requires higher doses than are recommended by most (Davis and colleagues, 1989). With a PTU dose that averaged 600 mg daily, only half of women had a remission, and in these, the dose was decreased to less than 300 mg daily within 8 weeks. In a third, however, it was necessary to increase the dose. Serum free T_4 is considered a better indicator of thyroid status than TSH during the first 2 to 3 months of treatment for hyperthyroidism (National Academy of Clinical Biochemistry Guidelines, 2002).

Subtotal thyroidectomy can be performed after thyrotoxicosis is medically controlled. This seldom is done during pregnancy but may be appropriate for the very few women who cannot adhere to medical treatment or in whom drug therapy proves toxic (Davison and co-workers, 2001). **Ablation with therapeutic radioactive iodine is contraindicated during pregnancy**. Therapeutic doses for maternal thyroid disease may also cause fetal thyroid gland destruction. Thus, when given unintentionally, most clinicians recommend abortion. Any exposed infant must be carefully evaluated for hypothyroidism (Berg and colleagues, 1998). The incidence of fetal hypothyroidism depends on gestational age and radioiodine dose (Berlin, 2001). There is no evidence that therapeutic radioiodine given before pregnancy causes fetal anomalies if enough time has passed to allow radiation effects to dissipate and the woman is euthyroid (Ayala and associates, 1998; Casara and colleagues, 1993). The International Commission on Radiological Protection has recommended that women avoid pregnancy for 6 months after radioablative therapy (Brent, 2008).

Pregnancy Outcome

Women with thyrotoxicosis have pregnancy outcomes that largely depend on whether metabolic control is achieved. For example, excess thyroxine may cause miscarriage (Anselmo and associates, 2004). In untreated women or in those who remain hyperthyroid despite therapy, there is a higher incidence of

TABLE 53-2. Pregnancy Outcomes in 239 Women with Overt Thyrotoxicosis

Factor	Treated and Euthyroid (n = 149)	Uncontrolled Thyrotoxicosis (n = 90)
Maternal outcome		
Preeclampsia	17 (11%)	15 (17%)
Heart failure	1	7 (8%)
Death	—	1
Perinatal outcome		
Preterm delivery	12 (8%)	29 (32%)
Growth restriction	11 (7%)	15 (17%)
Stillbirth	0/59	6/33 (18%)
Thyrotoxicosis	1	2
Hypothyroidism	4	0
Goiter	2	0

Data from Davis (1989), Kriplani (1994), Millar (1994), and all their colleagues.

preeclampsia, heart failure, and adverse perinatal outcomes (Table 53-2). Perinatal mortality rates varied from 6 to 12 percent in several studies.

Fetal and Neonatal Effects

In most cases, the perinate is euthyroid. In some, however, hyper- or hypothyroidism can develop with or without a goiter (Fig. 53-3). Clinical hyperthyroidism occurs in approximately 1 percent of neonates born to women with Graves disease (Luton and colleagues, 2005). If fetal thyroid disease is suspected, nomograms are available for sonographically measured thyroid volume (Ranzini and co-workers, 2001). Newborns exposed to excessive maternal thyroxine may have any of several clinical presentations.

FIGURE 53-3 Term neonate delivered of a woman with a 3-year history of thyrotoxicosis that recurred at 26 weeks' gestation. The mother was given methimazole, 30 mg orally daily, and she was euthyroid at delivery. Laboratory studies showed that the infant was hypothyroid.

1. The fetus or newborn may manifest goitrous thyrotoxicosis caused by placental transfer of thyroid-stimulating immunoglobulins. *Nonimmune hydrops* and fetal demise have been reported with fetal thyrotoxicosis (Nachum and co-workers, 2003; Stulberg and Davies, 2000). In a study of 72 pregnant women with Graves disease, Luton and colleagues (2005) reported that none of the fetuses in 31 low-risk mothers had a goiter, and all were euthyroid at delivery. Low risk was defined by no antithyroid medications during the third trimester or absence of antithyroid antibodies. Conversely, in a group of 41 women who either were taking antithyroid medication at delivery or had thyroid receptor antibodies, 11 fetuses—27 percent—had sonographic evidence of a goiter at 32 weeks. Seven of these 11 were determined to be hypothyroid, and the remainder were hyperthyroid. If the fetus is thyrotoxic, treatment is by adjustment of maternal thionamide drugs (Duncombe and Dickinson, 2001). Occasionally, neonatal thyrotoxicosis may also require short-course antithyroid drug treatment.
2. Fetal exposure to maternally administered thionamides as described above may cause goitrous hypothyroidism (Fig. 53-3). Although there are theoretical neurological implications of fetal hypothyroidism, reports of adverse fetal effects seem to have been exaggerated. Available data indicate that thionamides carry an extremely small risk for causing neonatal hypothyroidism (Momotani and associates, 1997; O'Doherty and colleagues, 1999). For example, of the 239 treated thyrotoxic women shown in Table 53-1, there was evidence of hypothyroidism in only four infants despite relatively high maternal doses of propylthiouracil. Furthermore, at least four long-term studies report no abnormal

intellectual and physical development of these children (Mestman, 1998). If hypothyroidism is identified, the fetus can be treated by a reduction in maternal antithyroid medication and injection of intra-amnionic thyroxine if necessary.

3. The fetus may develop nongoitrous hypothyroidism from transplacental passage of maternal thyrotropin-receptor blocking antibodies (Gallagher and associates, 2001).
4. Even after maternal thyroid gland ablation, usually with ^{131}I radioiodine, fetal thyrotoxicosis may result from transplacental thyroid-stimulating antibodies.

Fetal Diagnosis. Fetal thyroid function evaluation is somewhat controversial. Although fetal thyroid sonographic assessment has been reported in women taking thionamide drugs or those with thyroid-stimulating antibodies, most investigators do not currently recommend routine evaluation (Cohen and associates, 2003; Luton and colleagues, 2005). For example, Kilpatrick (2003) recommends fetal antibody testing only if the mother has previously undergone ^{131}I ablation. Because fetal hyper- or hypothyroidism may cause hydrops, growth restriction, goiter, or tachycardia, fetal blood sampling seems appropriate if these conditions develop during pregnancy complicated by Graves disease (Brand and co-workers, 2005).

Thyroid Storm and Heart Failure

Thyroid storm is an acute, life-threatening, hypermetabolic state and is rare in pregnancy. In contrast, pulmonary hypertension and heart failure from cardiomyopathy caused by the profound myocardial effects of thyroxine is common in pregnant women (Sheffield and Cunningham, 2004). As shown in Table 53-2, heart failure developed in 8 percent of 90 women with uncontrolled thyrotoxicosis. In these women, cardiomyopathy is characterized by a high-output state, which may lead to a dilated cardiomyopathy (Fadel and colleagues, 2000; Klein and Ojamaa, 1998). The pregnant woman with thyrotoxicosis has minimal cardiac reserve, and decompensation is usually precipitated by preeclampsia, anemia, sepsis, or a combination of these. Fortunately, thyroxine-induced cardiomyopathy and pulmonary hypertension are frequently reversible (Sheffield and Cunningham, 2004; Siu and associates, 2007; Vydt and colleagues, 2006).

Management. Treatment for thyroid storm or heart failure is similar and should be carried out in an intensive care unit (Zeeman and colleagues, 2003). Specific treatment consists of 1000 mg of PTU given orally or crushed and placed through a nasogastric tube. PTU is continued in 200-mg doses every 6 hours. An hour after initial PTU administration, iodide is given to inhibit thyroidal release of T_3 and T_4. It is given intravenously as 500 to 1000 mg of sodium iodide every 8 hours; orally as 5 drops of supersaturated solution of potassium iodide (SSKI) every 8 hours; or as Lugol solution, 10 drops orally every 8 hours. With a history of iodine-induced anaphylaxis, lithium carbonate, 300 mg every 6 hours, is given instead (Burch and Wartofsky, 1993). Most authorities recommend dexamethasone, 2 mg intravenously every 6 hours for four doses, to further block peripheral conversion of T_4 to T_3. If a β-blocker drug is given to control tachycardia, its effect on heart failure must be considered. Propranolol, labetalol, and esmolol have all been used successfully intrapartum (Bowman and colleagues, 1998). Coexisting severe preeclampsia, infection, or anemia should be aggressively managed.

Hyperemesis Gravidarum and Gestational Thyrotoxicosis

Many women with hyperemesis gravidarum have abnormally high serum thyroxine levels and low thyrotropin levels (see Chap. 49, p. 1050). This results from thyrotropin receptor stimulation from massive—but normal for pregnancy—concentrations of hCG. This transient condition is also termed *gestational thyrotoxicosis.* Even if associated with hyperemesis, antithyroid drugs are not warranted (American College of Obstetricians and Gynecologists, 2002). Serum thyroxine and thyrotropin values become more normal by midpregnancy.

Gestational Trophoblastic Disease

Thyroxine levels in women with molar pregnancy usually are appreciably elevated. As discussed, abnormally high hCG levels lead to overstimulation of the TSH receptor. Because these tumors are now usually diagnosed early, clinically apparent hyperthyroidism has become less common (Goodwin and Hershman, 1997). With definitive treatment, serum free-T_4 levels usually normalize in parallel with the decline in hCG concentrations. This is discussed further in Chapter 11 (p. 260).

Subclinical Hyperthyroidism

Introduction into clinical practice of third-generation thyrotropin assays with an analytical sensitivity of 0.002 mU/mL makes it possible to identify subclinical thyroid disorders. These biochemically defined extremes usually represent normal biological variations but may herald the earliest stages of thyroid dysfunction. *Subclinical hyperthyroidism* is characterized by an abnormally low serum thyrotropin concentration in concert with thyroxine hormone levels within the normal reference range (Surks and associates, 2004). Long-term effects of persistent subclinical thyrotoxicosis include osteoporosis, cardiovascular morbidity, and progression to overt thyrotoxicosis or thyroid failure. Casey and Leveno (2006) identified subclinical hyperthyroidism in 1.7 percent of pregnant women (Table 53-1). Importantly, these investigators showed that subclinical hyperthyroidism was not associated with adverse pregnancy outcomes.

Management

Currently there is no convincing evidence that subclinical hyperthyroidism should be treated in nonpregnant individuals. Thus, it seems especially unwarranted in pregnancy because antithyroid drugs reach the fetus. Women identified with subclinical hyperthyroidism may benefit from periodic surveillance, and approximately half eventually have normal thyrotropin concentrations.

Hypothyroidism

Overt hypothyroidism complicates from 2 to 3 pregnancies per 1000 (Casey and colleagues, 2005; Cleary-Goldman and associates, 2008). It is characterized by insidious nonspecific clinical findings that include fatigue, constipation, cold intolerance, muscle cramps, and weight gain. A pathologically enlarged thyroid gland depends on the etiology of hypothyroidism and is more likely in women in areas of endemic iodine deficiency or those with Hashimoto thyroiditis. Other findings include edema, dry skin, hair loss, and prolonged relaxation phase of deep tendon reflexes. *Clinical* or *overt hypothyroidism* is diagnosed when an abnormally high serum thyrotropin level is accompanied by an abnormally low thyroxine level. *Subclinical hypothyroidism* is defined by an elevated serum thyrotropin level and *normal* serum thyroxine concentration (Surks and associates, 2004).

Overt Hypothyroidism and Pregnancy

The most common cause of hypothyroidism in pregnancy is Hashimoto thyroiditis, characterized by glandular destruction from autoantibodies, particularly antithyroid peroxidase antibodies. Clinical identification of hypothyroidism is especially difficult during pregnancy because many of the signs or symptoms are also common to pregnancy itself. Thyroid testing should be performed on symptomatic women or those with a history of thyroid disease (American College of Obstetricians and Gynecologists, 2002). *Severe* hypothyroidism with pregnancy is uncommon, probably because it is often associated with infertility and increased miscarriage rates (Abalovich and colleagues, 2002).

Treatment. Replacement therapy for hypothyroidism is with levothyroxine in doses of 1 to 2 μg/kg/day or approximately 100 μg daily. Serum thyrotropin levels are measured at 4- to 6-week intervals, and the thyroxine dose is adjusted by 25- to 50-μg increments until normal TSH values between 0.5 and 2.5 mU/L are reached. Pregnancy is associated with an increase in thyroxine requirements in approximately a third of supplemented women (Alexander and associates, 2004). Because a similar increased requirement is seen in women with postmenopausal hypothyroidism after estrogen replacement, the increased demand in pregnancy is believed to be related to increased estrogen production (Alexander and colleagues, 2004; Arafah, 2001).

Increased thyroxine requirements begin as early as 5 weeks. Thus, significant hypothyroidism may develop early in women without thyroid reserve such as those with a previous thyroidectomy, history of radioiodine ablation, or those undergoing assisted reproductive techniques (Alexander, 2004; Loh, 2009; Rotondi, 2004, and all their colleagues). Increasing thyroxine replacement by 25 percent at pregnancy confirmation will reduce this likelihood. All other women with hypothyroidism should undergo TSH testing at initiation of prenatal care.

Pregnancy Outcome with Overt Hypothyroidism. Observational studies, although limited, indicate that there are excessive adverse perinatal outcomes associated with overt thyroxine deficiency (Table 53-3). With appropriate replacement therapy however, several recent studies show no increase in perinatal morbidity rates (Matalon, 2006; Tan, 2006; Wolfberg, 2005; and all their co-workers). However, Wikner and co-workers (2008) found an increased risk for some pregnancy complications even in those taking replacement therapy. Most experts agree that adequate hormone replacement during pregnancy minimizes the risk of adverse outcomes and most complications (Abalovich and associates, 2002).

Fetal and Neonatal Effects. There is no doubt that maternal and fetal thyroid abnormalities are related. In both, thyroid function is dependent on adequate iodide intake, and its deficiency early in pregnancy can cause both maternal and fetal hypothyroidism. And as discussed, maternal TSH-receptor-blocking antibodies can cross the placenta and cause fetal thyroid dysfunction. The more common antithyroid peroxidase and antithyroglobulin antibodies, however, have little or no effect on

TABLE 53-3. Pregnancy Complications in 112 Women with Hypothyroidism

	Hypothyroidism (Percent)	
Complications	Overt (n = 49)	Subclinical (n = 63)
Preeclampsia	31	16
Placental abruption	8	0
Cardiac dysfunction	3	2
Birthweight less than 2000 g[a]	31	19
Stillbirths	8	2[b]

[a]Preterm or term delivery were the only outcomes reported by Abalovich and colleagues (2002).
[b]One infant died from syphilis.
Modified from Abalovich (2002), Davis (1988), and Leung (1993), and all their associates.

fetal thyroid function even though they too cross the placenta (Fisher, 1997). Maternal Hashimoto thyroiditis is not typically associated with fetal thyroid dysfunction. In fact, prevalence of fetal hypothyroidism in women with Hashimoto thyroiditis is estimated to be only 1 in 180,000 neonates (Brown and co-workers, 1996).

Subclinical Hypothyroidism

The incidence of subclinical hypothyroidism in women between 18 and 45 years of age is about 5 percent (Canaris and colleagues, 2000). In two large studies totaling more than 25,000 pregnant women screened in the first half of pregnancy, subclinical hypothyroidism was identified in 1.7 and 2.3 percent of women (Table 53-1). The rate of progression to overt thyroid failure is impacted by TSH level, age, other disorders such as diabetes, and presence of antithyroid antibodies. Diez and Iglesias (2004) prospectively followed 93 nonpregnant women with subclinical hypothyroidism for 5 years and reported that in a third, TSH values became normal. In the other two thirds, those women whose TSH levels were 10 to 15 mU/L developed overt disease at a rate of 19 per 100 patient-years. Those women whose TSH levels were < 10 mU/L developed overt hypothyroidism at a rate of 2 per 100 patient-years. The U.S. Preventative Services Task Force on screening for subclinical hypothyroidism also reported that nearly all patients who develop overt hypothyroidism within 5 years have an initial TSH level greater than 10 mU/L (Helfand, 2004; Karmisholt and associates, 2008). TSH analyses have a much higher variance at these higher levels. Consequently, the likelihood of development of overt hypothyroidism during pregnancy in otherwise healthy women with subclinical hypothyroidism seems unlikely.

Subclinical Hypothyroidism and Pregnancy

Small observational studies shown in Table 53-3 were suggestive that subclinical hypothyroidism might be associated with adverse pregnancy outcomes. Interest was further heightened by two studies that suggested that undiagnosed maternal thyroid hypofunction may impair fetal neuropsychological development. In one study, Pop and associates (1999) described 22 women who had free T_4 levels below the 10th percentile in early pregnancy whose offspring were at increased risk for impaired psychomotor development. In the other study, Haddow and colleagues (1999) retrospectively evaluated children born to 48 untreated women whose serum thyrotropin values exceeded the 98th percentile. Some had diminished school performance, reading recognition, and IQ scores. Although described as "subclinically hypothyroid," these women had an abnormally low mean serum free thyroxine level and thus likely had overt hypothyroidism.

