The use of nipple stimulation in the third stage of labor also has been shown to increase uterine pressures and to decrease third-stage duration and blood loss (Irons and associates, 1994). Indeed, results were similar to those achieved using the combination of oxytocin (5 units) and ergometrine (0.5 mg).

Water Intoxication. The considerable antidiuretic action of oxytocin can cause water intoxication. With high-dose oxytocin, it is possible to produce water intoxication if the oxytocin is administered in a large volume of electrolyte-free aqueous dextrose solution (Whalley and Pritchard, 1963). For example, Schwartz and Jones (1978) described convulsions in both the mother and her newborn following administration of 6.5 liters of 5-percent dextrose solution and 36 units of oxytocin predelivery. The sodium concentration in cord plasma was 114 mEq/L.

In general, if oxytocin is to be administered in high doses for a considerable period of time, its concentration should be increased rather than increasing the flow rate of a more dilute solution (see Chap. 22, p. 507). Consideration also should be given to use of either normal saline or lactated Ringer solution in these circumstances.

Ergonovine and Methylergonovine

These are ergot alkaloids with similar activity levels in myometrium. Methylergonovine is also called ergometrine and ergostetrine. Whether given intravenously, intramuscularly, or orally, both these agents are powerful stimulants of myometrial contraction, exerting an effect that may persist for hours. In pregnant women, an intravenous dose of as little as 0.1 mg or an oral dose of only 0.25 mg results in a tetanic uterine contraction. Effects develop almost immediately after intravenous injection of the drug and within a few minutes after intramuscular or oral administration. Moreover, the response is sustained with little tendency toward relaxation. For this reason, they are dangerous for the fetus and mother prior to delivery.

Parenteral administration of ergot alkaloids, especially by the intravenous route, sometimes initiates transient hypertension. This is more likely to be severe in the woman with gestational hypertension or who is prone to develop hypertension. Browning (1974) described serious side effects attributable to 0.5 mg of ergonovine administered intramuscularly to four postpartum women. Two of these promptly became severely hypertensive, the third became hypertensive and convulsed, and the fourth suffered cardiac arrest. We have seen an instance of such profound vasoconstriction from these compounds when given intravenously that all peripheral pulses were lost, and sodium nitroprusside was required to restore perfusion. Unfortunately, the mother sustained cerebral hypoxic ischemic injury.

Studies of Oxytocin and Ergot Alkaloids. Choy and co-workers (2002) randomly assigned 991 women to receive intravenous oxytocin or intramuscular syntometrine for prevention of third-stage blood loss. Syntometrine is a combined oxytocin and ergonovine agent. They reported oxytocin to be preferable because syntometrine induced hypertension in 3 percent of women. In a similar study of 600 women, Orji and associates (2008) also reported no differences except for increased nausea, vomiting, and hypertension in the syntometrine group.

Munn and co-workers (2001) compared two oxytocin dosage regimens for prevention of uterine atony at cesarean delivery. Either 10 units or 80 units of oxytocin in 500 mL of lactated Ringer solution were infused during the 30 minutes following delivery of the newborn. The rate of uterine atony was significantly lower in the high-dose regimen group compared with that of the lower-dose group—19 versus 39 percent, respectively.

Prostaglandins

Analogs of prostaglandins are not used routinely for management of third-stage labor. Villar and colleagues (2002) reviewed prophylactic use of misoprostol to prevent postpartum hemorrhage and concluded that oxytocin or oxytocin-ergot preparations are more effective. Other prostaglandins such as 15-methyl

prostaglandin $F_{2\alpha}$ are reserved for treatment of uterine atony with hemorrhage (see Chap. 35, p. 774).

"Fourth Stage" of Labor

The placenta, membranes, and umbilical cord should be examined for completeness and for anomalies, as described in Chapter 27. The hour immediately following delivery is critical, and it has been designated by some as the *fourth stage of labor*. Although oxytocics are administered, postpartum hemorrhage as the result of uterine atony is more likely at this time. Consequently, the uterus and perineum should be frequently evaluated. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) recommend that maternal blood pressure and pulse be recorded immediately after delivery and every 15 minutes for the first hour.

Lacerations of the Birth Canal

Lacerations of the vagina and perineum are classified as first- through fourth-degree lacerations or perineal tears. *First-degree* lacerations involve the fourchette, perineal skin, and vaginal mucous membrane but not the underlying fascia and muscle (Fig. 17-34). These included periurethral lacerations, which may bleed profusely. *Second-degree* lacerations involve, in addition, the fascia and muscles of the perineal body but not the anal sphincter. These tears usually extend upward on one or both sides of the vagina, forming an irregular triangular injury.

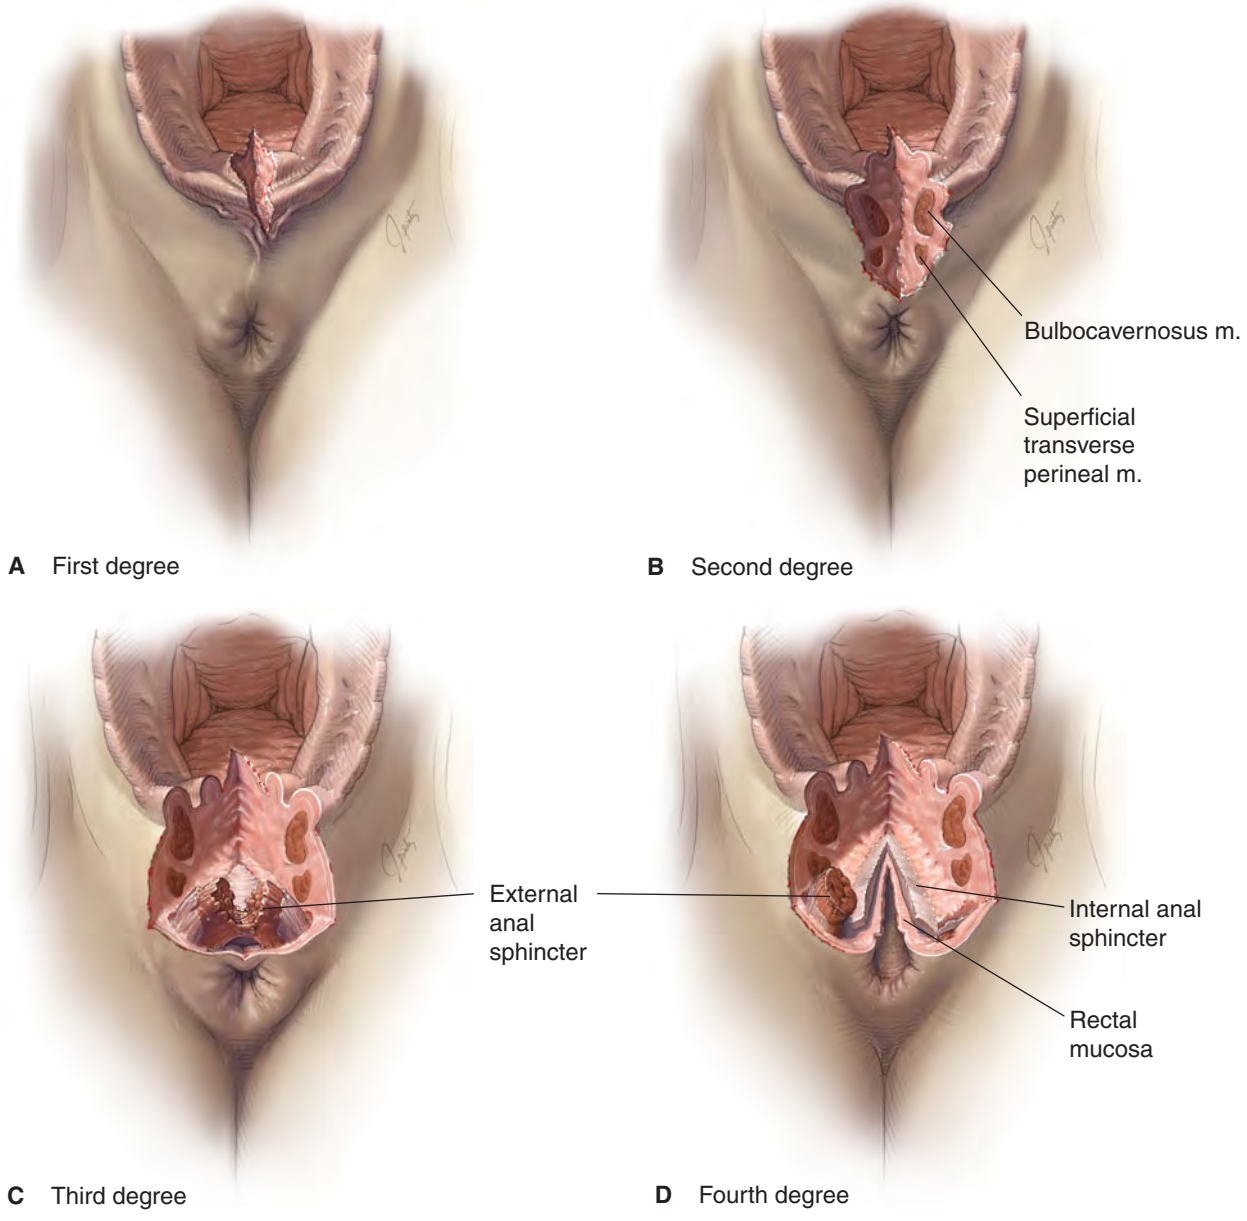

FIGURE 17-34 Classification of perineal lacerations. **A.** First-degree laceration is a superficial tear that involves the vaginal mucosa and/or perineal skin. **B.** A second-degree laceration extends into the fascia and muscles that surround the vagina. **C.** A third-degree laceration extends into or through the external anal sphincter muscle. **D.** A fourth-degree laceration extends into the anorectal lumen and thus involves disruption of both the external and internal anal sphincters. (Courtesy of Drs. Marlene Corton and Shayzreen Roshanravan.)

Third-degree lacerations extend farther to involve the anal sphincter. A *fourth-degree* laceration extends through the rectum's mucosa to expose its lumen.

Laceration Risks and Morbidity

Perineal tears may follow any vaginal delivery, but Combs and associates (1990) identified factors associated with an increased risk of third- and fourth-degree lacerations. These include midline episiotomy, nulliparity, second-stage arrest of labor, persistent occiput posterior position, mid or low forceps, use of local anesthetics, and Asian race.

Morbidity rates rise as laceration severity increases. Venkatesh and colleagues (1989) reported a 5-percent incidence of third- and fourth-degree perineal tears in 20,500 vaginal deliveries. Approximately 10 percent of these 1040 primary repairs had a postoperative wound disruption and two thirds required surgical correction. Williams and Chames (2006) found that mediolateral episiotomy was the most powerful predictor of wound disruption. Goldaber and associates (1993) found that 21 of 390 or 5.4 percent of women with fourth-degree lacerations experienced significant morbidity. There were 1.8 percent dehiscences, 2.8 percent infections with dehiscences, and 0.8 percent with isolated infections. Although administration of a perioperative 2-g intravenous dose of cefazolin reduced rates of this morbidity, it was not totally eliminated.

Because repair of perineal lacerations is virtually the same as that of episiotomy incisions, albeit sometimes less satisfactory because of tear irregularities, the technique of laceration repair is discussed with episiotomy repair.

Episiotomy

In a strict sense, episiotomy is incision of the pudenda. Perineotomy is incision of the perineum. In common parlance, however, the term *episiotomy* often is used synonymously with *perineotomy,* a practice that we follow here. The incision may be made in the midline, creating a *median* or *midline episiotomy.* It may also begin in the midline but be directed laterally and downward away from the rectum, termed a *mediolateral episiotomy.*

Purposes of Episiotomy

Although still a common obstetrical procedure, the use of episiotomy has decreased remarkably over the past 25 years. Weber and Meyn (2002) used the National Hospital Discharge Survey to analyze use of episiotomy between 1979 and 1997 in the United States. Approximately 65 percent of women delivered vaginally in 1979 had an episiotomy compared with 39 percent by 1997. By 2003, the rate had decreased to approximately 18 percent (Martin and colleagues, 2005). Through the 1970s, it was common practice to cut an episiotomy for almost all women having their first delivery. The reasons for its popularity included substitution of a straight surgical incision, which was easier to repair, for the ragged laceration that otherwise might result. The long-held beliefs that postoperative pain is less and healing improved with an episiotomy compared with a tear, however, appeared to be incorrect (Larsson and colleagues, 1991).

Another commonly cited but unproven benefit of routine episiotomy was that it prevented pelvic floor complications—that is, vaginal wall support defects and incontinence. A number of observational studies and randomized trials, however, showed that routine episiotomy is associated with an *increased* incidence of anal sphincter and rectal tears (Angioli, 2000; Eason, 2000; Nager and Helliwell, 2001; Rodriguez, 2008, and all their colleagues).

Carroli and Mignini (2009) reviewed the Cochrane Pregnancy and Childbirth Group trials registry. There were lower rates of posterior perineal trauma, surgical repair, and healing complications in the restricted-use group. Alternatively, the incidence of anterior perineal trauma was lower in the routine-use group.

With these findings came the realization that episiotomy did not protect the perineal body and contributed to anal sphincter incontinence by increasing the risk of third- and fourth-degree tears. Signorello and associates (2000) reported that fecal and flatus incontinence were increased four- to sixfold in women with an episiotomy compared with a group of women delivered with an intact perineum. Even compared with spontaneous lacerations, episiotomy tripled the risk of fecal incontinence and doubled it for flatus incontinence. Episiotomy without extension did not lower this risk. Despite repair of a third-degree extension, 30 to 40 percent of women have long-term anal incontinence (Gjessing and co-workers, 1998; Poen and colleagues, 1998). Finally, Alperin and associates (2008) recently reported that episiotomy performed for the first delivery conferred a fivefold risk for second-degree or worse lacerations with the second delivery.