To further evaluate any adverse effects, Casey and co-workers (2005) identified subclinical hypothyroidism in 2.3 percent of 17,298 women screened before midpregnancy. As shown in Table 53-4, these women had higher incidences of preterm birth, placental abruption, and admission of infants to the intensive care nursery compared with control women. In the study of 10,990 First- and Second-Trimester Evaluation of Risk (FASTER) Trial participants, Cleary-Goldman and associates (2008) did not find a link with these adverse obstetrical outcomes.

In a subsequent study of these 17,298 women with subclinical hypothyroidism, Casey and colleagues (2008) showed that 31 percent had antithyroid peroxidase antibodies compared with 4 percent of euthyroid controls. The cohort with TPO antibodies had a significant threefold risk for placental abruption. Cleary-Goldman and associates (2008) measured antithyroglobulin and antithyroid peroxidase antibodies in the FASTER Trial cohort of 10,990 women and reported an incidence of approximately 15 percent of either antibodies present. When both were present, risk for preterm prematurely ruptured membranes was increased by almost threefold.

Thyrotropin Screening in Pregnancy. Because of the 1999 studies cited above, some organizations have recommended routine prenatal screening and treatment for subclinical hypothyroidism (Gharib and associates, 2005). The American College of Obstetricians and Gynecologists (2002) concluded

TABLE 53-4. Pregnancy Outcomes in Women with Untreated Subclinical Hypothyroidism and Isolated Maternal Hypothyroxinemia Compared with Pregnant Women with Normal Thyroid Function Studies

Outcome	Normal TSH and Free T_4 (n = 16,011)	Subclinical Hypothyroidism (n = 598)	*P* value	Isolated Hypothyroxinemia (n = 233)	*P* value
Hypertension (%)	9	9	.68	11	.53
Placental abruption (%)	0.3	1.0	.03	0.4	.75
Gestational age delivered (%)					
≤36 weeks	6.0	7.0	.09	6.0	.84
≤34 weeks	2.5	4.3	.005	2.0	.44
≤32 weeks	1.0	2.2	.13	1.0	.47
RDS—ventilator (%)	1.5	2.5	.05	1.3	.78
Neonatal intensive care (%)	2.2	4.0	.005	1.3	.32

RDS = Respiratory distress syndrome; T_4 = thyroxine; TSH = thyroid-stimulating hormone.
Data from Casey and colleagues (2007).

that although observational data were consistent with the *possibility* that subclinical hypothyroidism was associated with adverse neuropsychological development, there have been no interventional trials to demonstrate improvement. The College thus recommended against implementation of screening until further studies were done to validate or refute these findings. One major concern is that it seems unlikely that treatment given *after* the period of early cerebral development would be totally efficacious to prevent neurological damage (Utiger, 1999).

These issues continue to be the source of debate. At least two consensus conferences were held to reconcile differing viewpoints. Two major groups recommended against routine prenatal thyrotropin screening (Surks and associates, 2004). Subsequently, however, representatives of the American Thyroid Association, American Association of Clinical Endocrinologists, and Endocrine Society published dissenting opinions and recommended routine screening and treatment (Gharib and colleagues, 2005). More recently, following a 2-year development process by an international task force, evaluation of high-risk pregnant women was recommended because current evidence does not justify routine pregnancy screening (Abalovich and co-workers, 2007). Finally, the American College of Obstetricians and Gynecologists (2007) also continues to recommend against routine screening.

Isolated Maternal Hypothyroxinemia

Women with low serum free-T_4 values but a normal range TSH level are considered to have *isolated maternal hypothyroxinemia*. This was identified by Casey and colleagues (2007) in 1.3 percent of more than 17,000 pregnant women screened before 20 weeks. Cleary-Goldman and associates (2008) found a 2.1-percent incidence in the FASTER Trial cohort. As discussed previously, offspring of women with isolated hypothyroxinemia have been reported to have neurodevelopmental difficulties at 3 weeks, 10 months, and 2 years of age (Kooistra and colleagues, 2006; Pop and associates 1999, 2003). These findings have not stimulated recommendations for prenatal serum thyroxine screening. Additionally, free T_4 estimates by crudely available immunoassays may not be accurate during pregnancy because of sensitivity to alterations in binding proteins (Lee and co-workers, 2009).

In a study of 233 women with isolated maternal hypothyroxinemia, Casey and colleagues (2007) reported that there were no increased adverse perinatal outcomes (see Table 53-4). And unlike subclinical hypothyroidism, these women had a low prevalence of antithyroid antibodies (see Fig. 53-2). Moreover, there was no correlation between their TSH and free T_4 levels. Cleary-Goldman and co-workers (2008) reported a twofold incidence of fetal macrosomia in these women. Taken together, these findings indicate the isolated maternal hypothyroxinemia has no apparent serious adverse effects on pregnancy outcome and may simply be a biochemical finding (Casey and co-workers, 2007). Because of this, routine screening for isolated hypothyroxinemia is not recommended.

Iodine Deficiency

Decreasing iodide fortification of table salt and bread products in the United States over the past 25 years resulted in occasional identification of iodide deficiency (Caldwell and colleagues, 2005; Hollowell and associates, 1998). At this time, however, general maternal iodine intake has stabilized. The most recent National Health and Nutrition Examination survey indicated that, overall, the population is again iodine sufficient (Caldwell and co-workers, 2005; Haddow and associates, 2007). Even so, experts agree that iodine nutrition in vulnerable populations such as pregnant women requires continued monitoring.

Iodine and Pregnancy

Adequate iodine is requisite for fetal neurological development beginning soon after conception, and abnormalities are dependent on the degree of deficiency. The World Health Organization (WHO) estimates at least 50 million people worldwide have varying degrees of preventable brain damage due to iodine deficiency (Brundtland, 2002). Although it is doubtful that *mild deficiency* causes intellectual impairment, supplementation does prevent fetal goiter (Fadeyev and colleagues, 2003). Conversely, *severe deficiency* is frequently associated with damage typically encountered with *endemic cretinism* (Delange and co-workers, 2001). Although not quantified, it is presumed that *moderate deficiency* has intermediate and variable effects on intellectual and psychomotor function (Glinoer, 2001).

The Institute of Medicine (2001) recommended daily iodine intake during pregnancy of 220 μg/day and 290 μg/day for lactating women. Iodine supplementation before pregnancy prevents neurological morbidity from severe deficiency and partially does so even if given after pregnancy is established (Cao and colleagues, 1994). The American Thyroid Association has recommended supplementation of pregnant or lactating women with 150 μg of iodine added to prenatal vitamins (Becker and colleagues, 2006). It has even been suggested that because most cases of maternal hypothyroxinemia world wide are related to relative iodine deficiency, suppplementation may obviate the need to consider thyroxine treatment in such women (Gyamfi and associates, 2009). Teng and co-workers (2006) have suggested that excessive iodine intake—defined as $>$ 300 mg/day—may lead to subclinical hypothyroidism and autoimmune thyroiditis.

Congenital Hypothyroidism

Because the clinical diagnosis of hypothyroidism in neonates is usually missed, universal newborn screening was introduced in 1974 and is now required by law. According to the National Newborn Screening and Genetics Resource Center (2008), 1 in 2500 newborns in the United States in 2007 had confirmed hypothyroidism. Developmental disorders of the thyroid gland such as agenesis and hypoplasia account for 80 to 90 percent of these cases (Topaloglu, 2006). The list of identified gene mutations that cause hypothyroidism continues to grow rapidly (Moreno and co-workers, 2008).

Early and aggressive thyroxine replacement is critical for infants with congenital hypothyroidism. Still some infants identified by screening programs with severe congenital hypothyroidism who were treated promptly will exhibit cognitive deficits into adolescence (Song and associates 2001). Therefore, the severity of congenital hypothyroidism, rather than timing of treatment, is an important factor in long-term cognitive outcomes

(Kempers and colleagues, 2006). Olivieri and colleagues (2002) reported that 8 percent of 1420 infants with congenital hypothyroidism also had other major congenital malformations.

Postpartum Thyroiditis

Transient autoimmune thyroiditis is consistently found in 5 to 10 percent of women during the first year after childbirth (Amino and colleagues, 2000; Dayan and Daniels, 1996). The propensity for thyroiditis antedates pregnancy and is directly related to increasing serum levels of thyroid autoantibodies. Women with high antibody titers in early pregnancy commonly are affected (Pearce and co-workers, 2003). Up to 25 percent of women with type 1 diabetes develop postpartum thyroid dysfunction (Alvarez-Marfany and associates, 1994). In some women with quiescent Graves disease, recurrent postpartum hyperthyroxinemia may be stimulated by thyroid destruction (Iitaka and co-workers, 2004).

Clinical Manifestations

In clinical practice, postpartum thyroiditis is diagnosed infrequently because it typically develops months after delivery and has vague and nonspecific symptoms. They often may be ascribed to the stresses of motherhood (Stagnaro-Green and Glinoer, 2004). The two recognized clinical phases of postpartum thyroiditis are summarized in Table 53-5. Between 1 and 4 months after delivery, approximately 4 percent of all women develop transient *destruction-induced thyrotoxicosis* from excessive release of hormone from glandular disruption (Lucas and colleagues, 2000). The onset is abrupt, and a small, painless goiter is commonly found. Although there may be many symptoms, only fatigue and palpitations are more frequent in thyrotoxic women compared with normal controls. The time course of this thyrotoxic phase usually is no longer than a few months and thionamides are ineffective. If symptoms are severe, a β-blocker may be given. Lucas and colleagues (2005) reported that all women with a purely hyperthyroid form of postpartum thyroiditis normalized and remained euthyroid.

Between 4 and 8 months postpartum, 2 to 5 percent of all women develop *hypothyroidism* from thyroiditis (Amino and colleagues, 2000). From thyroiditis onset, hypothyroidism can develop within one month. Thyromegaly and other symptoms are common and more prominent than during the thyrotoxic phase. Thyroxine replacement is typically given for 6 to 12 months, and the dose ranges from 25 to 75 μg/day.

Overall, women who experience either type of postpartum thyroiditis have approximately a 30-percent risk of eventually developing permanent hypothyroidism with an annual progression rate of 3.6 percent (Lucas, 2005; Muller, 2001; Premawardhana, 2000, and all their associates). Others may develop subclinical disease, but half of those with thyroiditis who are positive for peroxidase antibodies develop permanent hypothyroidism by 6 to 7 years.

An association between postpartum thyroiditis and postpartum depression has been proposed but remains unresolved. Lucas and co-workers (2001) found a 1.7-percent incidence of postpartum depression at 6 months in women with thyroiditis as well as in controls**.** Pederson and colleagues (2007) found a significant correlation between abnormal scores on the Edinburgh Postnatal Depression Scale and total thyroxine values in the low normal range during pregnancy in 31 women. Kuijpens and associates (2001) reported that thyroid peroxidase antibodies were a marker for postpartum depression in euthyroid women.

Nodular Thyroid Disease

Management of a palpable thyroid nodule during pregnancy depends on the stage of gestation. Small nodules detected by sensitive sonographic methods are common during pregnancy in some populations. For example, Kung and associates (2002) used high-resolution sonography and found that 15 percent of Chinese women had nodules larger than 2 mm. Almost half were multiple, and the nodules usually enlarged modestly across pregnancy and did not regress postpartum. Biopsy of those > 5 mm^3 that persisted at 3 months usually showed nodular hyperplasia, and none was malignant. In some studies, however, up to 40 percent of solitary nodules were malignant (Doherty and

TABLE 53-5. Clinical Phases of Postpartum Thyroid

	Phase of Postpartum Thyroiditis	
Factor	**Thyrotoxicosis**	**Hypothyroidism**
Onset	1–4 months	4–8 months
Incidence	4 percent	2–5 percent
Mechanism	Destruction-induced hormone release	Thyroid insufficiency
Symptoms	Small, painless goiter; fatigue, palpitations	Goiter, fatigue, inability to concentrate
Treatment	β-Blockers for symptoms	Thyroxine for 6–12 months
Sequelae	2/3 become euthyroid 1/3 develop hypothyroidism	1/3 permanently hypothyroid

co-workers, 1995; Rosen and Walfish, 1986). Even so, the majority were low-grade neoplasms.

Most recommend against *radioiodine scanning* in pregnancy, although tracer doses used are associated with minimal fetal irradiation (see Chap. 41, p. 921). *Sonographic* examination reliably detects nodules larger than 0.5 cm, and their solid or cystic nature also is determined. *Fine-needle aspiration* is an excellent method for assessment, and tumor markers and immunostaining are reliable to evaluate for malignancy (Bartolazzi and associates, 2001; Hegedüs, 2004).

Evaluation of thyroid cancer involves a multidisciplinary approach (American College of Obstetricians and Gynecologists, 2002). Most thyroid carcinomas are well differentiated and pursue an indolent course. Thus, some recommend that surgery be postponed until after delivery. Moosa and Mazzaferri (1997) studied 61 women with thyroid cancer diagnosed during pregnancy. In 75 percent, thyroidectomy was delayed until after delivery, and outcomes were similar to those in nonpregnant controls. In their reviews, Driggers and co-workers (1998) and Morris (1998) reported minimal fetal loss attributed to thyroid cancer surgery. We are of the view that thyroid surgery can be safely performed before 24 to 26 weeks. Surgery after this time *might* stimulate preterm labor.

PARATHYROID DISEASES

The function of *parathyroid hormone (PTH)* is to maintain extracellular fluid calcium concentration. This 115-amino acid hormone acts directly on bone and kidney and indirectly on small intestine through its effects on synthesis of vitamin D ($1,25(OH_2)D$) to increase serum calcium. Secretion is regulated by serum ionized calcium concentration through a negative feedback system. *Calcitonin* is a potent hypocalcemic parathyroid hormone that acts as a physiological parathyroid hormone antagonist. The interrelationships between these hormones and calcium metabolism, as well as *PTH-related protein* produced by fetal tissue, are discussed in Chapter 4 (p. 88).

Fetal calcium needs—300 mg/day in late pregnancy and a total of 30 g—as well as increased renal calcium loss from augmented glomerular filtration, substantively increase maternal calcium demands. Pregnancy is associated with a twofold increase in serum concentrations of 1,25-dihydroxyvitamin D, which increases gastrointestinal calcium absorption. This hormone is probably of placental and decidual origin because PTH levels are low normal or decreased during pregnancy (Molitch, 2000; Seely and colleagues, 1997). Total serum calcium levels decline with serum albumin concentrations, but ionized calcium levels remain unchanged (Dahlman and colleagues, 1994; Power and associates, 1999). Vargas Zapata and colleagues (2004), as well as others, have suggested a role for insulin-like growth factor-1 (IGF-1) in maternal calcium homeostasis and bone turnover, especially in mothers with low calcium intake.

Hyperparathyroidism

Hypercalcemia is caused by hyperparathyroidism or cancer in 90 percent of cases. Primary hyperparathyroidism is reported most often in women older than 50 (Miller and colleagues, 2008). Because many automated laboratory systems include serum calcium measurement, more cases are being detected (Mestman, 2002). It has a reported prevalence of 2 to 3 per 1000 women, but some have estimated the rate to be as high as 14 per 1000 when asymptomatic cases are included (Farford and colleagues, 2007; Schnatz and Thaxton, 2005). Almost 80 percent are caused by a solitary adenoma and another 15 percent by hyperfunction of all four glands. In the remainder, a malignancy and the cause of increased serum calcium are obvious. PTH produced by tumors is not identical to the natural hormone and may not be detected by routine assays.

In most patients, the serum calcium level is only elevated to within 1 mg/dL over the upper normal limit. This may help to explain why only 20 percent of those who have abnormally elevated levels are symptomatic (Bilezikian and Silverberg, 2004). In a fourth, however, symptoms become apparent when the serum calcium level continues to rise. *Hypercalcemic crisis* manifests as stupor, nausea, vomiting, weakness, fatigue, and dehydration.

Guidelines for management of asymptomatic hyperparathyroidism in nonpregnant patients were updated after a 2002 National Institutes of Health Workshop, reported by Bilezikian and Silverberg (2004). Based on long-term follow-up, indications for parathyroidectomy include a serum calcium level 1.0 mg/dL above the upper normal range, daily urine calcium excretion of 400 mg or more, reduced bone density, or age less than 50. Those not meeting these criteria should undergo semiannual calcium measurement.

Hyperparathyroidism in Pregnancy

In their review, Schnatz and Thaxton (2005) found fewer than 200 reported cases complicating pregnancy. As in nonpregnant patients, hyperparathyroidism is usually caused by a parathyroid adenoma. Cases of ectopic parathyroid hormone production and rare cases of parathyroid carcinoma have been reported (Montoro and colleagues, 2000). Symptoms include hyperemesis, generalized weakness, renal calculi, and psychiatric disorders. Occasionally, pancreatitis is the presenting finding (Dahan and Chang, 2001).

Pregnancy theoretically improves hyperparathyroidism because of significant calcium shunting to the fetus and augmented renal excretion (Power and colleagues, 1999). When the "protective effects" of pregnancy are withdrawn, however, there is significant danger of postpartum hypercalcemic crisis. Early reports described excessive stillbirths and preterm deliveries in pregnancies complicated by hyperparathyroidism (Shangold and associates, 1982). The more recent review by Schnatz and Thaxton (2005) cited above reported a 25-percent incidence of preeclampsia, however, other adverse effects were much less common.

Management in Pregnancy. If symptomatic, surgical removal of the parathyroid adenoma is preferable (Mestman, 2002). Elective neck exploration during pregnancy is usually well tolerated, even in the third trimester (Graham, 1998; Kort, 1999; Schnatz, 2005, and all their co-workers). In one woman,

a mediastinal adenoma was removed at 23 weeks (Rooney and co-workers, 1998).

If pregnant women are asymptomatic, they may be treated with oral phosphate, 1 to 1.5 g daily in divided doses. Serum calcium levels may decrease so that parathyroidectomy can be postponed until after delivery. For women with dangerously elevated serum calcium levels or those who are mentally obtunded with *hypercalcemic crisis*, emergency treatment is instituted. Diuresis with intravenous normal saline is begun so that urine flow exceeds 150 mL/hr. *Furosemide* is given in conventional doses to block tubular calcium reabsorption. Careful attention to prevent hypokalemia and hypomagnesemia is important. Adjunctive therapy includes *mithramycin,* which inhibits bone resorption; *calcitonin,* which decreases skeletal calcium release; and oral phosphorus.

Neonatal Effects. Normally, cord blood calcium levels are higher than maternal levels. With maternal hyperparathyroidism, abnormally elevated maternal and thence fetal levels further suppress fetal parathyroid function. Because of this, after birth, there is a rapidly decreasing newborn calcium level and 15 to 25 percent of these infants develop severe hypocalcemia with or without tetany (Molitch, 2000). Neonatal tetany or seizures should stimulate a search for maternal hyperparathyroidism (Beattie, 2000; Ip, 2003; Jaafar, 2004, and all their associates).

Hypoparathyroidism

The most common cause of hypocalcemia is hypoparathyroidism that usually follows parathyroid or thyroid surgery. Hypoparathyroidism is estimated to follow up to 7 percent of total thyroidectomies (Shoback, 2008). It is a rare condition, characterized by spasms of the facial muscles, muscle cramps, and paresthesias of the lips, tongue, fingers and feet. Chronically hypocalcemic pregnant women may have a fetus with skeletal demineralization resulting in multiple bone fractures in the neonatal period (Alikasifoglu and colleagues, 2005). Maternal treatment includes 1,25-dihydroxyvitamin D_3 (calcitriol), dihydrotachysterol, or large doses of vitamin D of 50,000 to 150,000 U/day; calcium gluconate or calcium lactate in doses of 3 to 5 g/day; and a diet low in phosphates. The fetal risks from large doses of vitamin D have not been established.

Pregnancy-Associated Osteoporosis

Even with remarkably increased calcium requirements, it is uncertain whether pregnancy causes osteopenia in most women (Kaur and associates, 2003; To and co-workers, 2003). In one study, Naylor and colleagues (2000) evaluated longitudinal bone mineral density change in 16 women during pregnancy. They documented loss of bone density in trabecular bone, but an increase in cortical bone sites. From their review, Thomas and Weisman (2006) cite a 3-to 4-percent average reduction in bone-mineral density during pregnancy. Feigenberg and associates (2008) found cortical bone mass reductions using ultrasound in young primiparas in the puerperium compared with nulligravid controls. Rarely, some women develop idiopathic osteoporosis while pregnant or lactating. Its incidence is estimated to be 4 per million women (Hellmeyer and colleagues, 2007).

The most common symptom of osteoporosis is back pain in late pregnancy or postpartum. Other symptoms are hip pain, either unilateral or bilateral, and difficulty in weight bearing (Dunne and colleagues, 1993; Smith and associates, 1995). In more than half of women, no apparent reason for osteopenia is found. Some known causes include heparin, prolonged bed rest, and corticosteroid therapy (Cunningham, 2005; von Mandach and co-workers, 2003). In a few cases, overt hyperparathyroidism or thyrotoxicosis eventually develops.

Treatment is problematical, but most clinicians recommend calcium and vitamin D supplementation. Long-term follow-up indicates that although bone density improves, these women, as well as their offspring, may have chronic osteopenia (Carbone and colleagues, 1995).

ADRENAL GLAND DISORDERS

Pregnancy has profound effects on adrenal cortical secretion and its control or stimulation. These interrelationships are discussed in detail in Chapter 5 (p. 129).

Pheochromocytoma

These tumors are common findings at autopsy but are infrequently diagnosed. Only 0.1 percent of hypertensive patients have a pheochromocytoma. These chromaffin tumors secrete catecholamines and usually are located in the adrenal medulla, although 10 percent are located in sympathetic ganglia. They are called the *10-percent tumor* because approximately 10 percent are bilateral, 10 percent are extra-adrenal, and 10 percent are malignant. There is an association with medullary thyroid carcinoma and hyperparathyroidism in some of the autosomally dominant or recessive *multiple endocrine neoplasia syndromes* as well as in neurofibromatosis and von Hippel-Lindau disease.

Symptoms are usually paroxysmal and manifest as hypertensive crisis, seizure disorders, or anxiety attacks. Hypertension is sustained in 60 percent of patients, but half of these also have paroxysmal crises. Other symptoms during paroxysmal attacks are headaches, profuse sweating, palpitations, chest pain, nausea and vomiting, and pallor or flushing.

The standard screening test is quantification of catecholamine metabolites in a 24-hour urine specimen (Keely, 1998). Diagnosis is established by measurement of a 24-hour urine collection with at least two of three assays for free catecholamines, metanephrines, or vanillylmandelic acid (VMA). Determination of plasma catecholamine levels may be accurate but is associated with technical difficulties (Conlin, 2001; Lenders and associates, 2002). Boyle and colleagues (2007) determined that measurement of urinary free metanephrine was superior to assessment of a VMA or urinary or plasma catecholamine level in 159 outpatients undergoing evaluation for pheochromocytoma. In nonpregnant patients, adrenal localization is usually successful with either computed tomography (CT) or magnetic resonance (MR) imaging. Occasionally ^{131}I-metaiodobenzylguanidine (MIBG) scanning is necessary to locate extra-adrenal tumors. For most cases, preferred treatment is laparoscopic adrenalectomy (Lal and Duh, 2003).

TABLE 53-6. Outcomes of Pregnancies Complicated by Pheochromocytoma and Reported in Two Contiguous Epochs

	Incidence in Percent	
Factor	1980–1987[a] (n = 48)	1988–1997[b] (n = 42)
Diagnosis		
Antepartum	51	83
Postpartum	36	14
Autopsy	12	2
Maternal mortality	16	4
Fetal wastage	26	11

[a]Data from Harper and colleagues (1989).
[b]Data from Ahlawat and associates (1999).

Pheochromocytoma Complicating Pregnancy

These tumors are rare but dangerous complications of pregnancy. Geelhoed (1983) cited an earlier review of 89 cases in which 43 mothers died. Maternal death was much more common if the tumor was not diagnosed antepartum—58 versus 18 percent. As seen in Table 53-6, with modern management, maternal mortality rates decreased from 16 to 4 percent, and maternal deaths are rare when the diagnosis is made antepartum.

Diagnosis is similar to that for nonpregnant patients. MR imaging is considered the radiological technique of choice during pregnancy because it almost always locates adrenal and extra-adrenal pheochromocytomas, such as that shown in Figure 53-4 (Manger, 2005). In many cases, the principal challenge is to differentiate preeclampsia from the hypertensive crisis caused by pheochromocytoma. Also, as in nonpregnant patients, there are individual considerations. For example, one postpartum woman described by Ahn and associates (2003) presented with dilated cardiomyopathy. Grimbert and colleagues (1999) diagnosed two pheochromocytomas during 56 pregnancies in 30 women with *von Hippel-Lindau disease*. Bassoon-Zaltzman and associates (1995) described a normotensive 20-week pregnant woman with intermittent ventricular tachycardia caused by a bladder pheochromocytoma.

FIGURE 53-4 Coronal magnetic resonance image taken in a 32-week pregnant woman shows a right-sided pheochromocytoma (*arrow*) and its position relative to the liver.

Management. Immediate control of hypertension and symptoms with an α-adrenergic blocker such as *phenoxybenzamine* is imperative. The dose is 10 to 30 mg, two to four times daily. After α-blockade is achieved, β-blockers may be given for tachycardia if necessary. In many cases, surgical exploration and tumor removal are performed during pregnancy (Miller and associates, 2005). Successful laparoscopic removal of adrenal tumors prior to 24 weeks has been reported (Janetschek, 1998; Junglee, 2007; Kim, 2006, and all their colleagues). When diagnosed later in pregnancy, either planned cesarean delivery with excision or postpartum tumor resection is appropriate.

Recurrent tumors are troublesome, and even with good blood pressure control, dangerous peripartum hypertension may develop. We have cared for three women in whom recurrent pheochromocytoma was identified during pregnancy. Hypertension was managed with phenoxybenzamine in all three. Two infants were healthy, but a third was stillborn in a mother with a massive tumor burden who was receiving phenoxybenzamine, 100 mg daily. In all three women, tumor resection was done postpartum. One woman died of persistent metastases several years later.

Cushing Syndrome

The most common cause of Cushing syndrome is long-term corticosteroid treatment. Cases of endogenous Cushing syndrome are typically due to *Cushing disease*, which is bilateral

adrenal hyperplasia stimulated by corticotropin-producing pituitary adenomas. Most are microadenomas smaller than 1 cm, and half are 5 mm or less. Rarely, abnormal secretion of hypothalamic corticotropin-releasing factor may cause corticotropic hyperplasia. Hyperplasia may also be caused by nonendocrine tumors that produce polypeptides similar to either corticotropin-releasing factor or corticotropin. Approximately a fourth of cases of Cushing syndrome are corticotropin-independent, and most of these are caused by an adrenal adenoma. Tumors are usually bilateral, and half are malignant. Occasionally, androgen excess may lead to severe virilization (Danilowicz and colleagues, 2002).

The typical body habitus is caused by adipose tissue deposition that characteristically results in *moon facies,* a *buffalo hump,* and *truncal obesity*. Fatigability and weakness, hypertension, hirsutism, and amenorrhea are each encountered in 75 to 85 percent of nonpregnant patients (Williams and Dluhy, 2001). Personality changes, cutaneous striae, and easy bruisability are common, and approximately 20 percent have nephrolithiasis. Diagnosis is verified by elevated plasma cortisol levels that cannot be suppressed by dexamethasone or by elevated 24-hour urine free cortisol excretion (Boscaro and colleagues, 2001). Neither test is totally accurate, and both are more difficult to interpret in obese patients. CT and MR imaging are used to localize pituitary and adrenal tumors or hyperplasia.

Pregnancy

Because most women have corticotropin-dependent Cushing syndrome, associated androgen excess may cause anovulation, and pregnancy is rare. In their review, Lindsay and colleagues (2005) identified fewer than 150 cases of Cushing syndrome in pregnancy. Kamiya and colleagues (1998) summarized 97 cases from the Japanese literature. The distribution of causes is different in pregnant women, and corticotropin-independent adrenal lesions account for approximately half of cases (Klibanski and co-workers, 2006). Indeed, most cases in the reviews cited were caused by adrenal tumors, of which 80 percent were benign. These reports stressed difficulties in diagnosis because of pregnancy-induced increases in plasma cortisol, corticotropin, and corticotropin-releasing factor. Measurement of 24-hour urinary free cortisol excretion is recommended, with consideration for normal elevation in pregnancy.

Pregnancy outcomes in women with Cushing syndrome are listed in Table 53-7. Heart failure is common during pregnancy and is a major cause of maternal mortality (Buescher and associates, 1992).

TABLE 53-7. Perinatal Complications in Pregnancies Complicated by Cushing Syndrome

Complication	Approximate Incidence in Percent
Maternal	
Hypertension	68
Diabetes	25
Preeclampsia	15
Osteoporosis/fracture	5
Psychiatric disorders	4
Cardiac failure	3
Mortality	2
Perinatal	
Fetal-growth restriction	21
Preterm delivery	43
Stillbirth	6
Neonatal death	2

Data from Lindsay and colleagues (2005).

Management

Long-term medical therapy for Cushing syndrome usually is ineffective, and definitive therapy is resection of the pituitary or adrenal adenoma or bilateral adrenalectomy for hyperplasia. During pregnancy, management of hypertension in mild cases may suffice until delivery. In their review, Lindsay and associates (2005) described primary medical therapy in 20 women with Cushing syndrome. Most were successfully treated with *metyrapone* as an interim treatment until definitive surgery was possible after delivery. A few cases were treated with oral *ketoconazole*, but because it also blocks testicular steroidogenesis, treatment during pregnancy with a male fetus is worrisome. *Mifepristone,* the norethindrone derivative used for abortion and labor induction, has shown promise for treating Cushing disease but should not be used in pregnancy. If necessary, pituitary adenomas can be treated by transsphenoidal resection (Boscaro and colleagues, 2001; Lindsay and associates, 2005). Removal of an adrenal adenoma in pregnancy can also be curative (Kamiya and colleagues, 1998; Keely, 1998).

Adrenal Deficiency

Primary adrenocortical insufficiency—*Addison disease*—is rare. More than 90 percent of the glands must be destroyed for symptoms to develop. *Idiopathic autoimmune adrenalitis* has surpassed tuberculosis and histoplasmosis as the most frequent cause. There is an increased incidence of concurrent Hashimoto thyroiditis, premature ovarian failure, type 1 diabetes, and Graves disease. These *polyglandular autoimmune syndromes* also include pernicious anemia, vitiligo, alopecia, nontropical sprue, and myasthenia gravis.

Adrenal Insufficiency and Pregnancy

Untreated adrenal hypofunction frequently causes infertility, but with replacement therapy, ovulation is restored. If untreated, common symptoms include weakness, fatigue, nausea and vomiting, and weight loss (Mestman, 2002). Because serum cortisol levels are increased during pregnancy, the finding of a low value should prompt an adrenocorticotropic hormone (ACTH) stimulation test to document the lack of response to infused corticotropin (Salvatori, 2005).

There are a few reports of hypoadrenalism complicating pregnancy. Successful pregnancy outcomes have been described in women diagnosed with adrenal insufficiency and treated before conception (Adonakis and colleagues, 2005; Ozdemir and associates, 2004). Most pregnant women with Addison disease are

already taking cortisone-like drugs. These should be continued, and women are observed for evidence of either inadequate or excessive steroid replacement. During labor, delivery, and postpartum, or after a surgical procedure, corticosteroid replacement must be increased appreciably to approximate the normal adrenal response—so-called *stress doses.* Hydrocortisone, 100 mg, is usually given intravenously every 8 hours. It is important that shock from causes other than adrenocortical insufficiency—for example, hemorrhage or sepsis—be recognized and treated promptly.

Primary Aldosteronism

Hyperaldosteronism is caused by an adrenal aldosteronoma in approximately 75 percent of cases, and idiopathic bilateral adrenal hyperplasia in the remainder (Ganguly, 1998). Findings include hypertension, hypokalemia, and muscle weakness. High serum or urine levels of aldosterone confirm the diagnosis.

Pregnancy and Hyperaldosteronism

Progesterone blocks aldosterone action, thus, there are very high levels of aldosterone in normal pregnancy (see Chap. 5, p. 129 and Appendix). Accordingly, there may be amelioration of symptoms and of electrolyte abnormalities during pregnancy (Murakami and associates, 2000). Medical management includes potassium supplementation and antihypertensive therapy. In many cases, hypertension responds to *spironolactone,* but β-blockers or calcium-channel blockers may be preferred because of the potential fetal antiandrogenic effects of the diuretic. Deruelle and colleagues (2004) reported successful use of *amiloride* in a pregnant woman. Tumor resection is curative, and laparoscopic adrenalectomy during the second trimester has been shown to be safe (Baron and associates, 1995; Kosaka and colleagues, 2006). Two women described by Nezu and co-workers (2000) were normotensive throughout pregnancy but were found to have an aldosteronoma postpartum after severe hypertension developed.

PITUITARY DISEASES

There is normal pituitary enlargement during pregnancy, predominately from lactotrophic cellular hyperplasia induced by estrogen stimulation (see Chap. 5, p. 126).

Prolactinomas

These adenomas are found relatively commonly since the advent of widely available assays for serum prolactin. Symptoms and findings include amenorrhea, galactorrhea, and hyperprolactinemia. Tumors are classified arbitrarily by their size measured by CT or MR imaging. A microadenoma is ≤ 10 mm, and a macroadenoma is > 10 mm. Treatment for microadenomas is usually with bromocriptine, a dopamine agonist and powerful prolactin inhibitor, which frequently restores ovulation. For suprasellar macroadenomas, most recommend surgical resection before pregnancy is attempted (Schlechte, 2007).