For all of these reasons, the American College of Obstetricians and Gynecologists (2006) has concluded that restricted use of episiotomy is preferred to routine use. We are of the view that the procedure should be applied selectively for appropriate indications. These include fetal indications such as shoulder dystocia and breech delivery, forceps or vacuum extractor deliveries, occiput posterior positions, and instances in which failure to perform an episiotomy will result in perineal rupture. *The final rule is that there is no substitute for surgical judgment and common sense.*

Timing of Episiotomy

If performed unnecessarily early, bleeding from the episiotomy may be considerable during the interim between incision and delivery. If it is performed too late, lacerations will not be prevented. Typically, episiotomy is completed when the head is visible during a contraction to a diameter of 3 to 4 cm (see Fig. 17-24). When used in conjunction with forceps delivery, most perform an episiotomy after application of the blades (see Chap. 23, p. 514).

Midline versus Mediolateral Episiotomy

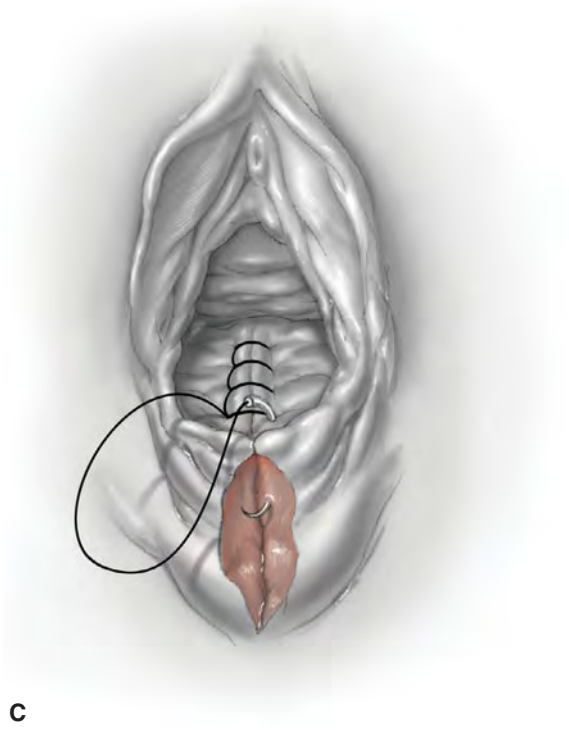
Differences between the two types of episiotomies are summarized in Table 17-5. Except for the important issue of third- and fourth-degree extensions, midline episiotomy is superior. Anthony

TABLE 17-5. Midline Versus Mediolateral Episiotomy

	Type of Episiotomy	
Characteristic	**Midline**	**Mediolateral**
Surgical repair	Easy	More difficult
Faulty healing	Rare	More common
Postoperative pain	Minimal	Common
Anatomical results	Excellent	Occasionally faulty
Blood loss	Less	More
Dyspareunia	Rare	Occasional
Extensions	Common	Uncommon

and colleagues (1994) presented data from the Dutch National Obstetric Database of more than 43,000 deliveries. They found a more than fourfold decrease in severe perineal lacerations following mediolateral episiotomy compared with rates after midline incision. Proper selection of cases can minimize this one disadvantage. For example, Kudish and co-workers (2006) advised against midline episiotomy with operative vaginal delivery because of an increased incidence of anal sphincter tears.

Episiotomy Repair



Typically, episiotomy repair is deferred until the placenta has been delivered. This policy permits undivided attention to the signs of placental separation and delivery. A further advantage is that episiotomy repair is not interrupted or disrupted by the obvious necessity of delivering the placenta, especially if manual removal must be performed. The major disadvantage is continuing blood loss until the repair is completed.

Technique. There are many ways to close an episiotomy incision, but *hemostasis and anatomical restoration without excessive suturing are essential* for success with any method. Adequate analgesia is imperative, and Sanders and co-workers (2002) emphasized that women without regional analgesia can experience high levels of pain during perineal suturing. A technique that commonly is employed is shown in Figure 17-35. Mornar and Perlow (2008) have shown that blunt needles are suitable and likely decrease the incidence of needlestick injuries. The suture material commonly used is 2-0 chromic catgut. Sutures made of polyglycolic acid derivatives are also commonly used. A decrease in postsurgical pain is cited as the major advantage of synthetic materials. However, closures with these materials occasionally require suture removal from the repair site because of pain or dyspareunia. Kettle and co-workers (2002) randomly assigned 1542 women with perineal lacerations or episiotomies to undergo continuous versus interrupted repair with rapidly absorbed polyglactin 910 (Vicryl Rapids, Ethicon) or standard polyglactin 910 sutures. The former typically is absorbed by 42 days and the latter not for approximately 90 days. The continuous method was associated with less perineal pain. The rapidly absorbed material was associated with lower rates of suture removal compared with standard polyglactin—3 versus 13 percent. In another randomized study comparing continuous

versus interrupted closure, Valenzuela (2009) and Kindberg (2008) and their associates found no differences in the techniques.

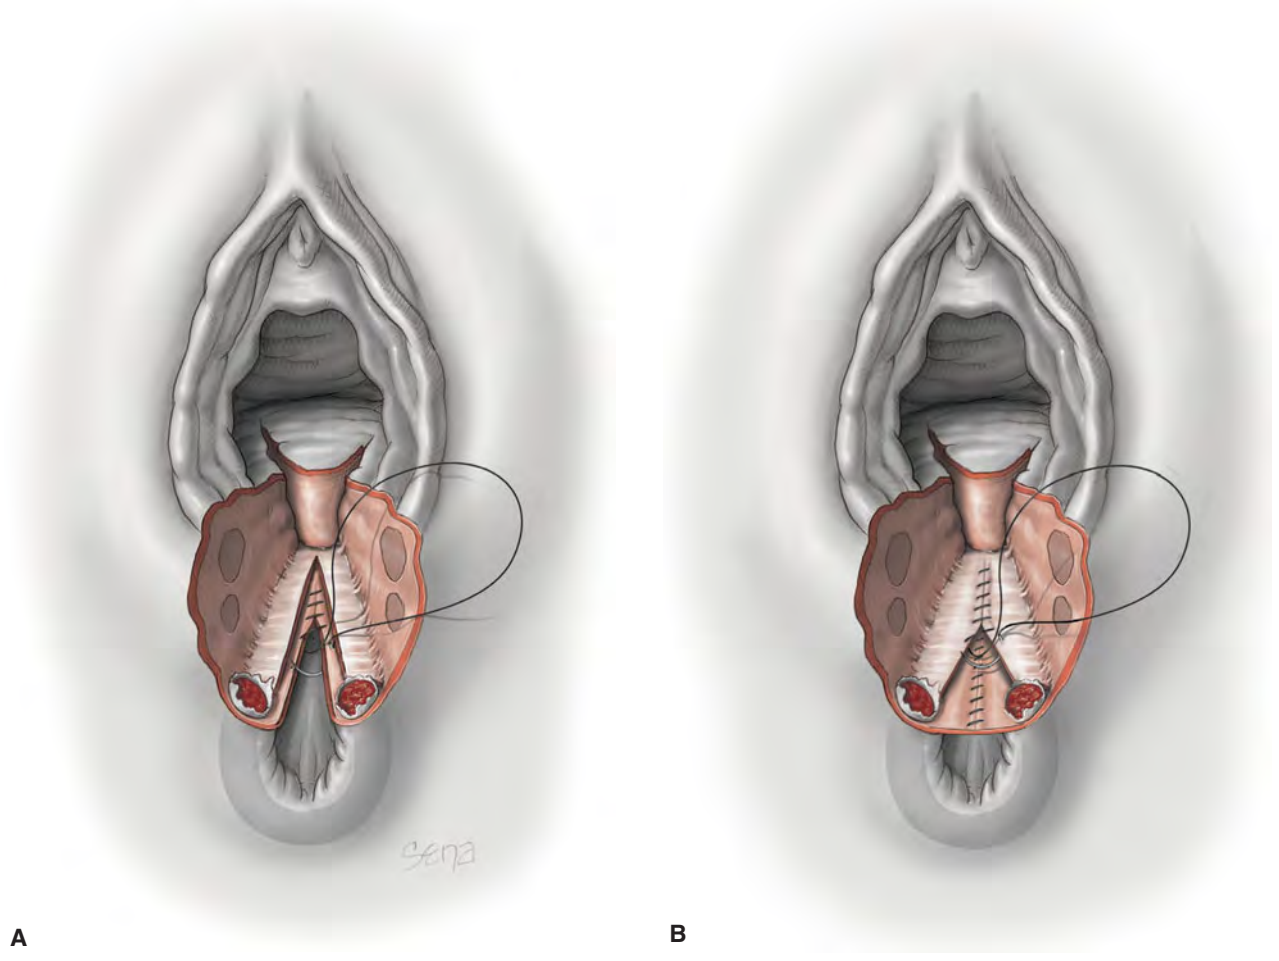
Repair of Fourth-Degree Laceration. The end-to-end technique of repairing a fourth-degree laceration is shown in Figure 17-36. Other techniques have been described, but in all, it is essential to approximate the torn edges of the rectal mucosa with sutures placed in the rectal muscularis approximately 0.5 cm apart. This muscular layer then is covered with a layer of fascia. Finally, the cut ends of the anal sphincter are isolated, approximated, and sutured together with three or four interrupted stitches. The remainder of the repair is the same as for an episiotomy.

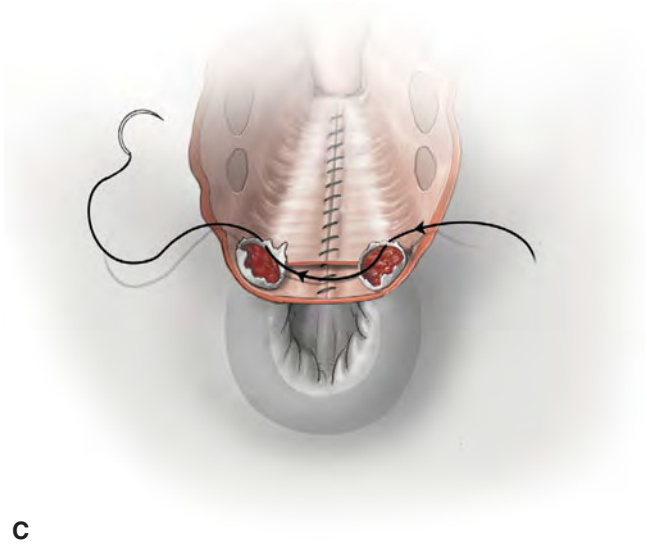
The overlapping technique is an alternative method to approximate the external anal sphincter. Despite promising initial results with this technique, more recent data based on a randomized controlled trial do not support that this method yields superior anatomical or functional results compared with those of the traditional end-to-end technique (Fitzpatrick and colleagues, 2000; Sultan and co-workers, 1999). Thus, more emphasis should be placed on prevention of anal sphincter lacerations (Cunningham, 2008). Postrepair, stool softeners should be prescribed for a week, and enemas should be avoided. Prophylactic antimicrobials should be considered, as described by Goldaber and associates (1993). Unfortunately, normal function is not always ensured even with correct and complete surgical repair. Some women may experience continuing fecal incontinence caused by injury to the innervation of the pelvic floor musculature (Roberts and co-workers, 1990).

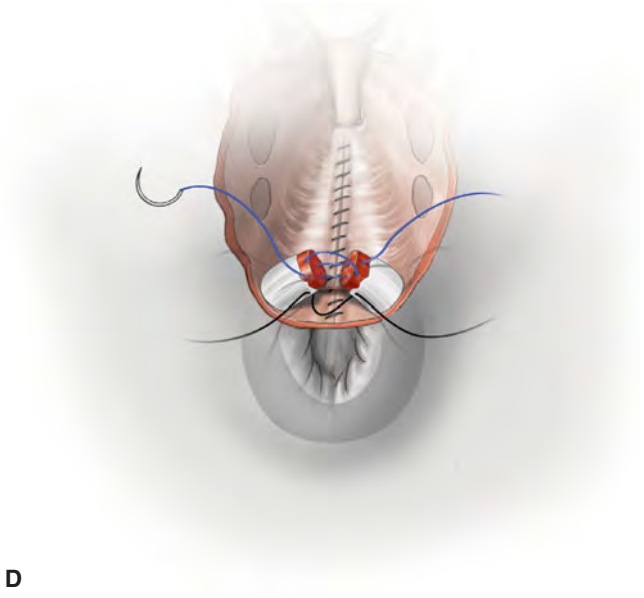
Pain after Episiotomy

Pudendal block analgesia will help to relieve perineal pain postoperatively (Aissaoui and associates, 2008). Application of ice packs helps to reduce swelling and allay discomfort. In one randomized trial, Minassian and colleagues (2002) reported that topical application of 5-percent lidocaine ointment was not effective in relieving episiotomy or perineal laceration discomfort. Analgesics such as codeine give considerable relief. **Because pain may be a signal of a large vulvar, paravaginal, or ischiorectal hematoma or perineal cellulitis, it is essential to examine these sites carefully if pain is severe or persistent.** Management of these complications is discussed in Chapter 35 (p. 783).