Prolactinomas and Pregnancy

In almost 250 pregnant women with previously untreated *microadenomas*, only four developed symptomatic enlargement during pregnancy (Molitch, 1985). Another 11 who remained asymptomatic had radiographic evidence of enlargement. Although the risk of tumor enlargement during pregnancy is less than 2 percent with microadenomas, symptomatic enlargement of *macroadenomas* is more common. For example, 15 to 35 percent of suprasellar macroadenomas have tumor enlargement that causes visual disturbances, headaches, and diabetes insipidus (Schlechte, 2007). Visual loss during pregnancy was described by Kupersmith and colleagues (1994) in six of eight women with macroadenomas.

Gillam and colleagues (2006) recommend that pregnant women with microadenomas be queried regularly for headaches and visual symptoms. Those with macroadenomas should have visual field testing during each trimester. CT or MR imaging is recommended only if symptoms develop. Serial serum prolactin levels are not recommended because of normal increases during pregnancy. Symptomatic tumor enlargement is treated immediately with bromocriptine, but macroprolactinomas may be relatively resistant (Shanis and Check, 1996). More than 6000 pregnant women have taken bromocriptine at some time during pregnancy, and there have been no adverse effects (Molitch, 2001). Surgery is recommended for women with no response. Gondim and colleagues (2003) have described transnasal transseptal endoscopic resection.

Acromegaly

This is caused by excessive growth hormone, usually from an acidophilic or a chromophobic pituitary adenoma. In normal pregnancy, pituitary growth hormone levels decrease as placental epitopes are secreted. Diagnosis is confirmed by the failure of an oral glucose tolerance test to suppress pituitary growth hormone (Melmed, 2006). Pregnancy is rare in women with acromegaly, possibly because half are hyperprolactinemic.

Management is similar to that for prolactinomas, with close monitoring for symptoms of tumor enlargement. Bromocriptine is not as effective as it is for prolactinomas, and surgery may be necessary for symptomatic tumor enlargement during pregnancy (Prager and Braunstein, 1995). Guven and associates (2006) reported a case of pituitary apoplexy necessitating emergent transsphenoidal adenomectomy and cesarean delivery at 34 weeks. Successful treatment of pregnant women with the somatostatin-receptor ligand, *octreotide,* and with the GH-analog, *pegvisomant,* has been reported (Brian, 2007; Herman-Bonert, 1998; Neal, 2000, and all their colleagues).

Diabetes Insipidus

The vasopressin deficiency evident in diabetes insipidus is usually due to a hypothalamic or pituitary stalk disorder rather than to a pituitary lesion (Lamberts and associates, 1998). True diabetes insipidus is a rare complication of pregnancy. Only a few cases have been cared for in the last 50 years at Parkland Hospital, during which time there were nearly 400,000 deliveries.

Therapy for diabetes insipidus is intranasal administration of *desmopressin,* the synthetic analog of vasopressin—1-deamino-8-D-arginine vasopressin (DDAVP). Ray (1998)

reviewed 53 cases in which DDAVP was used during pregnancy with no adverse sequelae. Most women require increased doses during pregnancy because of an increased metabolic clearance rate stimulated by placental vasopressinase (Lindheimer and Barron, 1994). By this same mechanism, *subclinical diabetes insipidus* may become symptomatic or cases of *transient diabetes insipidus* may be encountered during pregnancy (Brewster and Hayslett, 2005; Krege and associates, 1989).

In our experience, transient secondary diabetes insipidus is more likely encountered with *acute fatty liver of pregnancy* (see Chap. 50, p. 1064). This probably is due to altered vasopressinase clearance because of hepatic dysfunction. Harper and associates (1987) described transient disease in a 38-week pregnant woman with biopsy-proven viral hepatitis. Another cause of diabetes insipidus is pituitary infarction with severe obstetrical hemorrhage as described below.

Sheehan Syndrome

Sheehan (1937) reported that pituitary ischemia and necrosis associated with obstetrical blood loss could result in hypopituitarism. With modern methods of treatment for hemorrhagic shock, Sheehan syndrome is now seldom encountered (Feinberg and associates, 2005; Vaphiades and colleagues, 2003). It has also been reported with infarction of a macroadenoma (Kaiser, 2001). A recently encountered case at Parkland Hospital is shown in **Figure 53-5**. Another case caused by hemorrhage and necrosis of lymphocytic hypophysitis was described by Lee and Pless (2003). With acute hemorrhage, affected women may have persistent hypotension, tachycardia, hypoglycemia, and failure of lactation. Subsequent deficiencies of some or all pituitary responsive hormones may develop. For example, as discussed above, diabetes insipidus with or without anterior pituitary deficiency has been described following massive obstetrical hemorrhage and prolonged shock (Kan and Calligerous, 1998). In 20 cases of Sheehan syndrome from Turkey reported by Dökmetas and associates (2006), latency between hemorrhage and onset of symptoms varied from 2 to 40 years.

Lymphocytic Hypophysitis

This autoimmune pituitary disorder is characterized by massive infiltration by lymphocytes and plasma cells with parenchymal destruction of the gland. Most cases are temporarily linked to pregnancy (Caturegli and associates, 2005**;** Madsen, 2000). There are varying degrees of hypopituitarism or symptoms of mass effect, including headaches and visual field defects. A sellar mass is seen with CT or MR imaging. A mass accompanied by a modestly elevated serum prolactin level—usually < 100 pg/mL—suggests lymphocytic hypophysitis, whereas levels > 200 pg/mL are encountered with a prolactinoma. Associated hypothyroidism is common. Pressman and colleagues (1995) reviewed 44 cases and found that 25 percent had other autoimmune diseases. Treatment is with hormone replacement, but the disease may be self-limited (Gagneja and associates, 1999). Surgery during pregnancy is warranted only in cases of severe chiasmal compression unresponsive to corticosteroid therapy (Lee and Pless, 2003).

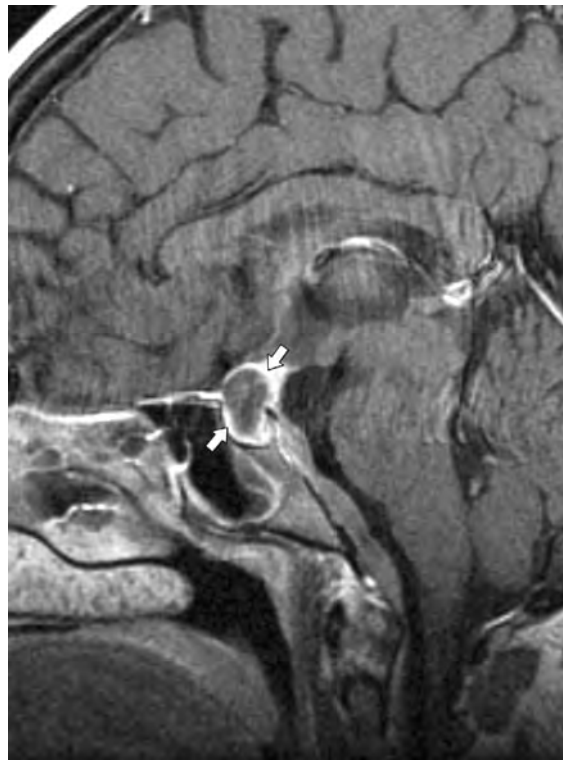

FIGURE 53-5 Sheehan syndrome in 23-year-old primipara who had major postpartum hemorrhage and hypotension intraoperatively with cesarean delivery. Magnetic resonance imaging was obtained because she failed to lactate, and her serum prolactin level was 18 ng/mL. Sagittal magnetic resonance (MR) image shows a large pituitary gland mass (*arrows*) consistent with hemorrhage. Follow-up MR imaging showed complete involution of the hematoma.

CHAPTER 54

Connective-Tissue Disorders

IMMUNE-MEDIATED CONNECTIVE-TISSUE DISEASES . . . 1145
SYSTEMIC LUPUS ERYTHEMATOSUS (SLE) 1146
ANTIPHOSPHOLIPID ANTIBODIES 1151
RHEUMATOID ARTHRITIS 1155
SYSTEMIC SCLEROSIS (SCLERODERMA) 1157
VASCULITIS SYNDROMES 1158
DERMATOMYOSITIS AND POLYMYOSITIS 1159
INHERITED CONNECTIVE-TISSUE DISORDERS 1159

Connective-tissue disorders, also referred to as *collagen-vascular disorders*, cause a variety of generalized clinical findings and are characterized by autoantibody-mediated connective-tissue abnormalities. These are also called *immune-complex diseases* because many involve deposition of immune complexes in specific organ or tissue sites. Some of these disorders are characterized by sterile inflammation, especially of the skin, joints, blood vessels, and kidneys, and are referred to as *rheumatic diseases*. For inexplicable reasons, many rheumatic diseases primarily affect women. Another major category of connective-tissue diseases includes inherited disorders of bone, skin, cartilage, blood vessels, and basement membranes. Examples include Marfan syndrome, osteogenesis imperfecta, and Ehlers-Danlos syndrome.

Relative to future pregnancies, hemopoietic stem-cell transplantation is becoming accepted therapy for severe autoimmune diseases that include systemic lupus erythematosus, systemic sclerosis, rheumatoid arthritis, and vasculitis. According to Marmont (2008), randomized clinical trials have been launched by the European Group of Blood and Marrow Transplantation (EBMT). At this time, however, even tentative conclusions are not yet available.

IMMUNE-MEDIATED CONNECTIVE-TISSUE DISEASES

Although the pathogenesis has not been elucidated, immune-mediated disorders can be separated into those clearly associated with and those without autoantibody formation. So-called *rheumatoid factor* is an autoantibody found in many autoimmune inflammatory conditions. Those associated with rheumatoid factor include systemic lupus erythematosus, rheumatoid arthritis, systemic sclerosis (scleroderma), mixed connective-tissue disease, dermatomyositis, polymyositis, and a variety of vasculitis syndromes. In contrast, the *seronegative spondyloarthropathies* do not display rheumatoid factor, but are strongly associated with the presence of the HLA-B27 antigen (Benjamin and Parham, 1992; Moll, 1994). These include ankylosing spondylitis, psoriatic arthritis, Reiter disease, and likely the arthritis syndromes associated with ulcerative colitis and Crohn disease.

Because renal involvement is common and often adversely affects pregnancy, a search for coexisting renal involvement is paramount. Hypertension likewise is common, and exacerbation during pregnancy frequently forces early delivery (Wolfberg and colleagues, 2004). In some of these immune-mediated diseases, *antiphospholipid antibodies* are formed that can cause injury to maternal vasculature and to the placenta.

Immunological Aspects

The immune system is designed to protect cells, tissues, and organs perceived as *self*, and to attack and destroy foreign or *nonself* antigenic material by the production of antibodies. This protection has two phases. The first is the *innate phase*, which is broad and rapid and is mediated through neutrophils,

macrophages, and complement. The second is the *adaptive phase*, which is precise and is caused by antigen-specific reactions through T and B lymphocytes that result in memory for future exposures (Parkin and Cohen, 2001).

For some as yet unknown reason, the immune system may be stimulated to begin producing antibodies directed against self or normal tissues. These "misdirected" antibodies are called *autoantibodies*. The stimulus responsible for their production is unknown, but may be due to bacterial or viral injury to genetically susceptible tissues.

Autoantibodies induce destruction by at least two mechanisms. The *cytotoxic mechanism* involves direct antibody attachment to a specific surface antigen, which results in cell injury or destruction. The *immune-complex mechanism* results in tissue damage when an antigen-antibody complex attaches to a susceptible tissue. The complex may then incite a complement response or *cascade*, resulting in the release of chemotactic substances that attract polymorphonuclear cells.

The *major histocompatibility complex (MHC)* is a series of 40 to 50 genes located on the short arm of chromosome 6, and is known as the *human leukocyte antigen (HLA)* complex. These genetic loci code for distinct cell-surface glycoproteins, including transplantation antigens, and are involved in self and nonself recognition. Class I antigens include HLA-A, -B, and -C. Class II antigens include HLA-DR, -DQ, and –DP. Through complex interactions that include T- and B-cell stimulation and interaction with immunoglobulins and the complement system, nonself antigens or, in the abnormal state, self antigens in normal tissue are destroyed.

Immune-Mediated Disease and Pregnancy

Very few immune disorders arise only during pregnancy. Maternal isoimmunization from fetal red cell or platelet antigens is the most common (see Chap. 29, p. 618). Some theories of the causes of preeclampsia-eclampsia (see Chap. 34, p. 709) and recurrent abortion (see Chap. 9, p. 225) implicate an immunological basis.

Some pregnancy-induced immune alterations may modulate connective-tissue disorders (see Chap. 5, p. 116). For example, one considered important is the predominance of T2 helper cells over the cytokine-producing T1 helper cells (Keeling and Oswald, 2009). Although it is generally thought that these immunological changes have negligible effects on immune-mediated collagen-vascular disorders, the effects of large amounts of estrogen, progesterone, and prolactin must be considered. For example, estrogens upregulate and androgens downregulate T-cell response, and a number of cytokines are regulated by sex hormones (Häupl and associates, 2008a; Refojo and colleagues, 2003). Progesterone is an immunosuppresive (Cutolo and co-workers, 2006). In addition, given that autoimmune rheumatic diseases mostly affect women, Lockshin (2002) postulates a modulating effect of hormones rather than a causative role. Østensen and Villiger (2007) suggest that the hormonal and immunological alterations in pregnancy may correct the altered immunoregulation in rheumatoid arthritis.

Fetal Cell Microchimerism

Fetal cells and DNA are present in maternal blood starting in the first trimester (Sitar and associates, 2005; Waldorf and Nelson, 2008). *Fetal cell microchimerism* is an intriguing phenomenon that has been used to help explain the predilection of autoimmune disorders for women (Adams and Nelson, 2004). By this putative mechanism, persistent fetal cells in the maternal circulation stimulate the production of autoantibodies that underlie some autoimmune conditions. In this scheme, fetal cells such as thymocytes become engrafted in maternal tissues, and "immortal" long-lived lymphocytes circulate. Lupus may therefore represent a chronic graft-versus-host response to transplacentally acquired fetal cells, which is also suggested for some thyroid diseases and systemic sclerosis (Artlett and associates, 1998; Jimenez and Artlett, 2005; Srivatsa and associates, 2001).

Women with lupus who have given birth to a male(e) have also been found to have male cells in every histologically abnormal tissue type, but not in normal tissue. Although this suggests that fetal cells may be associated with lupus, it is unclear if this causes or is an effect of disease progression or if it even is unrelated (Johnson and colleagues, 2001). Microchimerism with rheumatoid arthritis-associated HLA alleles has also been described in women with rheumatoid arthritis compared with nonaffected controls (Rak and co-workers, 2009). Interestingly, microchimeric cells may play a beneficial role by helping to repair damaged or diseased tissue (Barinaga, 2002).

SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)

Lupus is a heterogeneous autoimmune disease with a complex pathogenesis that results in interactions between susceptibility genes and environmental factors that cause an abnormal immune response (Hahn, 2008). Immune system abnormalities include overactive B lymphocytes that are responsible for autoantibody production. These result in tissue and cellular damage when autoantibodies or immune complexes are directed at one or more cellular nuclear components (Tsokos, 2001). Some autoantibodies produced in patients with lupus are shown in **Table 54-1**.

Almost 90 percent of cases of lupus are in women, and its prevalence in those of childbearing age is about 1 in 500 (Lockshin and Sammaritano, 2000). Because of this, the disease is encountered relatively frequently during pregnancy. The 15-year survival rate is 80 percent (Rahman and Isenberg, 2008). Infection, lupus flares, end-organ failure, hypertension, strokes, and cardiovascular disease account for most deaths.

Genetic influences are implicated by a higher concordance with monozygotic compared with dizygotic twins—25 versus 2 percent, respectively, and a 10-percent frequency in patients with one affected family member. The relative risk of disease is increased if there is inheritance of the "autoimmunity gene" on chromosome 16 that predisposes to SLE, rheumatoid arthritis, Crohn disease, and psoriasis (Hahn, 2008). Other susceptibility genes include HLA-A1, B8, DR3, and DRB1; IRF5; and STAT 4 as well as others (Hom and associates, 2008; Rahman and Isenberg, 2008).

Clinical Findings

Lupus is notoriously variable in its presentation, course, and outcome (Rahman and Isenberg, 2008). Clinical manifestations may be confined initially to one organ system, with others

TABLE 54-1. Some Autoantibodies Produced in Patients with Systemic Lupus Erythematosus (SLE)

Antibody	Prevalence (percent)	Clinical Associations
Antinuclear (ANA)	84–98	Best screening test, multiple antibodies; a second negative test makes SLE unlikely
Anti-double-stranded (ds)-DNA	62–70	High titers SLE-specific; may correlate with nephritis and vasculitis activity
Anti-Sm	30–38	Specific for SLE
Anti-RNP	33–40	Not SLE specific, correlates with myositis, esophageal dysmotility; a defining antibody for mixed-connective tissue disease
Anti-Ro (SS-A)	30–49	Not SLE specific; associated with Sjögren syndrome, cutaneous lupus, ANA-negative lupus, neonatal lupus with heart block
Anti-La (SS-B)	10–35	Present in SLE—possibly decreased risk of nephritis; Sjögren syndrome, neonatal lupus with heart block
Antihistone	70	Common in drug-induced lupus (95%)
Antiphospholipid	21–50	Lupus anticoagulant and anticardiolipin antibodies associated with thrombosis, fetal loss, thrombocytopenia, valvular heart disease; false-positive test for syphilis
Antierythrocyte	60	Overt hemolysis uncommon
Antiplatelet	30	Thrombocytopenia in 15%; poor clinical test

Data from Arbuckle and colleagues (2003), Hahn (2008), and Shmerling (2003).

becoming involved as the disease progresses (Table 54-2). Alternatively, lupus may initially manifest by multisystem involvement. Common findings are malaise, fever, arthritis, rash, pleuropericarditis, photosensitivity, anemia, and cognitive dysfunction. At least half of patients have renal involvement. *Libman-Sacks endocarditis* was described with lupus but likely is due to presence of subsequently discussed anticardiolipin antibodies (Hojnik and associates, 1996). These valvular lesions may cause thromboembolic seeding but uncommonly lead to hemodynamic dysfunction (Moyssakis and colleagues, 2002). There is also evidence that lupus is associated with decline in attention, memory, and reasoning (Kozora and associates, 2008).