Signorello and co-workers (2001) surveyed 615 women 6 months postpartum and reported that those delivered with an intact perineum reported better sexual function compared with







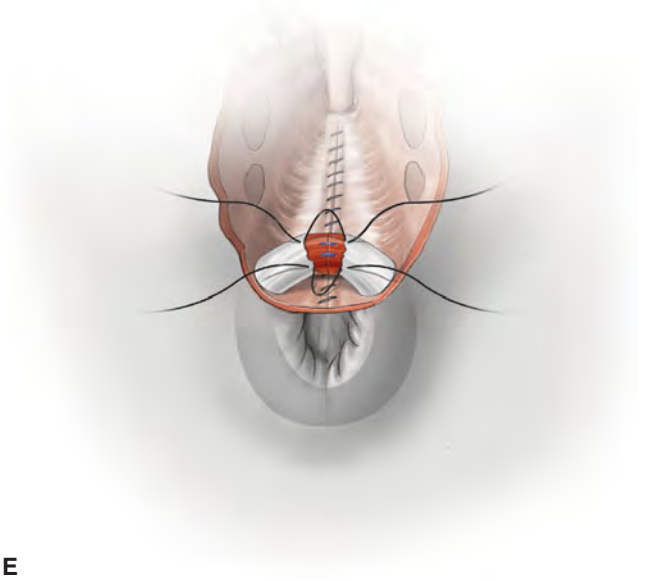


FIGURE 17-36 Layered repair of a fourth-degree perineal laceration. **A.** Approximation of the anorectal mucosa and submucosa in a running or interrupted fashion using fine absorbable suture such as 3-0 or 4-0 chromic or Vicryl. During this suturing, the superior extent of the anterior anal laceration is identified, and the sutures are placed through the submucosa of the anorectum approximately 0.5 cm apart down to the anal verge. **B.** A second layer is placed through the rectal muscularis using 3-0 Vicryl suture in a running or interrupted fashion. This "reinforcing layer" should incorporate the torn ends of the internal anal sphincter, which is identified as the thickening of the circular smooth muscle layer at the distal 2 to 3 cm of the anal canal. It can be identified as the glistening white fibrous structure lying between the anal canal submucosa and the fibers of the external anal sphincter (EAS). In many cases, the internal sphincter retracts laterally and must be sought and retrieved for repair. (*Continued*)

C

D

E

FIGURE 17-36 *Continued*. In overview, with traditional end-to-end approximation of the EAS, a suture is placed through the EAS muscle, and four to six simple interrupted 2-0 or 3-0 Vicryl sutures are placed at the 3, 6, 9, and 12 o'clock positions through the EAS muscle's connective tissue capsule. The sutures through the inferior and posterior portions of the sphincter should be placed first and tied last to aid this part of the repair. Initially with closure, the disrupted ends of the striated (EAS) muscle and capsule are identified and grasped with Allis clamps.**C.** Suture through the posterior wall of the external anal sphincter (EAS) capsule. **D.** Sutures through the EAS (*blue suture*) and inferior capsule wall. **E.** Sutures to reapproximate the anterior and superior walls of the EAS capsule. The remainder of the repair is similar to that described for a midline episiotomy in FIGURE 17-35.

those who had perineal trauma. In another follow-up of 2490 women, Rådestad and associates (2008) reported delayed intercourse at 3 and 6 months, but not at 1 year in women with and without perineal trauma. Finally, Brubaker and colleagues (2008) reported that women with anal sphincter lacerations at delivery had decreased sexual activity at 6 months.

LABOR MANAGEMENT PROTOCOLS

An orderly and systematic approach to labor management results in reproducible maternal and perinatal outcomes. This was recently proven by Althabe and co-workers (2008), who randomized implementation of evidence-based care in 19 hospitals in Argentina and Uruguay. Several labor management protocols are subsequently presented. These include those from the National Maternity Hospital in Dublin, the World Health Organization, and from Parkland Hospital.

Active Management of Labor

More than 30 years ago, O'Driscoll and colleagues (1984) at the National Maternity Hospital in Dublin pioneered the concept that a disciplined, standardized labor management protocol reduced the number of cesarean deliveries for dystocia. Their overall cesarean delivery rate was 5 percent in the 1970s and 1980s with such management. The approach is now referred to as *active management of labor*. Two of its components—amniotomy and oxytocin—have been widely used, especially in English-speaking countries outside the United States (Thornton and Lilford, 1994). With this protocol, labor is diagnosed when painful contractions are

accompanied by complete cervical effacement, bloody "show," or ruptured membranes. Women with such findings are committed to delivery within 12 hours. Pelvic examination is performed each hour for the next 3 hours, and thereafter at 2-hour intervals. When dilatation has not increased by at least 1 cm/hr, amniotomy is performed. Progress is again assessed at 2 hours and high-dose oxytocin infusion, described in Chapter 22 (p. 506), is started unless dilatation of at least 1 cm/hr is documented. Women are constantly attended by midwives.

If membranes rupture prior to admission, oxytocin is begun for no progress at the 1-hour mark. No special equipment is used, either to dispense oxytocin or to monitor its effects, and electronic uterine contraction monitoring is not used. Oxytocin is dispensed by gravity and regulated by a personal nurse. The solution contains 10 units of oxytocin in 1 L of dextrose and water. The total dose may not exceed 10 units, and the infusion rate may not exceed 30 to 40 mU/min. In the Dublin protocol, scalp blood sampling is used as the definitive test for fetal distress.

López-Zeno and colleagues (1992) prospectively compared such active management with their "traditional" approach to labor management at Northwestern Memorial Hospital in Chicago. They randomly assigned 705 nulliparas with uncomplicated pregnancies in spontaneous labor at term. The cesarean delivery rate was statistically lower with active versus traditional management—10.5 versus 14.1 percent, respectively. Subsequent studies did not show this. Wei and associates (2009) in a Cochrane database review found a modest reduction in cesarean delivery rates when active management of labor was compared with standard care. Frigoletto and co-workers (1995) reported another randomized trial with 1934 nulliparous women at Brigham and Women's Hospital in Boston. Although they found that such management somewhat shortened labor, it did not affect the cesarean delivery rate. These observations have since been reported by many others (Impey, 2000; Nicholson, 2008; Rogers, 1997; Sadler, 2000, and all their associates). The American College of Obstetricians and Gynecologists (2003a) concluded that active management of labor may shorten labor, although it has not consistently been shown to reduce rates of cesarean delivery. In a recent Cochrane Database systematic analysis, Brown and colleagues (2008) reached similar conclusions.

World Health Organization Partogram

A *partogram* was designed by the World Health Organization (WHO) for use in developing countries (Dujardin and co-workers, 1992). According to Orji (2008), the partograph is similar for nulliparas and multiparas. Labor is divided into a latent phase, which should last no longer than 8 hours, and an active phase. The active phase starts at 3 cm dilatation, and progress should be no slower than 1 cm/hr. A 4-hour wait is recommended before intervention when the active phase is slow. Labor is graphed, and analysis includes use of alert and action lines. Lavender and colleagues (2006) randomized 3000 nulliparous women to labor interventions at 2 hours versus 4 hours as recommended by WHO. Their cesarean delivery rate was unaffected, and they concluded that interventions such as amniotomy and oxytocin were needlessly increased using the 2-hour time interval. After their recent Cochrane Database systematic review, Lavender and associates (2008) do not recommend use of the partograph for standard labor management.

Parkland Hospital Labor Management Protocol

During the 1980s, the obstetrical volume at Parkland Hospital doubled to approximately 15,000 births per year. In response, a second delivery unit for women with uncomplicated term pregnancies was designed. This provided a unique opportunity to implement and evaluate a standardized protocol for labor management. Its design was based on the approach that had evolved at our hospital up to that time. This emphasized the implementation of specific, sequential interventions when abnormal labor was suspected. This approach currently is used in both complicated and uncomplicated pregnancies.

Women are admitted if active labor—defined as cervical dilatation of 3 to 4 cm or more in the presence of uterine contractions—is diagnosed or if ruptured membranes are confirmed. Management guidelines summarized in **Figure 17-37** stipulate that a pelvic examination be performed approximately every 2 hours. Ineffective labor is suspected when the cervix does not dilate within approximately 2 hours of admission. Amniotomy is then performed, and labor progress determined at the next 2-hour evaluation. In women whose labors do not progress, an intrauterine pressure catheter is placed to assess uterine function. Hypotonic contractions and no cervical dilatation after an additional 2 to 3 hours result in stimulation of labor using the high-dose oxytocin regimen described in Chapter 22 (p. 506). The goal is uterine activity of 200 to 250 Montevideo units for 2 to 4 hours before dystocia can be diagnosed.

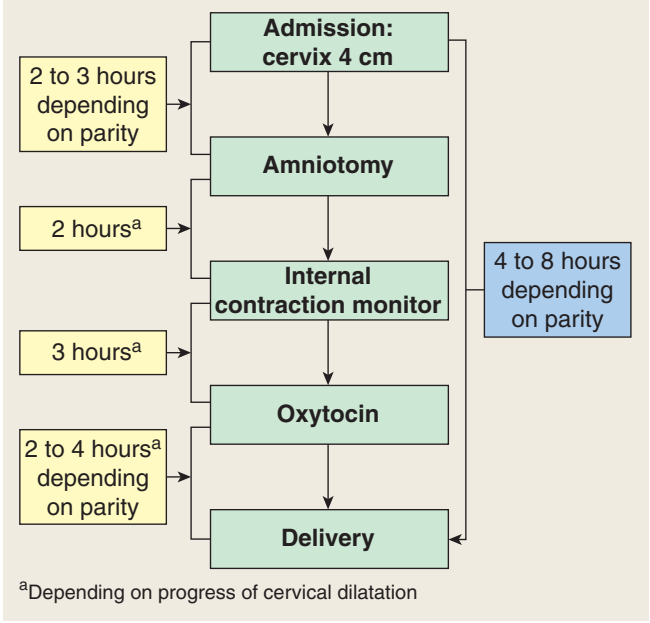

FIGURE 17-37 Schematic of labor management protocol in use at Parkland hospital. The total admission-to-delivery times are shorter than the potential sum of the intervention intervals because not every woman requires every intervention.

Dilatation rates of 1 to 2 cm/hr are accepted as evidence of progress after satisfactory uterine activity has been established with oxytocin. As shown in Figure 17-37, this can require up to 8 hours or more before cesarean delivery is performed for dystocia. The cumulative time required to effect this stepwise management approach permits many women to establish effective labor. This management protocol has been evaluated in more than 20,000 women with uncomplicated pregnancies. Cesarean delivery rates in nulliparous and parous women were 8.7 and 1.5 percent, respectively. Importantly, these labor interventions and the relatively infrequent use of cesarean delivery did not jeopardize the fetus-newborn.

CHAPTER 18

Intrapartum Assessment

ELECTRONIC FETAL MONITORING 410
OTHER INTRAPARTUM ASSESSMENT TECHNIQUES 426
FETAL DISTRESS 429
INTRAPARTUM SURVEILLANCE OF UTERINE ACTIVITY . . 437

Following earlier work by Hon (1958), continuous electronic fetal monitoring (EFM) was introduced into obstetrical practice in the late 1960s. No longer were intrapartum fetal surveillance and the suspicion of fetal distress based upon periodic auscultation with a fetoscope. Instead, the continuous graph-paper portrayal of the fetal heart rate was potentially diagnostic in assessing pathophysiological events affecting the fetus. Indeed, there were great expectations that:

- Electronic fetal heart rate monitoring provided accurate information
- The information was of value in diagnosing fetal distress
- It would be possible to intervene to prevent fetal death or morbidity
- Continuous electronic fetal heart rate monitoring was superior to intermittent methods.

When first introduced, electronic fetal heart rate monitoring was used primarily in complicated pregnancies, but gradually became used in most pregnancies. By 1978, it was estimated that nearly two thirds of American women were being monitored electronically during labor (Banta and Thacker, 1979). In 2002, approximately 3.4 million American women, comprising 85 percent of all live births, underwent electronic fetal monitoring (Martin and colleagues, 2003). Indeed, fetal monitoring has become the most prevalent obstetrical procedure in the United States (American College of Obstetricians and Gynecologists, 2005).

ELECTRONIC FETAL MONITORING

Internal Electronic Monitoring

The fetal heart rate may be measured by attaching a bipolar spiral electrode directly to the fetus (**Fig. 18-1**). The wire electrode penetrates the fetal scalp, and the second pole is a metal wing on the electrode. Vaginal body fluids create a saline electrical bridge that completes the circuit and permits measurement of the voltage differences between the two poles. The two wires of the bipolar electrode are attached to a reference electrode on the maternal thigh to eliminate electrical interference. The electrical fetal cardiac signal—P wave, QRS complex, and T wave—is amplified and fed into a cardiotachometer for heart rate calculation. The peak R-wave voltage is the portion of the fetal electrocardiogram most reliably detected.

An example of the method of fetal heart rate processing employed when a scalp electrode is used is shown in **Figure 18-2**. Time (t) in milliseconds between fetal R waves is fed into a cardiotachometer, where a new fetal heart rate is set with the arrival of each new R wave. As also shown in Figure 18-2, a premature atrial contraction is computed as a heart rate acceleration because the interval (t_2) is shorter than the preceding one (t_1). The phenomenon of continuous R-to-R wave fetal heart rate computation is known as *beat-to-beat variability.* The physiological event being counted, however, is not a mechanical event corresponding to a heartbeat but rather an electrical event.