Laboratory Findings

Identification of antinuclear antibodies (ANA) is the best screening test, however, a positive test result is not specific for lupus. For example, low titers are found in normal individuals, other autoimmune diseases, acute viral infections, and chronic inflammatory processes. Several drugs can also cause a positive

TABLE 54-2. Clinical Manifestations of Systemic Lupus Erythematosus

Organ System	Clinical Manifestations	Percent
Systemic	Fatigue, malaise, fever, weight loss	95
Musculoskeletal	Arthralgias, myalgias, polyarthritis, myopathy	95
Hematological	Anemia, hemolysis, leukopenia, thrombocytopenia, lupus anticoagulant, splenomegaly	85
Cutaneous	Malar (butterfly) rash, discoid rash, photosensitivity, oral ulcers, alopecia, skin rashes	80
Neurological	Cognitive dysfunction, mood disorder, headache, seizures	60
Cardiopulmonary	Pleuritis, pericarditis, myocarditis, pneumonitis, Libman-Sacks endocarditis, pulmonary hypertension	60
Renal	Proteinuria, casts, nephrotic syndrome, renal failure	30–50
Gastrointestinal	Anorexia, nausea, pain, diarrhea	40
Vascular	Thrombosis: venous (10%), arterial (5%)	15
Ocular	Conjunctivitis	15

Modified from Hahn (2008), with permission.

reaction. Antibodies to double-stranded DNA (dsDNA) and to Smith (Sm) antigens are relatively specific for lupus, whereas other antibodies are not (see Table 54-1). More than 100 antigen-autoantibody pairs have been described in SLE (Sherer and coworkers, 2004).

Anemia is common, and there may be leukopenia and thrombocytopenia. Proteinuria and casts are found in the half of patients with glomerular lesions, and there may be renal insufficiency. Nephropathy is more common when antiphospholipid antibodies are found (Moroni and colleagues, 2004). Other laboratory findings include false-positive syphilis serology, prolonged partial thromboplastin time, and positive serum rheumatoid factor assay. Elevated serum D-dimer levels commonly follow a flare or infection, but unexplained persistent elevations are associated with a high risk for thrombosis (Wu and associates, 2008).

Diagnosis

The revised criteria of the American Rheumatism Association for diagnosis of systemic lupus are listed in Table 54-3. If any four or more of these 11 criteria are present, serially or simultaneously, the diagnosis of lupus is made.

Drug-Induced Lupus

Numerous drugs have been reported to induce a lupus-like syndrome. These include procainamide, quinidine, hydralazine, α-methyldopa, phenytoin, and phenobarbital. Drug-induced lupus is rarely associated with glomerulonephritis and usually regresses when the medication is discontinued (Rubin, 1997).

Lupus and Pregnancy

Of nearly 16.7 million pregnancies in the United States from 2000 to 2003, 13,555 were complicated by lupus—an incidence of approximately 1 in 1250 pregnancies (Clowse and associates, 2008). Over the past several decades, pregnancy outcomes in women with SLE have improved remarkably. Important factors for pregnancy outcome include whether disease is active at the beginning of pregnancy, age and parity, coexistence of other medical or obstetrical disorders, and whether antiphospholipid antibodies are detected (see p. 1151).

During pregnancy, lupus improves in a third of women, remains unchanged in a third, and worsens in the remaining third. Thus, in any given pregnancy, the clinical condition can worsen or *flare* without warning (Khamashta and colleagues, 1997). Petri (1998) reported a 7-percent risk of major morbidity during pregnancy. Common complications in a cohort of 13,555 women with SLE during pregnancy are shown in Table 54-4. The maternal mortality and morbidity rate was 325 per 100,000—a massively increased rate. **It is certain that lupus can be life threatening to both the mother and her fetus-infant.** In general, pregnancy outcome is better if:

- Lupus activity has been quiescent for at least 6 months before conception
- There is no active renal involvement manifest by proteinuria or renal dysfunction
- Superimposed preeclampsia does not develop
- There is no evidence of antiphospholipid antibody activity.

TABLE 54-3. The 1997 Revised Criteria of the American Rheumatism Association for Systemic Lupus Erythematosus (SLE)

Criteria[a]	Comments
Malar rash	Malar erythema
Discoid rash	Erythematous patches, scaling, follicular plugging
Photosensitivity	Exposure to UV light causes rash
Oral ulcers	Usually painless oral and nasopharyngeal ulcers
Arthritis	Nonerosive involving two or more peripheral joints
Serositis	Pleuritis or pericarditis
Renal disorder	Proteinuria greater than 0.5 g/day or > 3+ dipstick, or cellular casts
Neurological disorders	Seizures or psychosis without other cause
Hematological disorders	Hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia
Immunological disorders	Anti-dsDNA or anti-Sm antibodies, or false-positive VDRL, abnormal level of IgM or IgG anticardiolipin antibodies, or lupus anticoagulant
Antinuclear antibodies	Abnormal titer of ANAs

[a]If four or more criteria are present at any time during disease course, SLE can be diagnosed with 75-percent specificity and 95-percent sensitivity.
ANAs = antinuclear antibodies; dsDNA = double-stranded DNA; Sm = Smith; UV = ultraviolet; VDRL = Venereal Disease Research Laboratory.
From Hochberg (1997), with permission.

Lupus Nephritis

The prognosis for women with SLE and glomerulonephritis has improved remarkably over the past 30 years (Moroni and Ponticelli, 2005). Women with renal disease have a high incidence of gestational hypertension and preeclampsia, but if their disease remains in remission, they usually have good pregnancy outcomes (Huong, 2001; Moroni, 2002; Packham, 1992, and all their colleagues). Of the 125 pregnancies reported by Lockshin (1989), 63 percent of women with preexisting renal disease developed preeclampsia compared with only 14 percent of those without underlying renal disease. Moroni and Ponticelli (2005) reviewed results published between 1980 and 2003. Of a total of 309 pregnancies complicated by established lupus

TABLE 54-4. Complications in 13,555 Pregnancies in Women with Systemic Lupus Erythematosus

Complications	Percent
Comorbid illness	
Pregestational diabetes	5.6
Thrombophilia	4.0
Hypertension	3.9
Renal failure	0.2
Pulmonary hypertension	0.2
Pregnancy complications	
Preeclampsia	22.5
Preterm labor	20.8
Fetal-growth restriction	5.6
Eclampsia	0.5
Medical complications	
Anemia	12.6
Thrombocytopenia	4.3
Thrombotic—stroke, pulmonary embolism, deep-vein thrombosis	1.7
Infections—pneumonia, sepsis syndrome	2.2
Maternal morbidity-mortality rate	325/100,000

Data from Clowse and colleagues (2008).

nephritis, 30 percent suffered a flare, and 40 percent of these had associated renal insufficiency. The maternal mortality rate was 1.3 percent.

There are two recent studies describing pregnancy outcomes in women with lupus nephritis. Wagner and co-workers (2009) compared outcomes of 58 women cared for during 90 pregnancies at the Mayo Clinic. Active nephritis was associated with a significantly higher incidence of maternal complications—57 versus 11 percent—compared with women without nephritis. Quiescent nephritis had a nonsignificant effect on preeclampsia rates compared with lupus patients without renal impairment. The fetal death rate with active maternal nephritis was 35 compared with 9 percent in those with quiescent nephritis. Imbasciati and associates (2009) described outcomes in 113 pregnancies in 81 women with known lupus nephritis. During a third of pregnancies, there was a renal flare. Nine pregnancy were excluded to due miscarriage. Of the 104 remaining pregnancies, a third were delivered preterm, a third of infants weighed < 2500 g, and the perinatal mortality rate was 6 percent.

Most authorities recommend continuation of immunosuppressive therapy for nephritis during pregnancy. It is not clear whether the dosage should be increased peripartum. Although it is often stated that this is the time that activation or exacerbations are most likely to develop, the evidence is not conclusive.

Lupus versus Preeclampsia-Eclampsia

Chronic hypertension complicates up to 30 percent of pregnancies in women with SLE (Egerman and colleagues, 2005). Moreover, preeclampsia is common, and superimposed preeclampsia is encountered even more often in those with nephropathy and in women with antiphospholipid antibodies (Bertsias and associates, 2008). It may be difficult, if not impossible, to differentiate lupus nephropathy from severe preeclampsia if organs other than the kidney are not involved (Petri, 2007). We are of the view that decreased complement values or increased anti-DNA titers are not useful to identify worsening lupus activity in this setting. If identified, however, they reportedly support the diagnosis of a reactivation of lupus nephritis, termed *renal flare*. Central nervous system involvement with lupus may culminate in convulsions similar to those of eclampsia. Thrombocytopenia, with or without hemolysis, may further confuse the diagnosis because of its similarity to the hemolysis, elevated liver enzymes, low platelet count (HELLP) syndrome. Management is identical to that for preeclampsia-eclampsia, described in Chapter 34 (p. 728).

Management During Pregnancy

Management consists primarily of monitoring the maternal clinical and laboratory conditions as well as fetal well-being. Pregnancy-induced thrombocytopenia and proteinuria resemble lupus disease activity, and the identification of a lupus flare is confounded by the increase in facial and palmar erythema of normal pregnancy (Lockshin and Sammaritano, 2003). Some authorities have advocated a number of numerical scales to emphasize ongoing disease activity. Components are weighted for severity, both with the SLE-Pregnancy Disease Activity Index (SLEPDAI) and the Lupus Activity Index (Buyon and colleagues, 1999; Ruiz-Irastorza and associates, 2004).

Monitoring of lupus activity and identification of pending lupus flares by a variety of laboratory techniques has been recommended. The sedimentation rate may be misleading because of pregnancy-induced hyperfibrinogenemia. Serum complement levels are also normally increased in pregnancy (see Chap. 5, p. 116 and the Appendix.). And although falling or low levels of complement components C_3, C_4, and CH_{50} are more likely to be associated with active disease, higher levels provide no assurance against disease activation. Our experiences, as well as those of Varner and co-workers (1983) and Lockshin and Druzin (1995), are that there is no correlation between clinical manifestations of disease and complement levels.

Serial hematological studies may detect changes in disease activity. Hemolysis is characterized by a positive Coombs test, anemia, reticulocytosis, and unconjugated hyperbilirubinemia. Thrombocytopenia, leukopenia, or both may develop. According to Lockshin and Druzin (1995), chronic thrombocytopenia in early pregnancy may be due to *antiphospholipid antibodies*. Later, thrombocytopenia may indicate the onset of preeclampsia.

Serum transaminase activity reflects hepatic involvement, as does a rise in serum bilirubin. Azathioprine therapy also may induce enzyme elevations. Urine is tested frequently to detect new-onset or worsening proteinuria. Overt proteinuria that persists is an ominous sign, even more so if accompanied by other evidence of the nephrotic syndrome or abnormal serum creatinine levels.

The fetus should be closely observed for adverse effects. Fetal growth is monitored, and careful attention is given to the development of hypertension. Singsen and colleagues (1985) and Petri (1998) recommend screening for anti-SS-A and anti-SS-B antibodies, and if found, fetal cardiac function should be evaluated. Although we routinely evaluate the fetus for arrhythmias, we do not screen for these antibodies. As discussed in Chapter 15 (p. 345), antepartum fetal surveillance is done as outlined by the American College of Obstetricians and Gynecologists (2007a). Unless hypertension develops or there is evidence of fetal compromise or growth restriction, pregnancy is allowed to progress to term. Peripartum corticosteroids in "stress doses" are given to women who are taking these drugs or who recently have done so.

Pharmacological Treatment

There is no cure, and complete remissions are rare. Approximately a fourth of patients have mild disease, which is not life threatening, but may be disabling because of pain and fatigue. Arthralgia and serositis are managed by *nonsteroidal anti-inflammatory drugs*, including aspirin. Because of the risk of premature closure of the fetal ductus arteriosus, therapeutic doses probably should not be used after 24 weeks (Briggs and colleagues, 2005). Low-dose aspirin, however, can be used safely throughout gestation. Severe disease is managed with *corticosteroids* such as prednisone, 1 to 2 mg/kg per day. After the disease is controlled, this dose is tapered to a daily dose of 10 to 15 mg each morning. Corticosteroid therapy can result in the development of gestational or even type 1 diabetes. Long-term antibody-based immunoadsorption has been used in pregnancy for removal of autoantibodies and lipoproteins in women with serious complications who did not respond to conventional therapy (Dittrich and colleagues, 2002).

Immunosuppressive agents such as *azathioprine* are beneficial in controlling active disease (Contreras and colleagues, 2004; Hahn, 2008). In nonpregnant patients, these are usually reserved for lupus nephritis or disease that is steroid resistant. Azathioprine has a good safety record during pregnancy (Petri, 2007). Its recommended daily oral dose is 2 to 3 mg/kg. According to Buhimschi and Weiner (2009), *cyclophosphamide* is teratogenic, and although not usually recommended during pregnancy, severe disease may be treated after 12 weeks. As discussed in Chapter 14 (pp. 320 and 322), other medications to be avoided include *mycophenolate mofetil* and *methotrexate* (Anderka and colleagues, 2009; FDA Alert, 2008).

Antimalarials help control skin disease. Although these agents cross the placenta, *hydroxychloroquine* has not been associated with congenital malformations. Because of the long half life of antimalarials and because discontinuing therapy can precipitate a lupus flare, most authors recommend their continuation (Borden and Parke, 2001; Harris, 2002). Levy and colleagues (2001) randomly assigned 20 pregnant women to hydroxychloroquine or placebo and reported improvement in SLEPDAI scores with drug use compared with placebo administration.

When severe disease supervenes—usually a lupus flare—high-dose glucocorticoid therapy is given. Petri (2007) recommends pulse therapy consisting of methylprednisolone, 1000 mg given intravenously over 90 minutes daily for 3 days, then a return to maintenance doses if possible.

Perinatal Mortality and Morbidity

Adverse perinatal outcomes are increased significantly in pregnancies complicated by lupus. These include preterm delivery, fetal-growth restriction, stillbirths, and neonatal lupus. Outcomes are worse with a lupus flare; significant proteinuria; renal impairment; and with chronic hypertension, development of preeclampsia, or both (Aggarwal, 1999; Scott, 2002; Wagner, 2009, and all their associates). The recent observations of Lee and co-workers (2009) are worrisome. In a mouse SLE model, they showed that autoantibodies directed against the *N*-methyl-D-aspartate neuroreceptor caused fetal neurotoxicity and speculate that this might account for the high incidence of learning disorders in children of affected mothers.

The reasons at least partially responsible for adverse fetal consequences include decidual vasculopathy with placental infarction and decreased perfusion (Hanly and colleagues, 1988; Lubbe and Liggins, 1984). Anti-SS-A (Ro) and anti-SS-B (La) antibodies may damage the fetal heart and conduction system, causing neonatal death (Alexander and co-workers, 1992; Tseng and Buyon, 1997). Women with livedo reticularis and lupus or a lupus-like illness, but who do not produce antiphospholipid antibodies, display increased rates of pregnancy complications (Sangle and associates, 2005).

Neonatal Lupus

This unusual syndrome is characterized by skin lesions, or *lupus dermatitis*; a variable number of hematological and systemic derangements; and occasionally congenital heart block (Boh, 2004; Lee, 2009). Although usually associated with anti-SS-A and -SS-B antibodies, McGeachv and Lam (2009) described an affected infant in whom only anti-RNP antibodies were found. Thrombocytopenia and hepatic involvement is seen in 5 to 10 percent. One report suggests that neonatal lupus may appear up to 4 weeks after birth (Stirnemann and associates, 2002). Lockshin and co-workers (1988) prospectively followed 91 infants born to women with lupus. Four had definite neonatal lupus and four had possible disease. Clinical manifestations, which include cutaneous lupus, thrombocytopenia, and autoimmune hemolysis, are transient and clear within a few months (Lee and Weston, 1984). The recurrence risk in subsequent offspring for neonatal lupus is 25 percent (Julkunen and colleagues, 1993).