Electrical cardiac complexes detected by the electrode include those generated by the mother. Although the maternal electrocardiogram (ECG) signal is approximately five times stronger than the fetal ECG, its amplitude is diminished when it is recorded through the fetal scalp electrode. In a live fetus, this low maternal ECG signal is detected but masked by the fetal ECG. If the fetus is dead, the weaker maternal signal will be

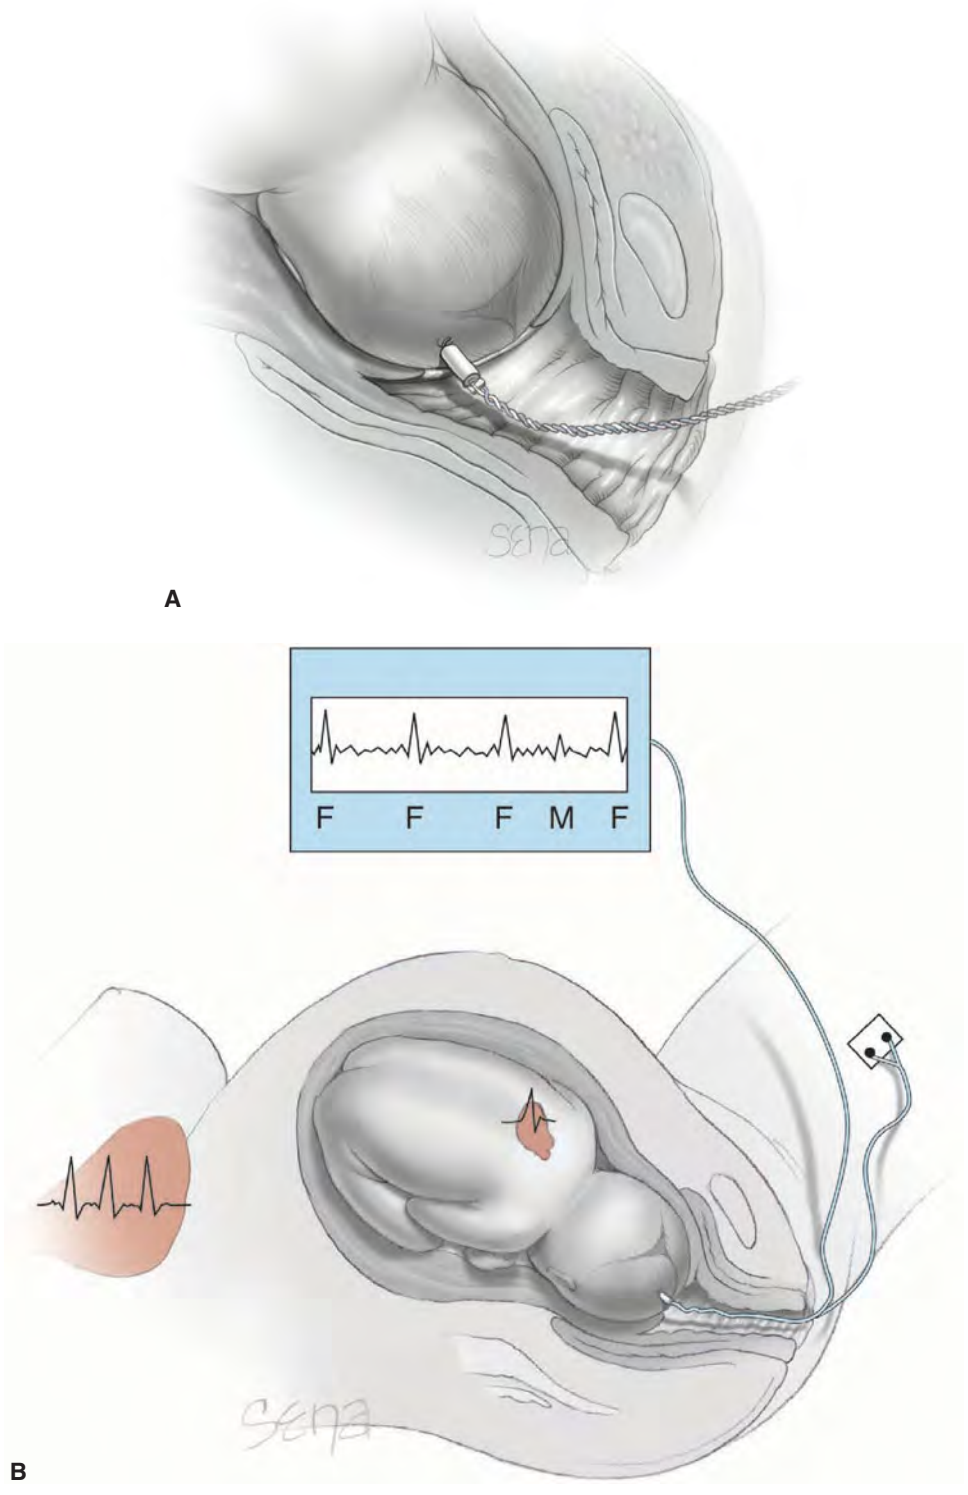

FIGURE 18-1 Internal electronic fetal monitoring. **A.** Scalp electrode penetrates the fetal scalp by means of a coiled electrode. **B.** Schematic representation of a bipolar electrode attached to the fetal scalp for detection of fetal QRS complexes (F). Also shown is the maternal heart and corresponding electrical complex (M) that is detected.

amplified and displayed as the "fetal" heart rate (Freeman and co-workers, 2003). Shown in Figure 18-3 are simultaneous recordings of maternal chest wall ECG signals and fetal scalp electrode ECG signals. This fetus is experiencing premature atrial contractions, which cause the cardiotachometer to rapidly and erratically seek new heart rates, resulting in the "spiking" shown in the standard fetal monitor tracing. Importantly, when the fetus is dead, the maternal R waves are still detected by the scalp electrode as the next best signal and are counted by the cardiotachometer (Fig. 18-4).

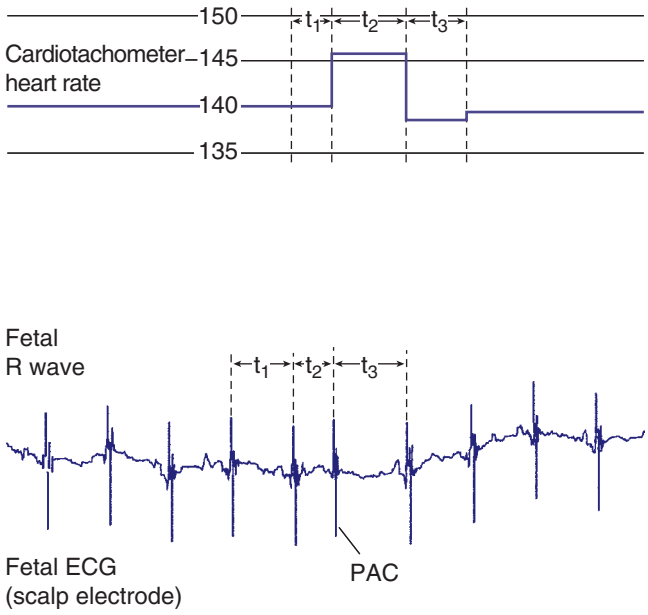

FIGURE 18-2 Schematic representation of fetal electrocardiographic signals used to compute continuing beat-to-beat heart rate with scalp electrodes. Time intervals (t_1, t_2, t_3) in milliseconds between successive fetal R waves are used by cardiotachometer to compute instantaneous fetal heart rate. (ECG = electrocardiogram; PAC = premature atrial contraction.)

External (Indirect) Electronic Monitoring

The necessity for membrane rupture and uterine invasion may be avoided by use of external detectors to monitor fetal heart action and uterine activity. External monitoring, however, does not provide the precision of fetal heart rate measurement or the quantification of uterine pressure afforded by internal monitoring.

The fetal heart rate is detected through the maternal abdominal wall using the *ultrasound Doppler principle* (Fig. 18-5). Ultrasound waves undergo a shift in frequency as they are reflected from moving fetal heart valves and from pulsatile blood ejected during systole (see Chap. 16, p. 362).

The unit consists of a transducer that emits ultrasound and a sensor to detect a shift in frequency of the reflected sound. The transducer is placed on the maternal abdomen at a site where fetal heart action is best detected. A coupling gel must be applied because air conducts ultrasound poorly. The device is held in position by a belt. Care should be taken that maternal arterial pulsations are not confused with fetal cardiac motion (Neilson and associates, 2008).

Ultrasound Doppler signals are edited electronically before fetal heart rate data are printed onto the bedside monitor tracing paper. Reflected ultrasound signals from moving fetal heart valves are analyzed through a microprocessor that compares incoming signals with the most recent previous signal. This process, called *autocorrelation*, is based on the premise that the fetal heart rate has regularity whereas "noise" is random and without regularity. Several fetal heart motions must be deemed electronically acceptable by the microprocessor before the fetal heart rate is printed. Such electronic editing has greatly improved the tracing quality of the externally recorded fetal heart rate.

Fetal Heart Rate Patterns

It is now generally accepted that interpretation of fetal heart rate patterns can be problematic because of the lack of agreement on definitions and nomenclature (American College of Obstetricians and Gynecologists, 2005). The National Institute of Child Health and Human Development (NICHD) Research Planning Workshop (1997) brought together investigators with expertise in the field to propose standardized, unambiguous definitions for interpretation of fetal heart rate patterns during labor. The definitions proposed as a result of this workshop will be used in this chapter (Table 18-1). First, it is important to recognize that interpretation of electronic fetal heart rate data is based on the visual pattern of the heart rate as portrayed on chart recorder graph paper. Thus, the choice of vertical and horizontal scaling greatly affects the appearance of the fetal heart rate. Scaling factors recommended by the workshop are 30 beats per minute (beats/min or bpm) per vertical cm (range, 30 to 240 beats/min) and 3 cm/min chart recorder paper speed. Fetal heart rate variation is falsely displayed at the slower 1 cm/min paper speed compared with that of the smoother baseline recorded at 3 cm/min (Fig. 18-6). Thus, pattern recognition can be considerably distorted depending on the scaling factors used.

Baseline Fetal Heart Activity

Baseline fetal heart activity refers to the modal characteristics that prevail apart from periodic accelerations or decelerations associated with uterine contractions. Descriptive characteristics of baseline fetal heart activity include *rate, beat-to-beat variability, fetal arrhythmia*, and distinct patterns such as *sinusoidal* or *saltatory* fetal heart rates.

Rate

With increasing fetal maturation, the heart rate decreases. This continues postnatally such that the average rate is 90 beats/min by age 8 (Behrman, 1992). Pillai and James (1990) longitudinally studied fetal heart rate characteristics in 43 normal pregnancies. The baseline fetal heart rate decreased an average of 24 beats/min between 16 weeks and term, or approximately 1 beat/min per week. It is postulated that this normal gradual slowing of the fetal heart rate corresponds to maturation of parasympathetic (vagal) heart control (Renou and co-workers, 1969).

The baseline fetal heart rate is the approximate mean rate rounded to increments of 5 beats/min during a 10-minute tracing segment. In any 10-minute window, the minimum interpretable baseline duration must be at least 2 minutes. If the baseline fetal heart rate is less than 110 beats/min, it is termed *bradycardia.* If the baseline rate is greater than 160 beats/min, it is termed *tachycardia.* The average fetal heart rate is considered the result of tonic balance between *accelerator* and *decelerator* influences on pacemaker cells. In this concept, the sympathetic system is the accelerator influence, and the parasympathetic system is the decelerator factor mediated via vagal slowing of heart rate (Dawes, 1985). Heart rate also is under the control of

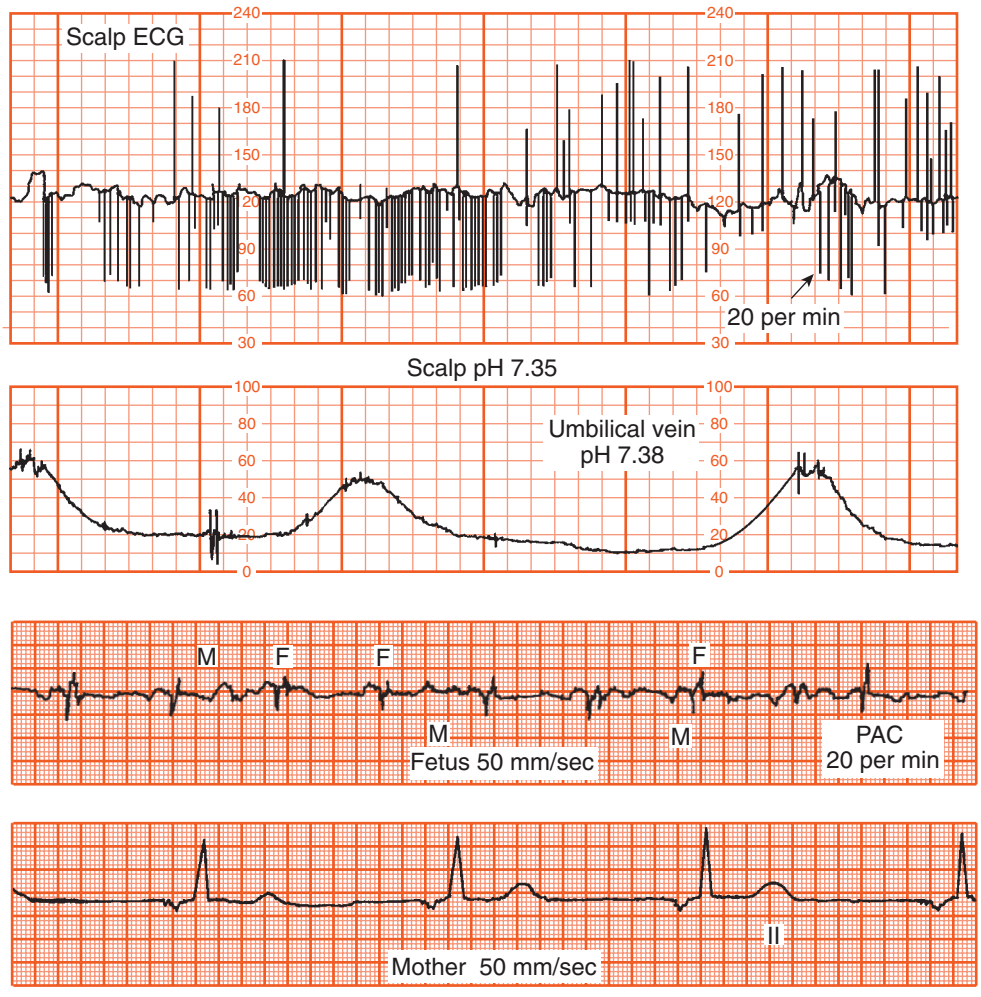

FIGURE 18-3 The top tracing shows standard fetal monitor tracing of heart rate using fetal scalp electrode. Spiking of the fetal rate in the monitor tracing is due to premature atrial contractions. The second panel displays accompanying contractions. The bottom two tracings represent cardiac electrical complexes detected from fetal scalp and maternal chest wall electrodes. (ECG = electrocardiogram; F = fetus; M = mother; PAC = fetal premature atrial contraction.)

arterial chemoreceptors such that both hypoxia and hypercapnia can modulate rate. More severe and prolonged hypoxia, with a rising blood lactate level and severe metabolic acidemia, induces a prolonged fall in heart rate (Thakor and Giussani, 2009).