Congenital Heart Block

This fetal complication results from diffuse myocarditis and fibrosis in the region between the atrioventricular (AV) node and bundle of His. Buyon and colleagues (1993) reported that congenital heart block occurred almost exclusively in fetuses of women with antibodies to the SS-A or SS-B antigens. These antibodies may also cause otherwise unexplained stillbirths (Ottaviani and co-workers, 2004). Even in the presence of such antibodies, however, the incidence of arrhythmia is only 3 percent (Lockshin and associates, 1988). The cardiac lesion is permanent, and a

pacemaker is generally necessary. Long-term prognosis is poor, and a third of affected infants die within 3 years (Waltuck and Buyon, 1994). The risk of recurrence in subsequent offspring is 10 to 15 percent (Julkunen and colleagues, 1993).

Maternal corticosteroid administration to treat fetal heart block is controversial. Shinohara and colleagues (1999) reported no heart block in 26 neonates whose mothers received corticosteroid maintenance therapy before 16 weeks. By contrast, 15 of 61 neonates with heart block were born to women in whom corticosteroid therapy was begun after 16 weeks. In an intriguing observational study from Israel, Rein and colleagues (2009) followed 70 fetuses of mothers positive for anti-SS-A or -SS-B antibodies prospectively with serial kinetocardiography (FKCG) to measure AV conduction time. In six fetuses, first-degree block developed at 21 to 34 weeks, and maternal dexamethasone treatment was associated with normalization of AV conduction in all within 3 to 14 days. There were no recurrences, and the infants all were well at a median follow-up of 4 years.

Long-Term Prognosis and Contraception

In general, women with lupus and chronic vascular or renal disease should limit family size because of morbidity associated with the disease as well as increased adverse perinatal outcomes. Two large multicenter clinical trials have shown that combination oral contraceptives (COCs) did not increase the incidence of lupus flares (Sánchez-Guerrero and colleagues, 2005; Petri and co-workers, 2005). Still, the American College of Obstetricians and Gynecologists (2006) recommends that COC use be avoided in women who have nephritis, antiphospholipid antibodies, or a vascular disease. Progestin-only implants and injections also provide effective contraception with no known effects on lupus flares. Concerns that intrauterine device (IUD) use and immunosuppressive therapy lead to increased infection rates in these patients are not evidenced based. Tubal sterilization may be advantageous and is performed with greatest safety postpartum or whenever the disease is quiescent.

ANTIPHOSPHOLIPID ANTIBODIES

Phospholipids are the main lipid constituents of cell and organelle membranes. Several antibodies directed against these various phospholipids and to proteins bound to phospholipids have been described. These antibodies include *lupus anticoagulant (LAC)* and *anticardiolipin antibodies (ACAs)*. They may be of IgG, IgM, and IgA classes, alone or in combination. Cardiolipin is but one of many phospholipids and is found in mitochondrial membranes and platelets.

The term *lupus anticoagulant* was introduced by Feinstein and Rapaport (1972) in a review of acquired inhibitors of coagulation. They described that certain patients with lupus had some coagulation tests that were prolonged and thus suggested anticoagulant activity. Paradoxically, the so-called anticoagulant is powerfully thrombotic in vivo, although LAC prolongs all phospholipid-dependent coagulation tests, including the prothrombin time, partial thromboplastin time, and Russell viper venom time. Each of these tests requires a phospholipid surface to which other clotting factors attach and combine (**Fig. 54-1**).

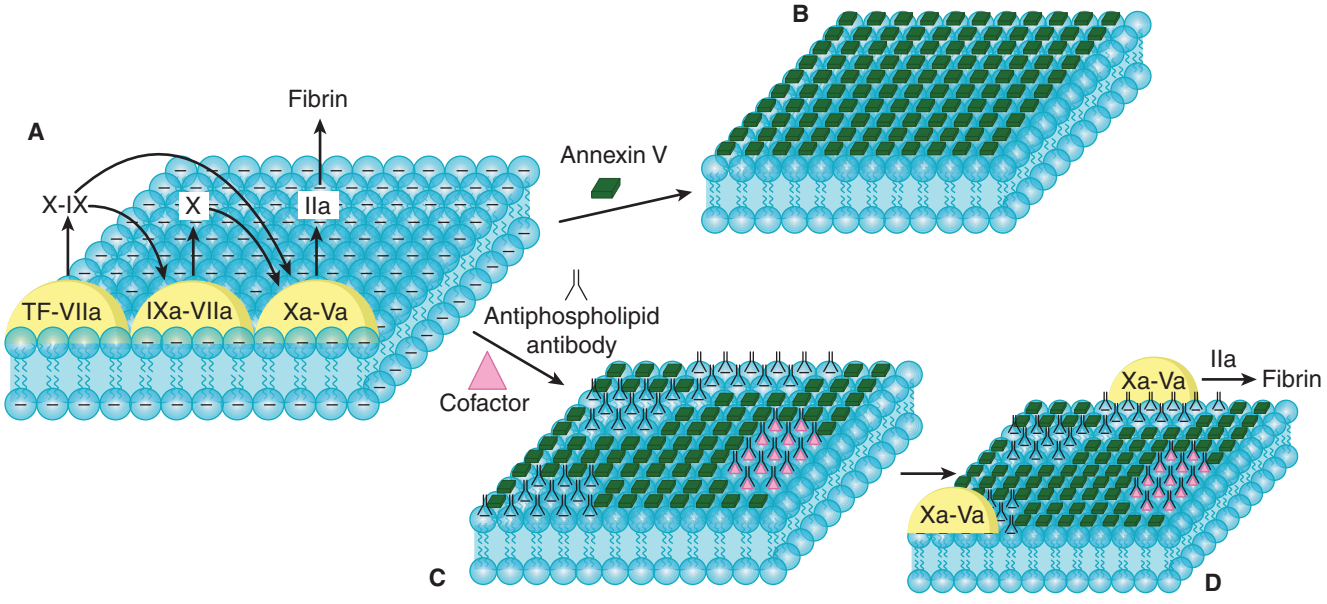

FIGURE 54-1 A. Negatively charged anionic phospholipids (*light blue circles*), as part of the cell-membrane bilayer, serve as potent cofactors for assembly of three coagulation complexes. These complexes include: tissue factor–VIIa (TF-VIIa) complex (*first, yellow half circle*), IXa-VIIIa complex (*second, yellow half circle*), and Xa-Va complex (*third*). The phospholipids thus accelerate blood coagulation by generating factors IXa and Xa. Factor Xa yields factor IIa (thrombin), which in turn cleaves fibrinogen to form fibrin. **B.** When antiphospholipid antibodies are absent, annexin V (*green squares*) forms clusters that bind to the surface of anionic phospholipids. Coagulation complexes are unable to bind to the surface phospholipids, and coagulation is inhibited. **C.** Through direct binding to surface phospholipids or through an interaction with protein-phospholipid cofactors, antiphospholipid antibodies disrupt the ability of annexin V to cluster on the phospholipid surface. **D.** These unbound areas, free of annexin V, permit more anionic phospholipids to be available to coagulation complexes. Coagulation is thus accelerated, and thrombosis promoted. (Adapted from Rand and colleagues, 1997a, 2008.)

Clinical Features

Antiphospholipid antibodies may be found in asymptomatic patients with or without lupus, or they may be associated with the *antiphospholipid antibody syndrome (APS)*. This syndrome is characterized by recurrent arterial or venous thromboses, thrombocytopenia, and fetal losses—especially stillbirths—during the second half of pregnancy (Branch and Khamashta, 2003; Oshiro and associates, 1996; Warren and Silver, 2004).

Antiphospholipid antibody syndrome may develop alone or in association with lupus or other autoimmune disorders. Central nervous system involvement is one of the most prominent clinical manifestations and includes arterial and venous thrombotic events, psychiatric features, and other nonthrombotic neurological syndromes (Sanna and co-workers, 2003). Renovascular involvement may lead to renal failure, and it may be difficult to differentiate from lupus nephitis (D'Cruz, 2009). Interestingly, APS may mimic the presentation of multiple sclerosis (Ruiz-Irastorza and associates, 2001). Finally, Ahmed and associates (2009) reported a woman who developed spontaneous cecal perforation postpartum presumably from antibody induced infarction.

Pathophysiology

Many patients with lupus have circulating antibodies specifically directed either against phospholipids or against phospholipid-binding proteins such as β_2-glycoprotein I (apolipoprotein H). Anticardiolipin antibodies apparently bind directly to β_2-glycoprotein I, and this protein acts as a co-factor in this antigen-antibody reaction (Chamley and co-workers, 1999). There is evidence that complement activation may contribute to pathogenesis (Avalos and Tsokos, 2009).

β_2-Glycoprotein I

The major activity of this protein appears to be its phospholipid-dependent anticoagulant inhibition of prothrombinase activity of platelets and ADP-induced platelet aggregation (Shi and colleagues, 1993). β_2-Glycoprotein I competitively inhibits the binding of coagulation factors, especially factor XII, and the prothrombinase complex to phospholipid surfaces. This prevents activation of the coagulation cascade. An antibody directed against β_2-glycoprotein I would bind and prevent it from acting as a phospholipid-dependent anticoagulant. β_2-Glycoprotein I is found in high concentrations on the surface of the syncytiotrophoblast. This seems intuitive because the decidua is a critical area in which to prevent coagulation. In addition, β_2-glycoprotein I may be involved in implantation because it is known that this protein binds heparin. Moreover, trophoblastic cells have heparin-like binding sites. Thus, a local loss of β_2-glycoprotein I by an antibody directed against it might prevent implantation or result in intervillous space thrombosis, or both (Chamley and associates, 1999).

Lupus Anticoagulant

LAC appears to require a cofactor for its in vitro anticoagulant function. Specifically, it does not bind directly to negatively charged phospholipids, but instead, LAC binds to phospholipid-bound prothrombin (Galli and Bevers, 1994). Other phospholipid-binding proteins may be involved in the pathophysiology of the antiphospholipid antibody syndrome. These include *protein C* and *protein S,* which are both endogenous anticoagulants, and *annexin V* (Robertson and Greaves, 2006). The last is also known as *placental anticoagulant protein I* or *lipocortin V*, and annexin V coats the syncytiotrophoblast in high concentration (Chamley and associates, 1999). Thus, an antibody that binds protein C or S would result in venous, arterial, or decidual thrombosis, whereas binding of annexin V would result in coagulation and thrombosis in the intervillous space (see Fig. 54-1).

Rand and co-workers (1997b) reported that placental tissue from pregnancy complicated by APS had significantly less apical membrane-associated annexin V than normal placenta. Exposure of placental villous cultures to five antiphospholipid IgGs also resulted in a significant reduction in apical membrane annexin V. In another study, there was a reduction in annexin V in endothelial cell tissue cultures exposed to antiphospholipid antibodies (Rand and colleagues, 1997a).

These discoveries led to the development of direct assays to measure antibodies against β_2-glycoprotein I and prothrombin. A number of investigators have found these to be increased in and associated with pregnancies complicated by APS (Destefano, 2009; Falcón, 1997; Yamada, 2009, and all their co-workers). Conversely, others have not observed a clinically significant association with these antibodies (Lee, 1999; Lynch, 1999; Manuck, 2009, and all their associates).

Association of Antiphospholipid Antibodies with Lupus

Patients with clinical lupus frequently also have lupus anticoagulant or antiphospholipid antibodies, or both. Love and Santoro (1990) reviewed 29 series that included more than 1000 patients with lupus and reported an average frequency of 34 percent for LAC and 44 percent for ACAs. In nearly half of those with positive testing, both antibodies were found.

In general, patients with LAC have higher levels of antiphospholipid antibodies, and about a third of those with biological false-positive tests for syphilis have ACAs (Branch, 1991). Only about 20 percent of patients with identifiable ACAs also have LAC. Importantly, in patients with lupus, documentation of either ACA or LAC is a risk factor for thrombosis, neurological disorders, and thrombocytopenia (Hahn, 2008). As discussed in Chapter 9 (p. 225), these antibodies have also been associated with excessive pregnancy loss (Robertson and Greaves, 2006). *Libman-Sacks endocarditis* is much more prevalent in patients with lupus who have antiphospholipid antibodies (Hojnik and colleagues, 1996). These antibodies have been associated with the development of "primary" vaso-occlusive disease involving different organs such as the kidney as discussed previously.

Antiphospholipid Antibodies and Normal Pregnancy

About 5 percent of all otherwise healthy *nonpregnant* individuals screened have nonspecific antiphospholipid antibodies in low titers. Lockwood and colleagues (1989) studied 737 normal pregnant women and found that two–0.3 percent–had lupus

anticoagulant and 16–2.2 percent–had elevated concentrations of either IgM- or IgG-ACAs. Harris and Spinnato (1991) studied 1449 consecutive pregnant women and found 1.8 percent were positive for IgG-ACAs and 4.3 percent for IgM-ACAs. Pattison and co-workers (1993) studied 933 consecutive prenatal patients and found nine–0.1 percent–with ACAs, 11–1.2 percent–with LACs, and two women with both. Yasuda and associates (1995) found that 7 percent of 860 pregnant Japanese women had ACAs. Taken together, these studies totalling almost 4000 normal pregnancies reported an average prevalence of 4.7 percent—the same as normal nonpregnant individuals.

Diagnosis of Antiphospholipid Antibody Syndrome (APS)

By international consensus, the syndrome is diagnosed on the basis of clinical and laboratory criteria (Levine and co-workers, 2002; Robertson and Greaves, 2006). These are shown in **Table 54-5**, and one of two clinical criteria, which include vascular thrombosis or certain pregnancy morbidity, must be present. In addition, at least two laboratory criteria that include LAC activity or medium- to high-positive specific IgG- or IgM-ACAs must be confirmed on two occasions 6 weeks apart.

Classification criteria shown in Table 54-5 also provide indications for testing. Branch and Khamashta (2003) recommend conservative interpretation of results based on repeated tests from a reliable laboratory that are consistent with each clinical case. Because only approximately 20 percent of patients with APS have a positive LAC reaction alone, both the clotting test to identify the LAC and the anticardiolipin enzyme-linked immunosorbent assay (ELISA) test must be performed. Giannakopoulos and associates (2009) describe a beta(2)GPI enzyme-linked immunosorbent assay in addition.

Efforts have been made to standardize ACA assays by using ELISA, and values are reported in units and expressed as *negative*, *low-positive, medium-positive,* or *high-positive* (Harris and colleagues, 1987a, b). Despite this, there still is no totally accurate standardization for these assays (Branch and Khamashta, 2003). Interlaboratory variation can be large, and agreement between commercial kits is also poor.

Tests for the LAC are nonspecific coagulation tests. The *partial thromboplastin time* is generally prolonged because the anticoagulant interferes with conversion of prothrombin to thrombin in vitro. Tests considered most specific are the *dilute Russell viper venom test* (*dRVVT*) and the *platelet neutralization procedure*. There is currently disagreement as to which of these is best for screening. If either is positive after addition of normal plasma, the diagnosis is confirmed.

Pathophysiology of Antiphospholipid Antibodies in Pregnancy

The combination of lupus anticoagulant and high levels of ACAs is strongly associated with decidual vasculopathy, placental infarction, fetal-growth restriction, early-onset preeclampsia, and recurrent fetal death. Some of these women, like those with lupus, also have a high incidence of venous and arterial thromboses, cerebral thrombosis, hemolytic anemia, thrombocytopenia, and pulmonary hypertension (American College of Obstetricians and Gynecologists, 2007b; Clowse and co-workers, 2008).

Mechanism of Action

It is not precisely known how these antibodies cause damage, but it is likely that their actions are multifactorial. According to Chamley and co-workers (1999), platelets may be damaged directly by antiphospholipid antibody or indirectly by binding β_2-glycoprotein I, which causes platelets to be susceptible to aggregation. Rand and colleagues (1997a, b, 1998) propose that phospholipid-containing endothelial cell or syncytiotrophoblast membranes may be damaged directly by the antiphospholipid antibody or indirectly by antibody binding to either β_2-glycoprotein I or annexin V (see Fig. 54-1). This prevents the cell membranes from protecting the syncytiotrophoblast and endothelium and results in exposure of basement membrane. It is known that damaged platelets adhere to exposed basement membrane of endothelium and syncytiotrophoblast and result in thrombus formation (Lubbe and Liggins, 1984).

There are other proposed mechanisms. Pierro and co-workers (1999) reported that antiphospholipid antibodies decreased

TABLE 54-5. Classification Criteria for the Antiphospholipid Antibody Syndrome

Criteria	
Clinical	
Thrombosis	Unexplained venous, arterial, or small vessel thrombosis in any organ or tissue
Pregnancy	One or more unexplained fetal losses after 10 weeks; three or more consecutive miscarriages before 10 weeks; or preterm delivery for severe preeclampsia or placental insufficiency before 34 completed weeks
Laboratory	
Anticardiolipin antibodies	IgG or IgM isotypes in medium to high titers at least 6 weeks apart
Lupus anticoagulant	Identified twice, at least 6 weeks apart

From International Consensus Statement (Wilson and colleagues, 1999) and the American College of Obstetricians and Gynecologists (2007b).

decidual production of the vasodilating prostaglandin E_2. Decreased protein C or S activity and increased prothrombin activation have been reported (Ogunyemi and associates, 2002; Zangari and colleagues, 1997). Amengual and co-workers (2003) presented evidence that thrombosis with APS is due to activation of the tissue factor pathway. Finally, there is evidence that uncontrolled placental complement activation by antiphospholipid antibodies may play a role in fetal loss and growth restriction (Holers and colleagues, 2002).

Adverse Pregnancy Outcomes

There is no doubt that antiphospholipid antibodies are associated with increased rates of fetal wastage (see Chap. 9, p. 225). In most early reports, however, women were usually included *because* they had repeated adverse outcomes. Moreover, as previously discussed, the incidence of antiphospholipid antibodies in the general obstetrical population is about 5 percent. Accordingly, data currently are too limited to draw precise conclusions concerning the impact of these antibodies on adverse pregnancy outcomes. Fetal deaths, however, are more characteristic than first-trimester miscarriages (Oshiro and co-workers, 1996; Roque and colleagues, 2001). It has also been shown that women with higher antibody titers have worse outcomes compared with those with low titers (Nodler and colleagues, 2009; Simchen and associates, 2009).

Looking at the issue another way, the incidence of these antibodies may be increased in adverse obstetrical outcomes associated with these syndromes. Polzin and colleagues (1991) identified antiphospholipid antibodies in a fourth of 37 women with growth-restricted fetuses, however, none had evidence for LAC. Approximately a third of women with APS will develop preeclampsia during pregnancy (Clark and colleagues, 2007b). And Branch and co-workers (1989) found a 16-percent incidence of antiphospholipid antibodies in 43 women with severe preeclampsia before 34 weeks. Six of the seven women with antibodies also had LAC, and one woman had multiple cerebral infarctions. Similarly, Moodley and associates (1995) found antibodies in 11 percent of 34 women with severe preeclampsia before 30 weeks.

When otherwise unexplained fetal deaths are examined, ACAs do not appear to play a significant role. Haddow and co-workers (1991) measured ACAs in 309 pregnancies with fetal death and found no differences compared with 618 normal pregnancies. In women with a history of recurrent pregnancy loss, those with antiphospholipid antibodies had a higher rate of preterm delivery (Clark and colleagues, 2007a). Despite a worse pregnancy outcome, there was no evidence of greater endothelial cell activation during pregnancy in women who were receiving treatment for APS (Stone and colleagues, 2003).

Treatment Guidelines

Because of the heterogeneity of studies, current treatment recommendations may be confusing to the clinician (Branch and Khamashta, 2003; Robertson and Greaves, 2006). The schema discussed on page 1153 is used to semiquantify antibody levels that bind immunoglobulins G, M, and A. Thus, GPL, MPL, and APL binding units are expressed as negative, low-positive, medium-positive, or high-positive (American College of Obstetricians and Gynecologists, 2007b). Low-positive titers of GPL or MPL anticardiolipin antibodies are of questionable clinical significance. And *any titer* of APL antibodies has no known relevance at this time.

As discussed in Chapter 47 (see p. 1017), women with prior thromboembolic events who have antiphospholipid antibodies are at risk for recurrence in subsequent pregnancies. Recommendations for management from the American College of Obstetricians and Gynecologists (2007b) and the American College of Chest Physicians (Baker and colleagues, 2008) are varied and listed in Table 47-6 (p. 1028). Some acceptable schemes include close antepartum observation with or without prophylactic- or intermediate-dose heparin, and some form of postpartum anticoagulation for 4 to 6 weeks. Less clear, some recommend that women with medium- or high-positive ACA titers or those with LAC activity and a previous second- or third-trimester fetal death not attributable to other causes should also be treated (Dizon-Townson and Branch, 1998; Lockshin and Druzin, 1995). Similarly, as discussed in Chapter 9 (p. 225), some report that women with recurrent early pregnancy loss and medium- or high-positive titers of antibodies may benefit from therapy (Robertson and Greaves, 2006).

Aspirin

Given in doses of 60 to 80 mg daily, aspirin blocks the conversion of arachidonic acid to thromboxane A_2 while sparing prostacyclin production. This results in reduced thromboxane A_2, which may cause platelet aggregation and vasoconstriction, while sparing prostacyclin, which has the opposite effect. There appear to be no major side effects from low-dose aspirin other than a slight risk of small-vessel bleeding during surgical procedures.

Heparin

Unfractionated heparin is given subcutaneously in dosages of 5000 to 10,000 units every 12 hours. Some prefer low-molecular-weight heparin. With therapeutic dosing, some recommend measurement of heparin levels because clotting tests may be altered by LAC (Cowchock, 1998). The rationale for heparin therapy is to prevent venous and arterial thrombotic episodes. Heparin therapy also prevents thrombosis in the microcirculation, including the decidual-trophoblastic interface (Toglia and Weg, 1996). As discussed, heparin binds to β_2-glycoprotein I, which coats the syncytiotrophoblast. This prevents binding of anticardiolipin and anti-β_2-glycoprotein I antibodies to their surfaces, which likely prevents cellular damage (Chamley and colleagues, 1999; Schousboe and Rasmussen, 1995). Heparin also binds to antiphospholipid antibodies in vitro and likely in vivo (Ermel and associates, 1995).

It is problematic that heparin therapy is associated with a number of complications that include bleeding, thrombocytopenia, osteopenia, and osteoporosis. A detailed description of the use of various heparins and their doses and adverse effects is found in Chapter 47 (p. 1021).

Immunotherapy

Glucocorticoids likely should not be used with *primary APS*—that is, without an associated connective-tissue disorder. Even

so, some patients with these conditions can be expected to develop an associated disorder such as lupus over time (Carbone and colleagues, 1999). In instances of *secondary APS* seen with lupus, the dose of prednisone should be maintained at the lowest effective level to prevent flares. Steroid therapy has significant adverse effects, including osteopenia, osteoporosis, and pathological fractures. Steroids also impede wound healing, and they induce gestational and overt diabetes (Laskin and co-workers, 1997).

Immunoglobulin therapy has usually been reserved for women with overt disease, heparin-induced thrombocytopenia, or both. It is used when other first-line therapies have failed, especially in the setting of preeclampsia and fetal-growth restriction (Cowchock, 1996, 1998; Heilmann and colleagues, 2003; Silver and Branch, 1997). Immunoglobulin is administered intravenously in doses of 0.4 g/kg daily for 5 days—total dose of 2 g/kg. This is repeated monthly, or it is given as a single dose of 1 g/kg each month. Treatment is expensive—at $50 per gram, one course for a 70-kg woman costs $7000 (Medical Letter, 2006). Immunoglobulin has been evaluated in a preliminary placebo-controlled study by Branch and colleagues (2000). In a retrospective study, Heilmann and associates (2008) treated 121 women with the syndrome with low-molecular-weight heparin plus aspirin, but only 43 additionally received IVIG in the dose described. This latter group had fewer late complications, but randomized trials are needed before its widespread application.

Immunosuppressive therapy has also not been well evaluated, but azathioprine and cyclosporine do not appear to improve standard therapies (Silver and Branch, 1997). As previously discussed, methotrexate, cyclophosphamide, and mycophenolate mofetil are contraindicated because of teratogenic potential (Briggs and associates, 2005; Buhimschi and Weiner, 2009).

Low-Dose Aspirin Plus Heparin

Current data suggest the most efficacious therapy to be low-dose heparin—7500 to 10,000 units administered subcutaneously, twice daily—given concurrently with low-dose aspirin, 60 to 80 mg once daily (American College of Obstetricians and Gynecologists, 2007b). If active lupus coexists, then prednisone is usually also given.

Effect of Treatment on Perinatal Loss

Regarding perinatal outcomes, Branch and Khamashta (2003) caution that recurrent fetal loss is still 20 to 30 percent even with treatments described above. In one study, Lockshin and co-workers (1989) reported that 23 of 32 women with a prior fetal death and antiphospholipid antibody levels greater than 40 IgG units had a recurrent fetal death despite treatment with prednisone, aspirin, or both. Conversely, some women with lupus and antiphospholipid antibodies have normal pregnancy outcomes without treatment. In addition, women with LAC and prior bad pregnancy outcomes have had liveborns without treatment (Trudinger and associates, 1988).

Because 30 percent of neonates demonstrate passively acquired antiphospholipid antibodies, there is concern for any adverse effects. According to Tincani and co-workers (2009), some findings suggest possible increased learning disabilities. And Simchen and colleagues (2009) reported a fourfold increased risk for perinatal strokes in these infants. More data are needed before firm conclusions can be drawn.

TABLE 54-6. American College of Rheumatology Revised 1987 Criteria for Classification of Rheumatoid Arthritis[a]

1. Morning joint stiffness
2. Arthritis of three or more joint areas
3. Arthritis of wrist, metacarpophalangeal joint, or proximal interphalangeal joint
4. Symmetrical arthritis
5. Rheumatoid nodules
6. Serum rheumatoid factor
7. Radiographic changes

[a] Four of seven criteria required for diagnosis.
Criteria 1-4 must be present for at least 6 weeks.
Criteria 2-5 must be observed by a physician.
Adapted from Lipsky (2008).

RHEUMATOID ARTHRITIS

This is a chronic multisystem disease of unknown cause with an immunologically mediated pathogenesis. Infiltrating T cells secrete cytokines that mediate inflammation and systemic symptoms. Its prevalence is about 0.8 percent, and women are affected three times more often than men (Lipsky, 2008). The cardinal feature is inflammatory synovitis that usually involves the peripheral joints. The disease has a propensity for cartilage destruction, bony erosions, and joint deformities. Onset is generally between 35 and 50 years. Diagnostic criteria are shown in Table 54-6.

There is a genetic predisposition, and the results of several studies have shown a higher disease concordance among monozygotic than dizygotic twins—15 versus 4 percent (Lee and Weinblatt, 2001). There is an association with the class II major histocompatibility complex molecule HLA-DR4 and HLA-DRB1 alleles (Harney and colleagues, 2003). Cigarette smoking also appears to increase the risk of rheumatoid arthritis in women (Papadopoulos and colleagues, 2005). As discussed subsequently, a protective effect of pregnancy has been reported for the development of rheumatoid arthritis (Hazes and colleagues, 1990).

Clinical Manifestations

Rheumatoid arthritis is a chronic polyarthritis with symptoms of synovitis, fatigue, anorexia, weakness, weight loss, depression, and vague musculoskeletal symptoms. The hands, wrists, knees, and feet are commonly involved. Pain, aggravated by movement, is accompanied by swelling and tenderness. Extra-articular manifestations include rheumatoid nodules, vasculitis, and pleuropulmonary symptoms. The 1987 revised criteria of the American College of Rheumatology shown in Table 54-6 have a 90-percent specificity and sensitivity for the diagnosis (Lipsky, 2008).

Management

Treatment is directed at pain relief, reduction of inflammation, protection of articular structures, and preservation of function. Physical and occupational therapy and self-management instructions are essential. Aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs) are the cornerstone of symptomatic therapy. However, they do not retard progression of disease. Conventional NSAIDs nonspecifically inhibit both cyclooxygenase-1 (COX-1)—an enzyme critical to normal platelet function, and COX-2—an enzyme which mediates inflammatory response mechanisms. Gastritis with acute bleeding is an unwanted side effect common to conventional NSAIDs. Specific COX-2 inhibitors have been used to avert this complication. There are now concerns, however, that long-term use of COX-2 inhibitors is associated with increased myocardial infarction, stroke, and heart failure (Solomon and associates, 2005). Thus, risks versus benefits of these medications must be considered.

Glucocorticoid therapy may be added to NSAIDs, and 7.5 mg of prednisone daily for the first 2 years of active disease substantively reduces progressive joint erosions (Kirwan and colleagues, 1995). Thus, corticosteroids are avoided if possible, but low-dose therapy is used by some, along with salicylates.

Because NSAIDs and glucocorticoids are primarily for symptomatic relief, the American College of Rheumatology (2002) recommends disease-modifying antirheumatic drugs (DMARDs). These have the potential to reduce or prevent joint damage and are given within 3 months of diagnosis. There are a variety of DMARDs, and many have considerable toxicity. These include hydroxychloroquine, sulfasalazine, leflunomide, and methotrexate (Vroom and colleagues, 2006). More recently, the tumor necrosis factor alpha (TNF-α) inhibitors, which include etanercept (*Enbrel*), adalimumab (*Humira*), and infliximab (*Remicade*), have been approved. Experience with these agents in pregnancy has been accruing. Berthelot and colleagues (2009) found more than 300 reported cases in their review with no fetal effects. In addition, the interleukin-1 receptor antagonist, anakinra (*Kineret*), and the antagonist to the B-cell CD20 antigen, rituximab (*Rituxan*), are now available. Drugs used less frequently include azathioprine, penicillamine, gold salts, minocycline, and cyclosporine. Orthopedic surgery for joint deformities, including replacement, is commonly performed.

Pregnancy and Rheumatoid Arthritis

Rheumatoid arthritis improves in up to 90 percent of affected women during pregnancy (de Man and associates, 2008). That said, some women develop disease during pregnancy, and others become worse (Nelson and Østensen, 1997). In addition, postpartum exacerbation is common (Østensen and Villiger, 2007). Barrett and co-workers (2000a) reported that a flare was more common if women were breast feeding. Barrett and co-workers (2000b) performed a prospective study in the United Kingdom, and 140 women recruited during the last trimester were seen at 1 and 6 months postpartum. There was only a modest fall in objective disease activity. Only 16 percent had complete remission. At least 25 percent had substantive levels of disability. Thus, although overall disease actually did not exacerbate postpartum, the mean number of inflamed joints increased significantly.

There are some studies that report a protective effect of pregnancy for women developing subsequent new-onset rheumatoid arthritis. Silman and associates (1992) performed a case-control study of 88 affected women. They found that although there was a protective effect of pregnancy in the long term, the likelihood of new-onset rheumatoid arthritis was increased sixfold during the first 3 postpartum months. Pikwer and colleagues (2009) reported a significant reduction in the risk of subsequent arthritis in women who breastfed longer than 12 months. Finally, Mandl and co-workers (2009) described long-term follow-up of more than 87,000 women followed in the Nurses' Health Study. From 1976 through 2002, 619 women developed rheumatoid arthritis—a prevalence of 0.7 percent. They found a twofold increased risk for its development in women with infants born weighing more than 4540 g—10 pounds. Other problems for macrosomic infants are discussed further in Chapter 38 (p. 853).

As an explanation, and as discussed previously, sex hormones supposedly interfere with a number of putative processes involved in arthritis pathogenesis, including immunoregulation and interactions with the cytokine system (Häupl and associates, 2008a, b). First, Unger and associates (1983) reported that amelioration of rheumatoid arthritis correlated with serum levels of *pregnancy-associated* α_2*-glycoprotein.* This compound has immunosuppressive properties. Second, Nelson and coworkers (1993) reported that amelioration of disease was associated with a disparity in HLA class II antigens between mother and fetus. They suggested that the maternal immune response to paternal HLA antigens may play a role in pregnancy-induced remission of arthritis. In addition to monocytes, there may be T-lymphocyte activation (Förger and co-workers, 2008).

Juvenile Rheumatoid Arthritis

This is a group of diseases that are the most common cause of chronic arthritis in children. They persist into adulthood. Østensen (1991) reviewed outcomes of 76 pregnancies in 51 affected Norwegian women. Pregnancy had no effects on presentation of disease, but disease activity became quiescent or remained so during pregnancy. Postpartum flares were common, as discussed for rheumatoid arthritis. Joint deformities were common in these women, and 15 of 20 cesarean deliveries were done for contracted pelves or joint prostheses. These observations are supported by the summary of similar results in 39 Polish women with a history of juvenile rheumatoid arthritis (Musiej-Nowakowska and Ploski, 1999).

Perinatal Outcome

There are no obvious adverse effects of rheumatoid arthritis on pregnancy outcome, including preterm labor (Klipple and Cecere, 1989). In a national population-based cohort study in Norway, however, Skomsvoll and colleagues (2002) reported that women with rheumatic disease with two previous poor pregnancy outcomes were at high risk for recurrent adverse outcomes. Although Kaplan (1986) reported that women who later develop the disease have had a higher-than-expected incidence of spontaneous abortion, Nelson and colleagues (1992) did not corroborate this.

Management During Pregnancy

Treatment of symptomatic women during pregnancy is with aspirin and NSAIDs, but with appropriate concerns for impaired hemostasis, prolonged gestation, and premature closure of the ductus arteriosus (Briggs and co-workers, 2005). Low-dose corticosteroids are also used as indicated. Gold compounds have been used in pregnancy, and of 14 women experiencing 20 pregnancies on gold therapy, 75 percent delivered healthy liveborns (Almarzouqi and colleagues, 2007).