Bradycardia. During the third trimester, the normal mean baseline fetal heart rate has generally been accepted to be between 120 and 160 beats/min. The lower normal limit is disputed internationally, with some investigators recommending 110 beats/min (Manassiev, 1996). Pragmatically, a rate between 100 and 119 beats/min, in the absence of other changes, usually is not considered to represent fetal compromise. Such low but potentially normal baseline heart rates also have been attributed to head compression from occiput posterior or transverse positions, particularly during second-stage labor (Young and Weinstein, 1976). Such mild bradycardias were observed in 2 percent of monitored pregnancies and averaged approximately 50 minutes in duration. Freeman and colleagues (2003) have concluded that bradycardia within the range of 80 to 120 beats/min with good variability is reassuring. Interpretation of rates less than 80 beats/min is problematic, and such rates generally are considered nonreassuring.

Some causes of fetal bradycardia include congenital heart block and serious fetal compromise (Jaeggi, 2008, Kodama, 2009, Larma, 2007, and all their associates). Figure 18-7 shows bradycardia in a fetus dying from placental abruption. Maternal hypothermia under general anesthesia for repair of a cerebral aneurysm or during maternal cardiopulmonary bypass for open-heart surgery also can cause fetal bradycardia. Sustained fetal bradycardia in the setting of severe pyelonephritis and maternal hypothermia also has been reported (Hankins and coworkers, 1997). These infants apparently are not harmed by several hours of such bradycardia.

Tachycardia. Fetal tachycardia is defined as a baseline heart rate in excess of 160 beats/min. The most common explanation for fetal tachycardia is maternal fever from chorioamnionitis, although fever from any source can increase baseline fetal heart rate. Such infections also have been observed to

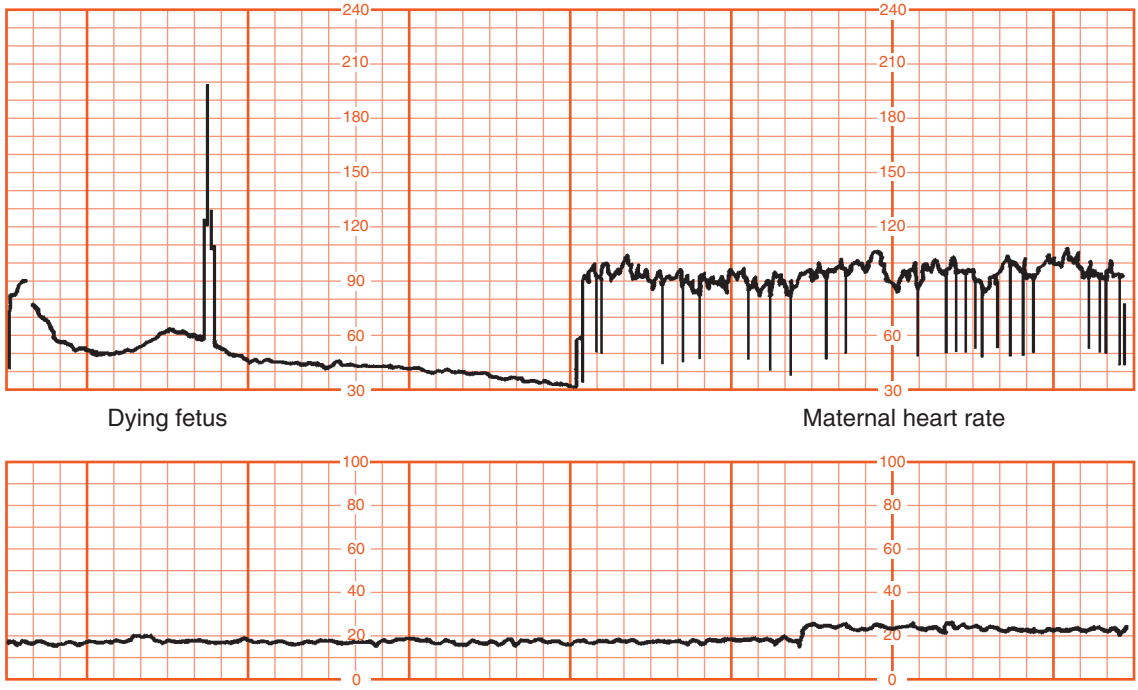

FIGURE 18-4 Placental abruption. In the upper panel, the fetal scalp electrode first detected the heart rate of the dying fetus. After fetal death, the maternal electrocardiogram complex is detected and recorded. The second panel displays an absence of uterine contractions.

induce fetal tachycardia before overt maternal fever is diagnosed (Gilstrap and associates, 1987). Fetal tachycardia caused by maternal infection typically is not associated with fetal compromise unless there are associated periodic heart rate changes or fetal sepsis.

Other causes of fetal tachycardia include fetal compromise, cardiac arrhythmias, and maternal administration of parasympathetic (atropine) or sympathomimetic (terbutaline) drugs. The key feature to distinguish fetal compromise in association with tachycardia seems to be concomitant heart rate decelerations. Prompt relief of the compromising event, such as correction of maternal hypotension caused by epidural analgesia, can result in fetal recovery.

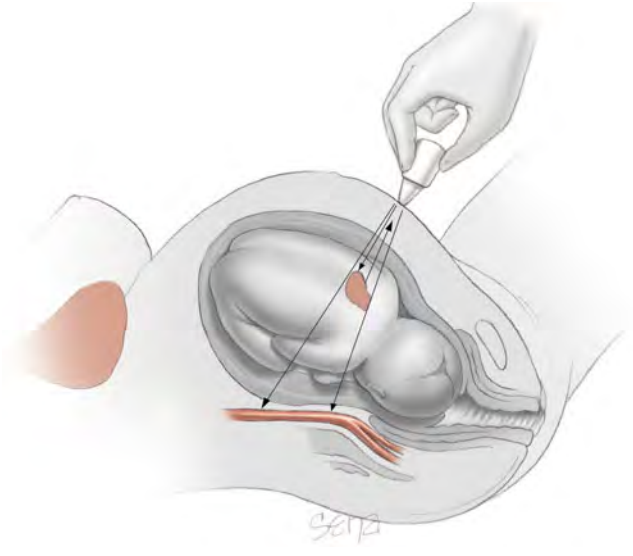

FIGURE 18-5 Ultrasound Doppler principle used externally to measure fetal heart motions. Pulsations of the maternal aorta also may be detected and erroneously counted. (Adapted from Klavan and co-workers, 1977, with permission.)

Wandering Baseline. This baseline rate is unsteady and "wanders" between 120 and 160 beats/min (Freeman and colleagues, 2003). This rare finding is suggestive of a neurologically abnormal fetus and may occur as a preterminal event.

Beat-to-Beat Variability

Baseline variability is an important index of cardiovascular function and appears to be regulated largely by the autonomic nervous system (Kozuma and colleagues, 1997). That is, a sympathetic and parasympathetic "push and pull" mediated via the sinoatrial node produces moment-to-moment or beat-to-beat oscillation of the baseline heart rate. Such change of the heart rate is defined as baseline variability. Variability is further divided into short term and long term.

Short-term variability reflects the instantaneous change in fetal heart rate from one beat—or R wave—to the next. This variability is a measure of the time interval between cardiac systoles (Fig. 18-8). Short-term variability can most reliably be determined to be normally present only when electrocardiac cycles are measured directly with a scalp electrode. *Long-term variability* is used to describe the oscillatory changes that occur during the course of 1 minute and result in the waviness of the baseline (Fig. 18-9). The normal frequency of such waves is three to five cycles per minute (Freeman and associates, 2003).

It should be recognized that precise quantitative analysis of both short- and long-term variability presents a number of

TABLE 18-1. The National Institute of Child Health and Human Development Research Planning Workshop Definitions of Fetal Heart Rate Patterns

Pattern	Workshop Interpretations
Baseline	• The mean FHR rounded to increments of 5 bpm during a 10-min segment, excluding: — Periodic or episodic changes — Periods of marked FHR variability — Segments of baseline that differ > 25 bpm
Baseline variability	• The baseline must be for a minimum of 2 min in any 10-min segment • Fluctuations in the FHR of two cycles per min or greater • Variability is visually quantified as the amplitude of peak-to-trough in bpm — Absent—amplitude range undetectable — Minimal—amplitude range detectable but ≤ 5 bpm — Moderate (normal)—amplitude range 6–25 bpm — Marked—amplitude range > 25 bpm
Acceleration	• A visually apparent increase—onset to peak in less than 30 sec—in the FHR from the most recently calculated baseline • The duration of an acceleration is defined as the time from the initial change in FHR from the baseline to the return of the FHR to the baseline • At 32 weeks and beyond, an acceleration has an acme of ≥ 15 bpm above baseline, with a duration of ≥ 15 sec but < 2 min • Before 32 weeks, an acceleration has an acme ≥ 10 bpm above baseline, with a duration of ≥ 10 sec but < 2 min • Prolonged acceleration lasts ≥ 2 min, but < 10 min • If an acceleration lasts ≥ 10 min, it is baseline change
Bradycardia	• Baseline FHR < 110 bpm
Early deceleration	• In association with a uterine contraction, a visually apparent, usually symmetrical, gradual—onset to nadir ≥ 30 sec—decrease in FHR with return to baseline • Nadir of the deceleration occurs at the same time as the peak of the contraction
Late deceleration	• In association with a uterine contraction, a visually apparent, gradual—onset to nadir ≥ 30 sec decrease in FHR with return to baseline • Onset, nadir, and recovery of the deceleration occur after the beginning, peak, and end of the contraction, respectively
Tachycardia	• Baseline FHR > 160 bpm
Variable deceleration	• An abrupt onset to nadir < 30 sec, visually apparent decrease in the FHR below the baseline • The decrease in FHR is ≥ 15 bpm, with a duration of ≥ 15 sec but < 2 min
Prolonged deceleration	• Visually apparent decrease in the FHR below the baseline • Deceleration is ≥ 15 bpm, lasting ≥ 2 min but < 10 min from onset to return to baseline

BPM = beats per minute; FHR = fetal heart rate.

frustrating problems due to technical and scaling factors. For example, Parer and co-workers (1985) evaluated 22 mathematical formulas designed to quantify heart rate variability and found most to be unsatisfactory. Consequently, most clinical interpretation is based on visual analysis with subjective judgment of the smoothness or flatness of the baseline. According to Freeman and colleagues (2003), there is no current evidence that the distinction between short- and long-term variability has any clinical relevance. Similarly, the NICHD Workshop (1997) did not recommend differentiating short- and long-term variability because in actual practice they are visually determined as a unit. The workshop panel defined baseline variability as those baseline fluctuations of two cycles per minute or greater. They recommended the criteria shown in **Figure 18-10** for quantification of variability. Normal beat-to-beat variability was accepted to be 6 to 25 beats/min.

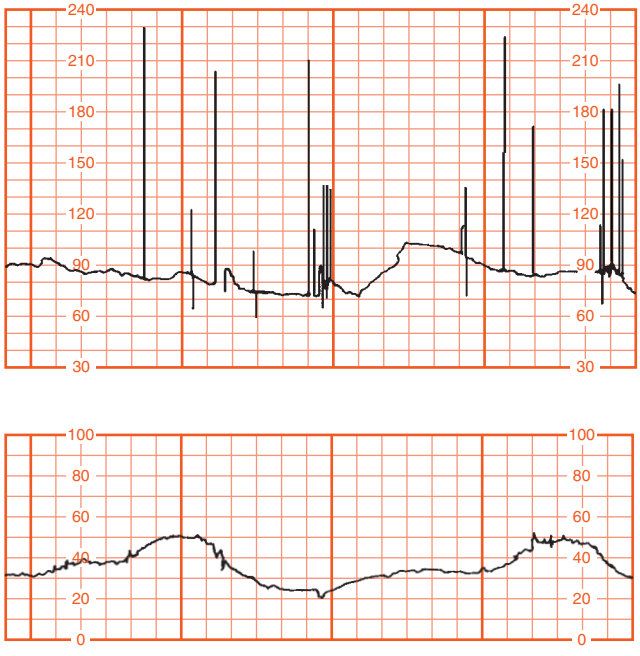

FIGURE 18-7 Fetal bradycardia measured with a scalp electrode (*upper panel*) in a pregnancy complicated by placental abruption and subsequent fetal death. Concurrent uterine contractions are shown in the (*lower panel*).

Increased Variability. Several physiological and pathological processes can affect or interfere with beat-to-beat variability. Dawes and co-workers (1981) described increased variability during *fetal breathing*. In healthy infants, short-term variability is attributable to respiratory sinus arrhythmia (Divon and associates, 1986). *Fetal body movements* also affect variability (Van Geijn and colleagues, 1980). Pillai and James (1990) reported increased baseline variability with *advancing gestation*. Up to 30 weeks, baseline characteristics were similar during both fetal rest and activity. After 30 weeks, fetal inactivity was

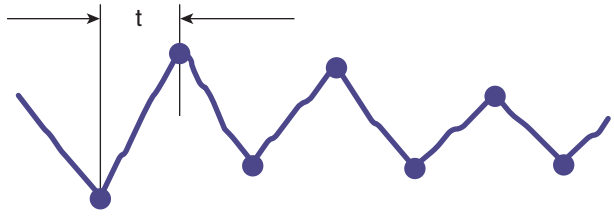

FIGURE 18-8 Schematic representation of short-term beat-to-beat variability measured by a fetal scalp electrode. (t = time interval between successive fetal R waves.) (Adapted from Klavan and coworkers, 1977.)

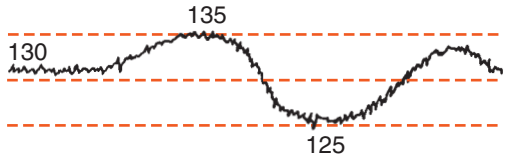

FIGURE 18-9 Schematic representation of long-term beat-to-beat variability of the fetal heart rate ranging between 125 and 135 beats/min. (Adapted from Klavan and associates, 1977.)

associated with diminished baseline variability and conversely, variability was increased during fetal activity. Fetal gender does not affect heart rate variability (Ogueh and Steer, 1998).

The baseline fetal heart rate becomes more physiologically fixed (less variable) as the rate increases. Conversely, there is more instability or variability of the baseline at lower heart rates. This phenomenon presumably reflects less cardiovascular physiological wandering as beat-to-beat intervals shorten due to increasing heart rate.