Immunosuppressive therapy with azathioprine, cyclophosphamide, or methotrexate is not routinely used during pregnancy. Of these, only azathioprine should be considered during early pregnancy because the other agents are teratogenic as discussed previously (Buhimschi and Weiner, 2009). (Ramsey-Goldman and Shilling, 1997). TNF-α drugs are considered category B for pregnancy, although data with regard to safety for a developing human fetus are limited (Roux and associates, 2007). Leflunomide is a pyrimidine synthesis inhibitor used for rheumatoid arthritis in nonpregnant patients. It is teratogenic in animals, and it is detectable up to 2 years in plasma after discontinuation (Briggs and associates, 2005). It has not been shown to be teratogenic for humans, but it should be avoided (Chambers and colleagues, 2007).

If cervical spine involvement exists, particular attention is warranted during pregnancy. Subluxation is common, and pregnancy, at least theoretically, predisposes to this because of joint laxity, as discussed in Chapter 5 (p. 129). In addition, there are anesthesia concerns regarding endotracheal intubation.

Contraception

Combination oral contraceptives are a logical choice because of their effectiveness and the possibility that they might improve rheumatoid arthritis (Bijlsma and Van Den Brink, 1992). In fact, all reversible methods of contraception discussed in Chapter 32 are appropriate.

SYSTEMIC SCLEROSIS (SCLERODERMA)

This is a chronic multisystem disorder of unknown etiology characterized by microvascular damage, immune system activation leading to inflammation, and excessive deposition of collagen in the skin and often in the lungs, heart, gastrointestinal tract, and kidneys. It is uncommon, displays a 3-to-1 female dominance and typically affects those aged 30 to 50 years (Varga, 2008).

This strong prevalence of scleroderma for women and its increased incidence in the years following childbirth contribute much to the hypothesis that *microchimerism* may be involved in the pathogenesis as discussed on page 1146. Artlett and co-workers (1998) demonstrated Y-chromosomal DNA in almost half—32 of 69 women—with systemic sclerosis compared with only 4 percent of controls. Rak and colleagues (2009) identified male microchimerism in peripheral blood mononuclear cells more frequently in women with limited versus diffuse disease—20 versus 5 percent. Fetal cells are likely present long before fibrosis develops (Sawaya and associates, 2004).

Clinical Course

The hallmark of the disease is overproduction of normal collagen. In the more benign form—*limited cutaneous systemic sclerosis*—progression is slow. With *diffuse cutaneous systemic sclerosis*, skin thickening progresses rapidly, and skin fibrosis is followed by gastrointestinal tract fibrosis, especially the distal esophagus (Varga, 2008). Pulmonary interstitial fibrosis along with vascular changes may cause pulmonary hypertension. Antinuclear antibodies are found in 95 percent of patients, and immunoincompetence is common.

Common symptoms are Raynaud phenomenon, which includes cold-induced episodic digital ischemia—in 95 percent, as well as swelling of the distal extremities and face. Half of patients have symptoms from esophageal involvement, especially fullness and epigastric burning pain. Pulmonary involvement is common and causes dyspnea. Mortality rates are high with renal or pulmonary involvement, and the 10-year survival rate is less than 50 percent. Renal failure causes half of the deaths. Women with limited cutaneous disease such as the *CREST syndrome—calcinosis, Raynaud phenomenon, esophageal involvement, sclerodactyly, and telangiectasia*—have milder disease.

Overlap syndrome refers to the presence of systemic sclerosis with features of other connective-tissue disorders. *Mixed-connective-tissue disease* is a term used for the syndrome involving features of lupus, systemic sclerosis, polymyositis, rheumatoid arthritis, and high titers of anti-RNP antibodies (see Table 54-1).

Although systemic sclerosis cannot be cured, treatment directed at end-organ involvement can relieve symptoms and improve function (Varga, 2008). Corticosteroids are helpful only for inflammatory myositis, pericarditis, and hemolytic anemia. Renal involvement and hypertension are common, and angiotensin-converting enzyme (ACE) inhibitors are usually effective treatment. As reviewed recently by Buhimschi and Weiner (2009), these agents are associated with severe fetal abnormalities (see also Chap. 14, p. 319). *Scleroderma renal crisis* develops in up to a fourth of these patients and is characterized by obliterative vasculopathy of the renal cortical arteries resulting in renal failure and malignant hypertension. Interstitial restrictive lung disease is common and becomes life-threatening. Cyclophosphamide provides some improvement (Tashkin and coworkers, 2006). As discussed in Chapter 44 (p. 970), associated pulmonary hypertension is usually fatal.

Pregnancy and Systemic Sclerosis

The prevalence of scleroderma in pregnancy can be estimated from the study of nearly 11.2 million pregnant women registered in the Nationwide Inpatient Sample. In this report, Chakravarty and colleagues (2008) reported that 504 women suffered from systemic sclerosis—a prevalence of about 1 in 22,000 pregnancies. These women usually have stable disease during gestation if their baseline function is good. As perhaps expected, dysphagia and reflux esophagitis are aggravated by pregnancy (Steen, 1999). Dysphagia results from loss of esophageal motility due to neuromuscular dysfunction. A decrease in amplitude or disappearance of peristaltic waves in the lower two thirds of the esophagus is seen using manometry. Symptomatic treatment for reflux is described in Chapter 49

(p. 1052). Chin and colleagues (1995) described a woman with scleroderma who developed a Mallory-Weiss tear from persistent vomiting.

Women with renal insufficiency and malignant hypertension have an increased incidence of superimposed preeclampsia. In the presence of rapidly worsening renal or cardiac disease, pregnancy termination should be considered. As discussed, renal crisis is life threatening and is treated with ACE inhibitors, but it does not improve with delivery (Gayed and Gordon, 2007) Pulmonary hypertension usually contraindicates pregnancy (see Chap. 44, p. 970).

Vaginal delivery may be anticipated, unless the soft tissue thickening wrought by scleroderma produces dystocia requiring abdominal delivery. Tracheal intubation for general anesthesia has special concerns because of limited ability of these women to open their mouths widely (Black and Stevens, 1989). Because of esophageal dysfunction, aspiration is also more likely, and epidural analgesia is preferable.

Pregnancy Outcomes

Maternal and fetal outcomes are related to the severity of underlying disease. In the past, a high cited incidence of maternal deaths was due to biased case reporting. In a review of 94 pregnancies, Maymon and Fejgin (1989) found that a third of women had exacerbations of symptoms during pregnancy. The maternal mortality rate was 15 percent and was due to hypertension, renal failure, or cardiopulmonary complications. The fetal mortality rate was 20 percent.

Steen and colleagues (1989, 1999) reported more optimistic outcomes in 214 women with systemic sclerosis, 45 percent of whom had had diffuse disease. Major complications included renal crisis in three women. There were increased rates of preterm birth. Chung and colleagues (2006) also reported increased rates of preterm delivery, fetal-growth restriction, and perinatal mortality. These are likely related to placental abnormalities that include decidual vasculopathy, acute atherosis, and infarcts. These reduce placental blood flow and are found in many cases (Doss and co-workers, 1998; Papakonstantinou and associates, 2007).

Contraception

Scleroderma may be associated with subfertility (Bernatsky and co-workers, 2008; Lambe and colleagues, 2004). For those who do not choose pregnancy, several reversible contraceptive methods are acceptable. That said, hormonal agents, especially combination oral contraceptives, probably should not be used, especially in women with pulmonary, cardiac, or renal involvement. Due to the progressive and often unrelenting nature of progressive systemic sclerosis, permanent sterilization should also be considered (see Chap. 33, p. 698).

VASCULITIS SYNDROMES

Inflammation and damage to blood vessels may be primary or due to another disease. Most cases are presumed to be caused by immunopathogenic mechanisms, specifically, immune-complex deposition (Langford and Fauci, 2008). These syndromes are difficult to classify because of overlap. Primary causes include polyarteritis nodosa, Wegener granulomatosis, Churg-Strauss syndrome, temporal or giant cell arteritis, Takayasu arteritis, Henoch-Schönlein purpura, Behçet syndrome, and cutaneous or hypersensitivity arteritis.

Polyarteritis Nodosa

This type of vasculitis is an uncommon disease with protean manifestations. The pathological lesion is necrotizing vasculitis of small and medium-sized arteries. The classical variety is one of the progressive vasculitis syndromes characterized clinically by myalgia, neuropathy, gastrointestinal disorders, hypertension, and renal disease. About a third of cases are associated with hepatitis B antigenemia (Langford and Fauci, 2008).

Symptoms are nonspecific and vague. Fever, weight loss, and malaise are present in more than half of cases. Renal failure, hypertension, and arthralgias are common. Diagnosis is made by biopsy, and treatment consists of high-dose prednisone plus cyclophosphamide. Vasculitis due to hepatitis B antigenemia responds to lamivudine (see Chap. 50, p. 1069).

Pregnancy

Only a few documented cases of polyarteritis nodosa in association with pregnancy have been reported. Although definitive conclusions are unclear, certainly if active arteritis is identified during pregnancy, mortality rates are high. Owen and Hauth (1989) reviewed the courses of 12 such pregnant women. In seven, polyarteritis first manifested during pregnancy, and it was rapidly fatal by 6 weeks postpartum. The diagnosis was not made until autopsy in six of the seven women. Four women continued pregnancy, resulting in one stillborn and three successful outcomes.

Wegener Granulomatosis

This is a necrotizing granulomatous vasculitis of the upper and lower respiratory tract and kidney. Common lesions include sinusitis and nasal disease—90 percent, pulmonary infiltrates or nodules—85 percent, glomerulonephritis—75 percent, and musculoskeletal lesions—65 percent (Sneller, 1995). It is uncommon and usually encountered after 50 years of age. The few cases reported in association with pregnancy were reviewed recently by Koukoura and colleagues (2008). Corticosteroids are the standard treatment. For moderate and severe cases in the late second or third trimester, the use of cyclophosphamide in combination with prednisolone is acceptable. Azathioprine, cyclosporine, and intravenous immunoglobulin can also be used.

Takayasu Arteritis

So-called *pulseless disease,* this syndrome is most prevalent in young women. It is a chronic inflammatory arteritis affecting large vessels. Unlike *temporal arteritis*, which occurs almost exclusively after 55 years of age, the onset of Takayasu arteritis is almost exclusively before age 40. It is associated with abnormal angiography of the upper aorta and its main branches, resulting in upper extremity vascular impairment. Death usually results

from congestive heart failure or cerebrovascular events. Computed tomography or magnetic resonance angiography can be used to detect this disorder prior to the development of severe vascular compromise (Numano and Kobayashi, 1999). Takayasu arteritis may respond symptomatically to corticosteroid therapy, however, it is not curative. Selection of surgical bypass or angioplasty has improved survival.

Severe renovascular hypertension, cardiac involvement, or pulmonary hypertension worsen pregnancy prognosis. Despite this, from their review of 14 cases, Nagey and colleagues (1983) reported good outcomes. Subsequent reports and reviews support this (Johnston and colleagues, 2002; Kraemer and coworkers, 2008). When the abdominal aorta is involved, however, pregnancy outcome may be disastrous (Sharma and associates, 2000). Blood pressure is taken in the lower extremity. Vaginal delivery is preferred, and epidural analgesia has been advocated for labor and delivery (Langford and Kerr, 2002). *Polymyalgia rheumatica*, closely related to giant-cell arteritis, was described in one case as developing at 34 weeks and responding to prednisone (Sasaki and colleagues, 2005).

Other Vasculitides

Vasculitis caused by *Henoch-Schönlein purpura* is uncommon after childhood, and Kalmantis and associates (2008) reviewed 15 pregnancies complicated by this vasculitis. Cutaneous lesions were found in three fourths. About half had arthralgias, and half had nephritis that included cases of nephrotic syndrome and acute renal failure. Despite this, all but one woman had a successful pregnancy outcome. Jadaon and colleagues (2005) described 135 pregnancies in 31 women with *Behçet disease* compared with matched nonaffected controls. Although there were no deleterious effects of pregnancy on the underlying disease, the miscarriage rate was significantly increased threefold. Hwang and coworkers (2009) described necrotizing villitis and decidual vasculitis in a placenta from a first-trimester pregnancy termination and another from a term delivery. *Churg-Strauss vasculitis* is rare in pregnancy. Hot and associates (2007) described a pregnant woman who responded to intravenous immune globulin (IVIG) therapy. Corradi and co-workers (2009) described an affected 35-year-old woman at term whose necrotizing vasculitis involved the heart, and she subsequently underwent heart transplantation.

DERMATOMYOSITIS AND POLYMYOSITIS

These are uncommon acute, subacute, or chronic inflammatory diseases of unknown cause that involve mainly skin and muscle. Polymyositis is a subacute inflammatory myopathy that is frequently associated with one of the autoimmune connective-tissue disorders. Dermatomyositis manifests as a characteristic rash accompanying or preceding weakness. Laboratory findings include elevated muscle enzyme levels in serum and an abnormal electromyogram. Confirmation is by biopsy, which shows perivascular and perimysial inflammatory infiltrates, vasculitis, and muscle fiber degeneration. It usually develops alone but can overlap with scleroderma or mixed connective-tissue disease.

Prevailing theories are that the syndromes are caused by viral infections, autoimmune disorders, or both. *About 15 percent of adults who develop dermatomyositis have an associated malignant tumor.* The time of appearance of the two diseases may be separated by several years. The most common sites of associated cancer are breast, lung, stomach, and ovary. The disease usually responds to high-dose corticosteroid therapy, immunosuppressive drugs such as azathioprine or methotrexate, or intravenous immune globulin (Dalakas, 2008; Williams and colleagues, 2007).

Experiences in pregnancy are garnered mostly from case series and reviews. Gutierrez and colleagues (1984) reviewed outcomes in 10 pregnancies among seven women with active disease and described three abortions, three perinatal deaths, and five preterm deliveries. Rosenzweig and colleagues (1989) reviewed 24 pregnancy outcomes in 18 women with primary polymyositis-dermatomyositis. In half, the diagnosis preceded pregnancy. Of these, a fourth had an exacerbation in the second or third trimester. Excluding abortions, there were two perinatal deaths and two growth-restricted neonates. In the other half in whom disease became manifest first during pregnancy, outcomes were less favorable. One woman died 6 weeks postpartum. Excluding abortions, half of the eight pregnancies resulted in perinatal death. Ohno and associates (1992) and Papapetropoulos and co-workers (1998) described similar cases. From their review, Doria and colleagues (2004) concluded that pregnancy outcome was related to disease activity and that new-onset disease was particularly aggressive.

INHERITED CONNECTIVE-TISSUE DISORDERS

These are among the most common genetic diseases and may involve bone, skin, cartilage, blood vessels, and basement membranes. Among others, they include Marfan and Ehlers-Danlos syndromes, osteogenesis imperfecta, chondrodysplasia, and epidermolysis bulla.

Marfan Syndrome

Marfan syndrome is a common autosomal dominant connective-tissue disorder and has a prevalence of 1 in 3000 to 5000 (Prockop and Czarny-Ratajczak, 2008). It affects both sexes equally. The syndrome is caused by mutation of the fibrillin-1 (*FBN1*) gene on the long arm of chromosome 15 (Loeys and colleagues, 2002). The *FBN1* gene has a high mutation rate, and there are many mild, subclinical cases. In severe disease, there is degeneration of the elastic lamina in the media of the aorta. This weakness predisposes to aortic dilatation or dissecting aneurysm that appears more likely in pregnancy (Mor-Yosef and colleagues, 1988; Savi and associates, 2007). Aortic dissection may occur after elective cesarean delivery. Marfan syndrome complicating pregnancy is discussed in detail in Chapter 44 (p. 976).

Ehlers–Danlos Syndrome

This disease is characterized by a variety of changes in connective tissue, including hyperelasticity of the skin. In the more severe types, there is a strong tendency for rupture of any of several arteries to cause either strokes or bleeding. Rupture of the colon or uterus has been described. There are several types of disease based on skin, joint, or other tissue involvement. Some

are autosomal dominant, some recessive, and some X-linked. Their aggregate prevalence is about 1 in 5000 (Prockop and Czarny-Ratajczak, 2008). Types I, II, and III are autosomally dominant, and each accounts for about 30 percent of cases. Type IV is uncommon, but is known to predispose to preterm delivery, maternal great-vessel rupture, postpartum bleeding, and uterine rupture (Pepin and co-workers, 2000). In most, the underlying molecular defect is that of collagen or procollagen.

In general, women with Ehlers-Danlos syndrome have an increased frequency of preterm rupture of membranes, preterm delivery, and antepartum and postpartum hemorrhage (Volkov and associates, 2006). Tissue fragility makes episiotomy repair and cesarean delivery difficult. Sorokin and colleagues (1994) surveyed female members of the Ehlers-Danlos National Foundation. They reported a stillbirth rate of 3 percent, a preterm delivery rate of 23 percent, a cesarean delivery rate of 8 percent, and problematic postpartum bleeding in 15 percent. A number of cases of spontaneous uterine rupture have been described (Rudd and associates, 1983; Walsh and co-workers, 2007). A maternal and fetal death from spontaneous rupture of the right iliac artery was described by Esaka and colleagues (2009). Finally, Bar-Yosef and colleagues (2008) described a newborn with multiple congenital skull fractures and intracranial hemorrhage caused by Ehlers-Danlos type VIIC.