Decreased Variability. Diminished beat-to-beat variability can be an ominous sign indicating a seriously compromised fetus. Paul and co-workers (1975) reported that loss of variability in combination with decelerations was associated with *fetal acidemia*. They analyzed variability in the 20 minutes preceding delivery in 194 pregnancies. Decreased variability was defined as 5 or fewer beats/min excursion of the baseline (see Fig. 18-10), whereas acceptable variability exceeded this range. Fetal scalp pH was measured 1119 times in these pregnancies, and mean values were found to be increasingly more acidemic when decreased variability was added to progressively intense heart rate decelerations. For example, mean fetal scalp pH of approximately 7.10 was found when severe decelerations were combined with 5 beats/min or less variability, compared with a pH approximately 7.20 when greater variability was associated with similarly severe decelerations. Severe *maternal acidemia* also can cause decreased fetal beat-to-beat variability, as shown in **Figure 18-11** in a mother with diabetic ketoacidosis.

The precise pathological mechanisms by which fetal hypoxemia results in diminished beat-to-beat variability are not totally understood. Interestingly, mild degrees of fetal hypoxemia have been reported actually to *increase* variability, at least at the outset of the hypoxic episode (Murotsuki and co-workers, 1997). According to Dawes (1985), it seems probable that the loss of variability is a result of metabolic acidemia that causes depression of the fetal brainstem or the heart itself. Thus, diminished beat-to-beat variability, when it reflects fetal compromise, likely reflects acidemia rather than hypoxia.

A common cause of diminished beat-to-beat variability is *analgesic drugs* given during labor (see Chap. 19, p. 446). A large variety of central nervous system depressant drugs can cause transient diminished beat-to-beat variability. Included are narcotics, barbiturates, phenothiazines, tranquilizers, and general anesthetics. Diminished variability occurs regularly within 5 to 10 minutes following intravenous meperidine administration, and the effects may last up to 60 minutes or longer depending on the dosage given (Petrie, 1993). Butorphanol given intravenously diminishes fetal heart rate reactivity (Schucker and associates, 1996). Hill and colleagues (2003), in a study performed at Parkland Hospital, found that 5 beats/min or less variability occurred in 30 percent of women given continuous intravenous meperidine compared with 7 percent in those given continuous labor epidural analgesia using 0.0625-percent bupivacaine and 2 μg/mL of fentanyl.

Magnesium sulfate, widely used in the United States for tocolysis as well as management of hypertensive women, has been arguably associated with diminished beat-to-beat variability. Hallak and colleagues (1999) randomly assigned 34 normal, nonlaboring women to standard magnesium sulfate infusion versus isotonic saline. Magnesium sulfate was associated with statistically decreased variability only in the third hour of the infusion. However, the average decrease in variability was deemed clinically insignificant because the mean variability was 2.7 beats/min in the third hour of magnesium infusion compared with 2.8 beats/min at baseline. Magnesium sulfate also blunted the frequency of accelerations.

It is generally believed that reduced baseline heart rate variability is the single most reliable sign of fetal compromise. For example, Smith and co-workers (1988) performed a computerized analysis of beat-to-beat variability in growth-restricted fetuses *before* labor. They observed that diminished variability (4.2 beats/min or less) that was maintained for 1 hour was diagnostic of developing acidemia and imminent fetal death. By contrast, Samueloff and associates (1994) evaluated variability as a predictor of fetal outcome during labor in 2200 consecutive deliveries. They concluded that variability by itself could not be used as the only indicator of fetal well-being. Conversely, they also concluded that good variability should not be interpreted as necessarily reassuring.

In summary, beat-to-beat variability is affected by a variety of pathological and physiological mechanisms. Variability has considerably different meaning depending on the clinical setting. The development of decreased variability in the absence of decelerations is unlikely to be due to fetal hypoxia (Davidson and coworkers, 1992). A persistently flat fetal heart rate baseline—absent variability—within the normal baseline rate range and without decelerations may reflect a previous insult to the fetus that has resulted in neurological damage (Freeman and colleagues, 2003).

Cardiac Arrhythmia

When fetal cardiac arrhythmias are first suspected using electronic monitoring, findings can include baseline bradycardia, tachycardia, or most commonly in our experience, *abrupt baseline spiking* (**Fig. 18-12**). Intermittent baseline bradycardia is frequently due to congenital heart block. As discussed in Chapter 54 (p. 1150), conduction defects, most commonly complete atrioventricular (AV) block, usually are found in association with maternal connective-tissue diseases. Documentation of an arrhythmia can only be accomplished, practically speaking, when scalp electrodes are used. Some fetal monitors can be adapted to output the scalp electrode signals into an electrocardiographic recorder. Because only a single lead is obtained, analysis and interpretation of rhythm and rate disturbances are severely limited.

Southall and associates (1980) studied antepartum fetal cardiac rate and rhythm disturbances in 934 normal pregnancies between 30 and 40 weeks. Arrhythmias, episodes of bradycardia less than 100 beats/min, or tachycardia greater than 180 beats/min were encountered in 3 percent. Most supraventricular arrhythmias are of little significance during labor unless there is coexistent heart failure as evidenced by fetal hydrops.

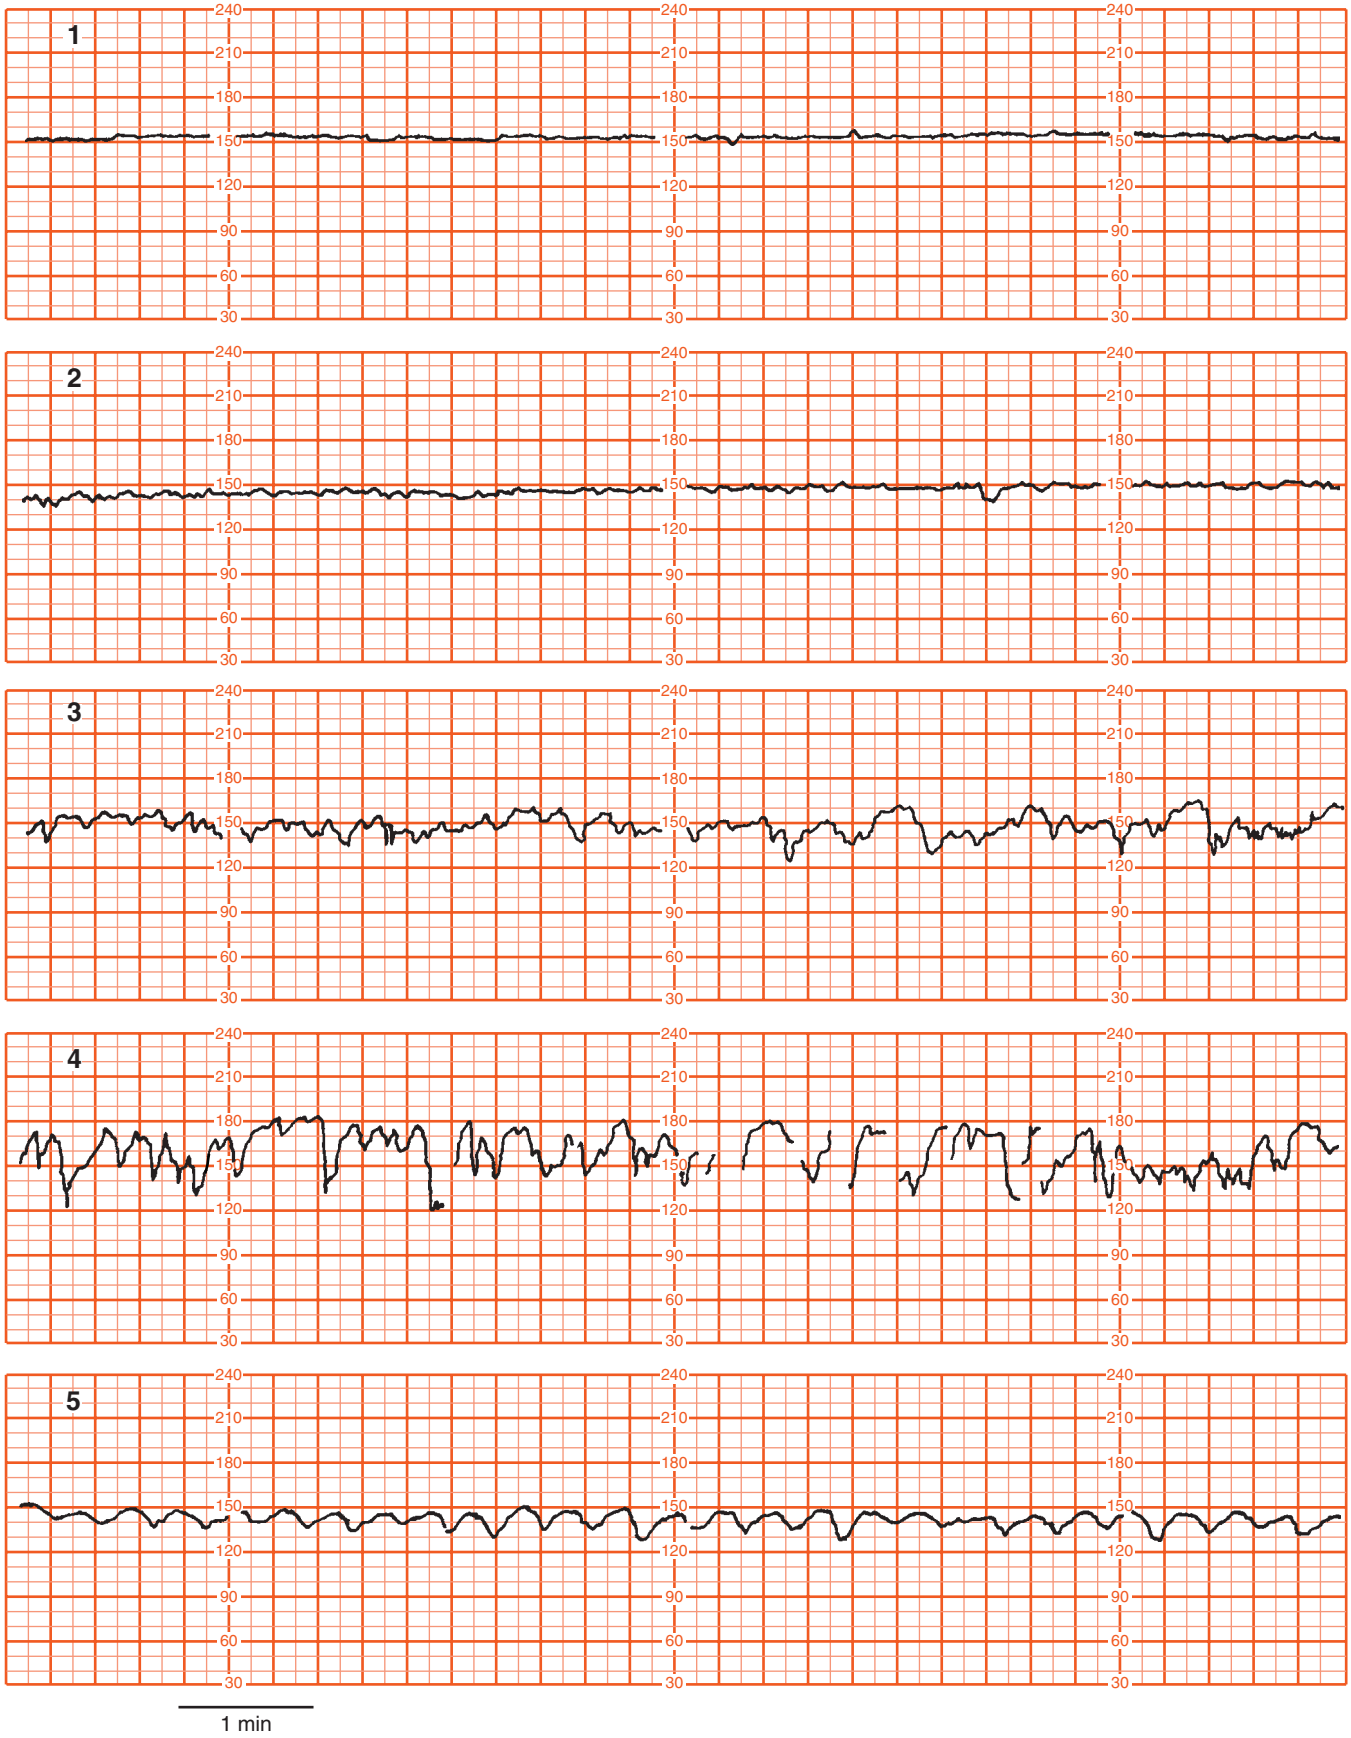

FIGURE 18-10 Panels 1–4: Grades of baseline fetal heart rate variability—irregular fluctuations in the baseline of 2 cycles per minute or greater. **1.** Undetectable, absent variability. **2.** Minimal variability, ≤5 beats/min. **3.** Moderate (normal) variability, 6 to 25 beats/min. **4.** Marked variability, >25 beats/min. **Panel 5:** Sinusoidal pattern. The sinusoidal pattern differs from variability in that it has a smooth, sinelike pattern of regular fluctuation and is excluded in the definition of fetal heart rate variability. (Adapted from National Institute of Child Health and Human Development Research Planning Workshop, 1997.)

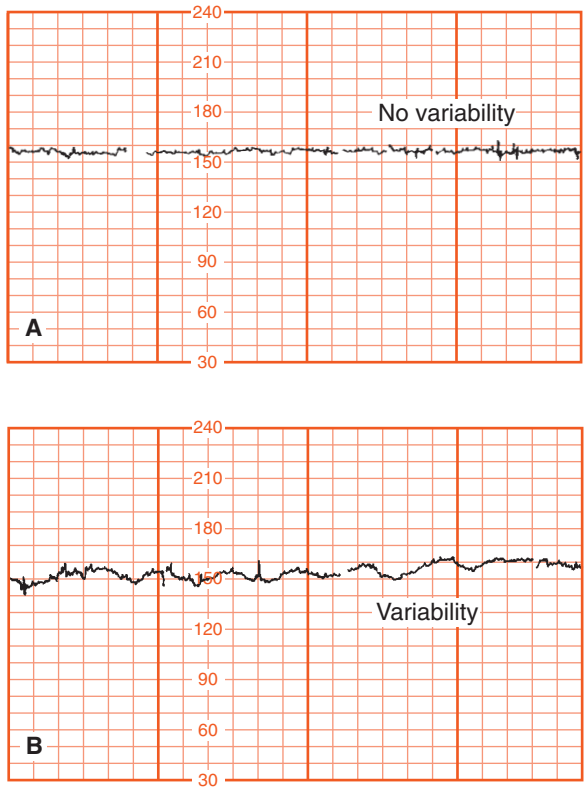

FIGURE 18-11 **A.** External fetal heart recording showing lack of long-term variability at 31 weeks during maternal diabetic ketoacidosis (pH 7.09). **B.** Recovery of fetal long-term variability after correction of maternal acidemia.

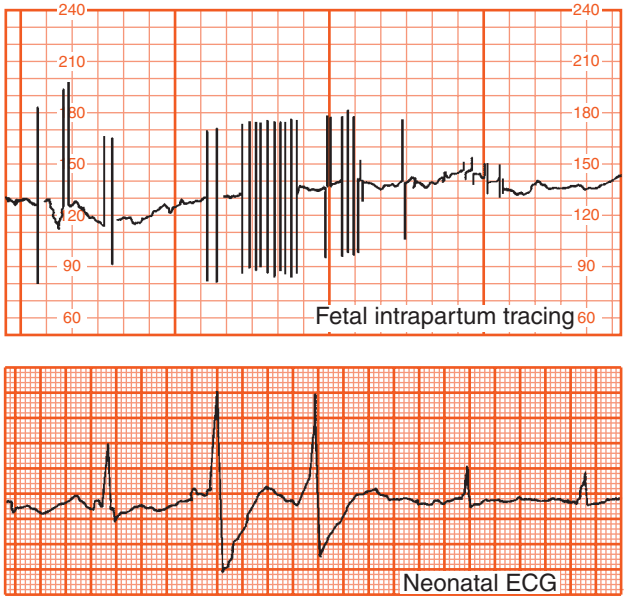

FIGURE 18-12 Internal fetal monitoring at term demonstrated occasional abrupt beat-to-beat fetal heart rate spiking due to erratic extrasystoles shown in the superimposed fetal electrocardiogram. The normal infant was delivered spontaneously and had a normal cardiac rhythm in the nursery.

Many supraventricular arrhythmias disappear in the immediate neonatal period, although some are associated with structural cardiac defects (Api and Carvalho, 2009). Copel and co-workers (2000) used echocardiography to evaluate 614 fetuses referred for auscultated irregular heart rate without hydrops. Only 10 fetuses (2 percent) were found to have significant arrhythmias, and all but one of these infant survived.

Boldt and colleagues (2003) followed 292 consecutive fetuses diagnosed with a cardiac arrhythmia through birth and into childhood. Atrial extrasystoles comprised the most common arrhythmia (68 percent), followed by atrial tachycardias (12 percent), atrioventricular block (12 percent), sinus bradycardia (5 percent), and ventricular extrasystoles (2.5 percent). Chromosomal anomalies were found in 1.7 percent of the fetuses. Fetal hydrops developed in 11 percent, and 2 percent had intrauterine death. Fetal hydrops was a bad prognostic finding. Overall, 93 percent of the study population was alive at a median follow-up period of 5 years, and 3 percent—7 infants, had neurological handicaps. Ninety-seven percent of the infants with atrial extrasystoles lived, and none suffered neurological injury. Only 6 percent required postnatal cardiac medications. Lopriore and associates (2009) found low rates of death and long-term neurological impairment in fetuses with supraventricular tachycardia or atrial flutter. In contrast, higher mortality rates were noted in those with atrioventricular block.

Although most fetal arrhythmias are of little consequence during labor when there is no evidence of fetal hydrops, such arrhythmias impair interpretation of intrapartum heart rate tracings. Sonographic evaluation of fetal anatomy as well as echocardiography may be useful. Some clinicians use fetal scalp sampling as an adjunct. Generally, in the absence of fetal hydrops, neonatal outcome is not measurably improved by pregnancy intervention. At Parkland Hospital, intrapartum fetal cardiac arrhythmias, especially in the presence of clear amnionic fluid, are managed conservatively. Freeman and colleagues (2003) have extensively reviewed interpretation of the fetal electrocardiogram during labor.

Sinusoidal Heart Rate

A true sinusoidal pattern such as that shown in panel 5 of Figure 18-10 may be observed with severe fetal anemia from Rh isoimmunization, feto-maternal hemorrhage, twin-twin transfusion syndrome, or vasa previa with bleeding; with fetal intracranial hemorrhage; and with severe fetal asphyxia (Modanlou and Murata, 2004). Insignificant sinusoidal patterns have been reported following administration of meperidine, morphine, alphaprodine, and butorphanol (Angel, 1984; Egley, 1991; Epstein, 1982, and all their associates). Shown in **Figure 18-13** is a sinusoidal pattern seen with maternal meperidine administration. An important characteristic of this pattern when due to narcotics is the sine frequency of 6 cycles per minute. A sinusoidal pattern also has been described with chorioamnionitis, fetal distress, and umbilical cord occlusion (Murphy and associates, 1991). Young and co-workers (1980a) and Johnson and colleagues (1981) concluded that intrapartum sinusoidal fetal heart patterns were not generally associated with fetal compromise.

Modanlou and Freeman (1982), based on their extensive review, proposed adoption of a strict definition:

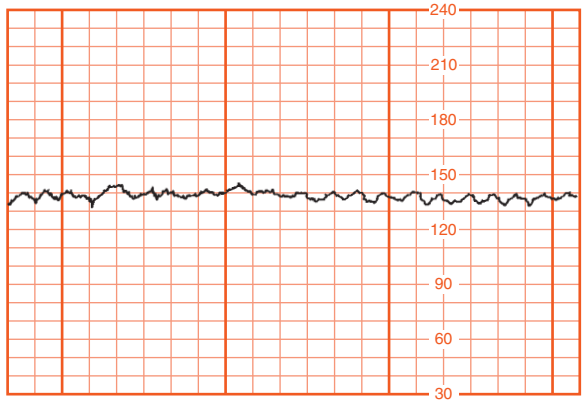

FIGURE 18-13 Sinusoidal fetal heart rate pattern associated with maternal intravenous meperidine administration. Sine waves are occurring at a rate of 6 cycles per minute.

1. Stable baseline heart rate of 120 to 160 beats/min with regular oscillations
2. Amplitude of 5 to 15 beats/min (rarely greater)
3. Long-term variability frequency of 2 to 5 cycles per minute.
4. Fixed or flat short-term variability
5. Oscillation of the sinusoidal waveform above or below a baseline
6. Absence of accelerations.

Although these criteria were selected to define a sinusoidal pattern that is most likely ominous, they observed that the pattern associated with alphaprodine is indistinguishable. Other investigators have proposed a classification of sinusoidal heart rate patterns into mild (amplitude 5 to 15 beats/min), intermediate (16 to 24 beats/min), and major (25 or more beats/min) to quantify fetal risk (Murphy and associates, 1991; Neesham and co-workers, 1993).

Some investigators have defined intrapartum sine wave–like baseline variation with periods of acceleration as *pseudosinusoidal.* Murphy and co-workers (1991) reported that pseudosinusoidal patterns were seen in 15 percent of monitored labors. Mild pseudosinusoidal patterns were associated with use of meperidine and epidural analgesia. Intermediate pseudosinusoidal patterns were linked to fetal sucking or transient episodes of fetal hypoxia caused by umbilical cord compression. Egley and colleagues (1991) reported that 4 percent of fetuses demonstrated sinusoidal patterns transiently during normal labor. These authors observed patterns for up to 90 minutes in some cases and also in association with oxytocin or alphaprodine usage, or both.

The pathophysiology of sinusoidal patterns is unclear, in part due to various definitions. There seems to be general agreement that *antepartum* sine wave baseline undulation portends severe fetal anemia. However, few D-isoimmunized fetuses develop this pattern (Nicolaides and associates, 1989). The sinusoidal pattern has been reported to develop or disappear after fetal transfusion (Del Valle and associates, 1992; Lowe and co-workers, 1984). Ikeda and colleagues (1999) have proposed, based on studies in fetal lambs, that the sinusoidal fetal heart rate pattern is related to waves of arterial blood pressure, reflecting oscillations in the baroreceptor–chemoreceptor feedback mechanism for control of the circulation.

Periodic Fetal Heart Rate Changes

The periodic fetal heart rate refers to deviations from baseline that are related to uterine contractions. *Acceleration* refers to an increase in fetal heart rate above baseline and *deceleration* to a decrease below the baseline rate. The nomenclature most commonly used in the United States is based upon the *timing* of the deceleration in relation to contractions—thus, *early, late,* or *variable* in onset related to the corresponding uterine contraction. The waveform of these decelerations is also significant for pattern recognition. In early and late decelerations, the slope of fetal heart rate change is gradual, resulting in a curvilinear and uniform or symmetrical waveform. With variable decelerations, the slope of fetal heart rate change is abrupt and erratic, giving the waveform a jagged appearance. It has been proposed that decelerations be defined as *recurrent* if they occur with 50 percent or more of contractions in any 20-minute period (NICHD Research Planning Workshop, 1997).

Another system now used less often to describe decelerations is based on the pathophysiological events considered most likely to cause the pattern. In this system, early decelerations are termed *head compression,* late decelerations are termed *uteroplacental insufficiency,* and variable decelerations become *cord compression patterns.* The nomenclature of type I (early), type II (late), and type III (variable) "dips" proposed by Caldeyro-Barcia and co-workers (1973) is not used in the United States.

Accelerations. An acceleration is a visually apparent abrupt increase—defined as onset of acceleration to a peak in less than 30 seconds—in the fetal heart rate baseline (NICHD Research Planning Workshop, 1997). According to Freeman and co-workers (2003), accelerations most often occur antepartum, in early labor, and in association with variable decelerations. Proposed mechanisms for intrapartum accelerations include fetal movement, stimulation by uterine contractions, umbilical cord occlusion, and fetal stimulation during pelvic examination. Fetal scalp blood sampling and acoustic stimulation also incite fetal heart rate acceleration (Clark and associates, 1982). Finally, acceleration can occur during labor without any apparent stimulus. Indeed, accelerations are common in labor and are nearly always associated with fetal movement. These accelerations are virtually always reassuring and almost always confirm that the fetus is not acidemic at that time.

Accelerations seem to have the same physiological explanations as beat-to-beat variability in that they represent intact neurohormonal cardiovascular control mechanisms linked to fetal behavioral states. Krebs and co-workers (1982) analyzed electronic heart rate tracings in nearly 2000 fetuses and found sporadic accelerations during labor in 99.8 percent. The presence of fetal heart accelerations during the first or last 30 minutes, or both, was a favorable sign for fetal well-being. The absence of such accelerations during labor, however, is not necessarily an unfavorable sign unless coincidental with other nonreassuring changes. There is about a 50-percent chance of acidemia in the fetus who fails to respond to stimulation in the presence of an otherwise nonreassuring pattern (Clark and colleagues, 1984; Smith and associates, 1986).

Early Deceleration. Early deceleration of the fetal heart rate consists of a gradual decrease and return to baseline associated with a contraction (Fig. 18-14). Such early deceleration was first

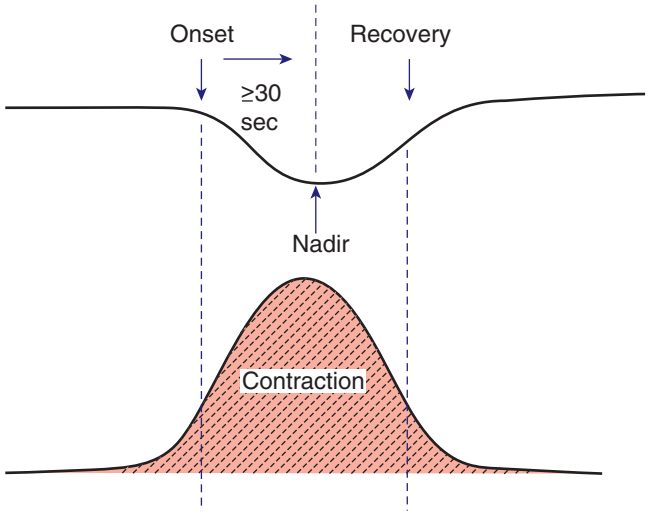

FIGURE 18-14 Features of early fetal heart rate deceleration. Characteristics include gradual decrease in the heart rate with both onset and recovery coincident with the onset and recovery of the contraction. The nadir of the deceleration is 30 seconds or more after the onset of the deceleration.

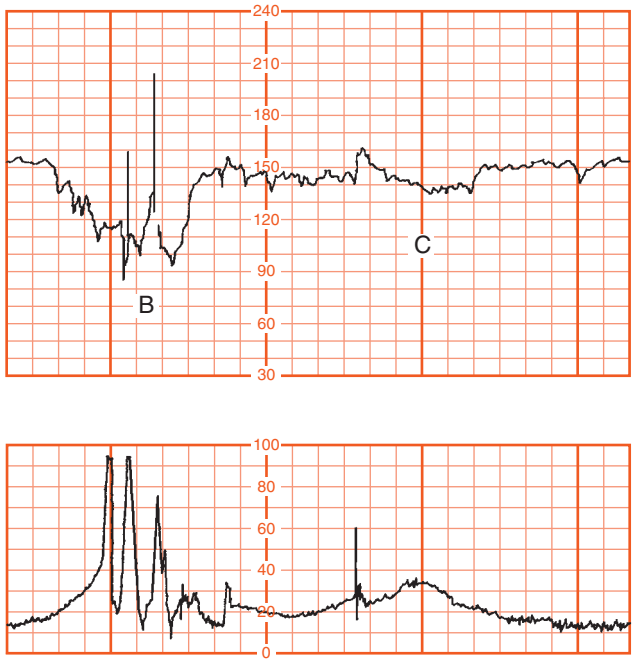

FIGURE 18-15 Two different fetal heart rate patterns during second-stage labor that are likely both due to head compression *(upper panel)*. Maternal pushing efforts *(lower panel)* correspond to the spikes with uterine contractions. Fetal heart rate deceleration **(C)**, is consistent with the pattern of head compression shown in Figure 18-14. Deceleration **(B),** however, is "variable" in appearance because of its jagged configuration and may alternatively represent cord occlusion.

described by Hon (1958). He observed that there was a drop in heart rate with uterine contractions and that this was related to cervical dilatation. He considered these findings to be physiological.

Freeman and co-workers (2003) defined early decelerations as those generally seen in active labor between 4 and 7 cm dilatation. In their definition, the degree of deceleration is generally proportional to the contraction strength and rarely falls below 100 to 110 beats/min or 20 to 30 beats/min below baseline. Such decelerations are common during active labor and are not associated with tachycardia, loss of variability, or other fetal heart rate changes. Importantly, early decelerations are not associated with fetal hypoxia, acidemia, or low Apgar scores.

Head compression probably causes vagal nerve activation as a result of dural stimulation, and that mediates the heart rate deceleration (Paul and colleagues, 1964). Ball and Parer (1992) concluded that fetal head compression is a likely cause not only of the deceleration shown in Figure 18-14 but also of those shown in **Figure 18-15**, which typically occur during second-stage labor. Indeed, they observed that head compression is the likely cause of many variable decelerations classically attributed to cord compression.

Late Deceleration. The fetal heart rate response to uterine contractions can be an index of either uterine perfusion or placental function. A late deceleration is a smooth, gradual, symmetrical decrease in fetal heart rate beginning at or after the peak of the contraction and returning to baseline only after the contraction has ended (American College of Obstetricians and Gynecologists, 1995). In most cases, the onset, nadir, and recovery of the deceleration occur after the beginning, peak, and ending of the contraction, respectively (**Fig. 18-16**). The magnitude of late decelerations is rarely more than 30 to 40 beats/min below baseline and typically not more than 10 to 20 beats/min. Late decelerations usually are not accompanied by accelerations.

Myers and associates (1973) studied monkeys in which they compromised uteroplacental perfusion by lowering maternal aortic blood pressure. The interval or lag from the contraction onset until the late deceleration onset was directly related to basal fetal oxygenation. They demonstrated that the length of the lag phase was predictive of the fetal P_{O_2} but not fetal pH. The lower the fetal P_{O_2} prior to contractions, the shorter the lag phase to onset of late decelerations. This lag period reflected the time necessary

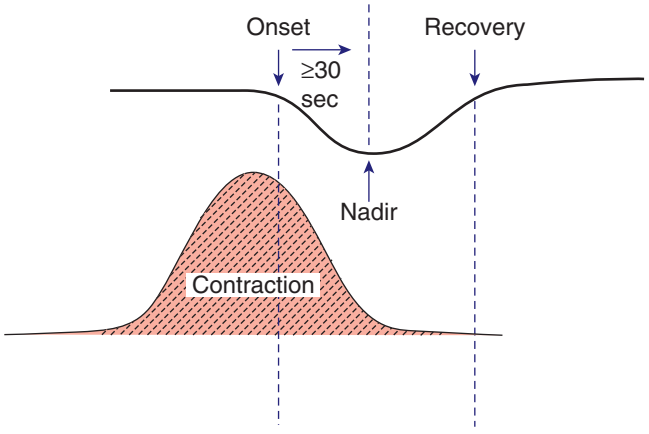

FIGURE 18-16 Features of late fetal heart rate deceleration. Characteristics include gradual decrease in the heart rate with the nadir and recovery occurring after the end of the contraction. The nadir of the deceleration occurs 30 seconds or more after the onset of the deceleration.

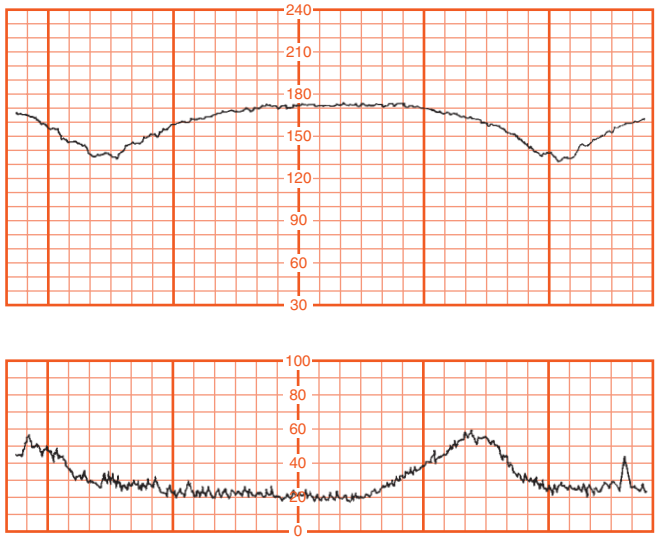

FIGURE 18-17 Late decelerations due to uteroplacental insufficiency resulting from placental abruption. Immediate cesarean delivery was performed. Umbilical artery pH was 7.05 and the Po_2 was 11 mm Hg.

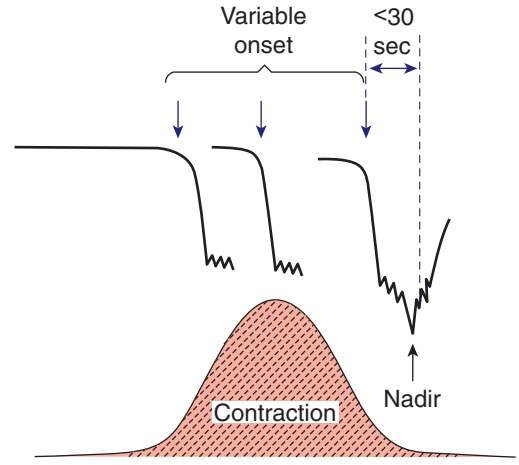

FIGURE 18-18 Features of variable fetal heart rate decelerations. Characteristics include an abrupt decrease in the heart rate and onset that commonly varies with successive contractions. The decelerations measure ≤15 beats/min for 15 seconds or longer and have an onset-to-nadir phase of less than 30 seconds. Total duration is less than 2 minutes.

for the fetal Po_2 to fall below a critical level necessary to stimulate arterial chemoreceptors, which mediated decelerations.

Murata and co-workers (1982) also showed that a late deceleration was the first fetal heart rate consequence of uteroplacental-induced hypoxia. During the course of progressive hypoxia that led to death over 2 to 13 days, monkey fetuses invariably exhibited late decelerations before development of acidemia. Variability of the baseline heart rate disappeared as acidemia developed.

A large number of clinical circumstances can result in late decelerations. Generally, any process that causes maternal hypotension, excessive uterine activity, or placental dysfunction can induce late decelerations. The two most common causes are hypotension from epidural analgesia and uterine hyperactivity caused by oxytocin stimulation. Maternal diseases such as hypertension, diabetes, and collagen-vascular disorders can cause chronic placental dysfunction. Placental abruption can cause acute late decelerations (Fig. 18-17).

Variable Decelerations. The most common deceleration patterns encountered during labor are variable decelerations attributed to umbilical cord occlusion. Melchior and Bernard (1985) identified variable decelerations in 40 percent of more than 7000 monitor tracings when labor had progressed to 5 cm dilatation and in 83 percent by the end of the first labor stage. Variable deceleration of the fetal heart rate is defined as a visually apparent *abrupt* decrease in rate. The onset of deceleration commonly varies with successive contractions (Fig. 18-18). The duration is less than 2 minutes.

Very early in the development of electronic monitoring, Hon (1959) tested the effects of umbilical cord compression on fetal heart rate (Fig. 18-19). Similar complete occlusion of the

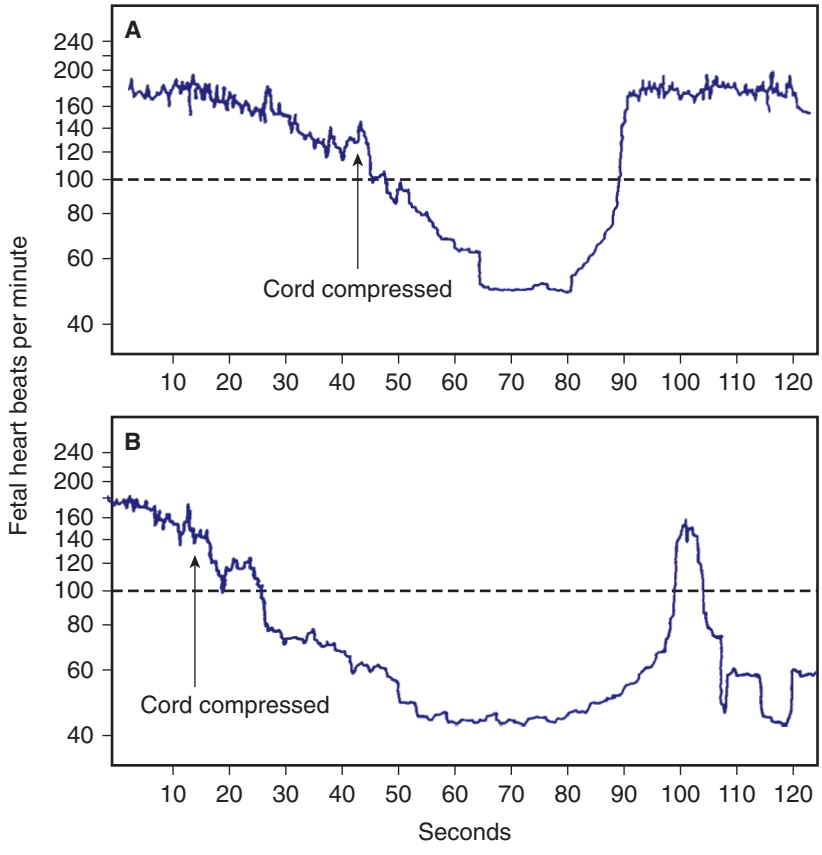

FIGURE 18-19 Fetal heart rate effects of cord compression. Panel **(A)** shows the effects of 25-second compression compared with those of 40 seconds in panel **(B)**. (This figure was redrawn from *American Journal of Obstetrics & Gynecology*, Vol. 78, No. 1, EH Hon, The fetal heart rate patterns preceding death in utero, pp. 47–56, Copyright Elsevier 1959.)

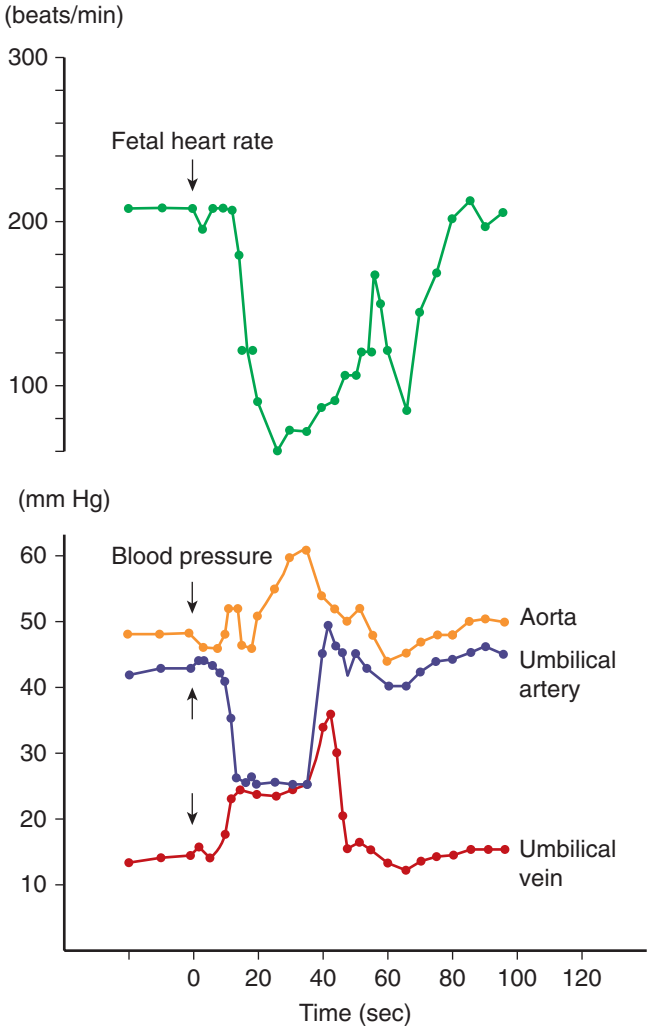

FIGURE 18-20 Total umbilical cord occlusion (*arrow*) in the sheep fetus is accompanied by an increase in fetal aortic blood pressure. Blood pressure changes in the umbilical vessels are also shown. (Adapted from Kunzel, 1985, with permission.)

umbilical cord in experimental animals produces abrupt, jagged-appearing deceleration of the fetal heart rate (Fig. 18-20). Concomitantly, fetal aortic pressure increases. Itskovitz and co-workers (1983) observed that variable decelerations in fetal lambs occurred only after umbilical blood flow was reduced by at least 50 percent.

Two types of variable decelerations are shown in Figure 18-21. The deceleration denoted by A is very much like that seen with complete umbilical cord occlusion in experimental animals (see Fig. 18-20). Deceleration B, however, has a different configuration because of the "shoulders" of acceleration before and after the deceleration component. Lee and co-workers (1975) proposed that this variation of variable deceleration was caused by differing degrees of partial cord occlusion. In this physiological scheme, occlusion of only the vein reduces fetal blood return, thereby triggering a baroreceptor-mediated acceleration. Subsequent complete occlusion results in fetal systemic hypertension due to obstruction of umbilical artery flow. This stimulates a baroreceptor-mediated deceleration. Presumably, the aftercoming shoulder of acceleration represents the same events occurring in reverse (Fig. 18-22).

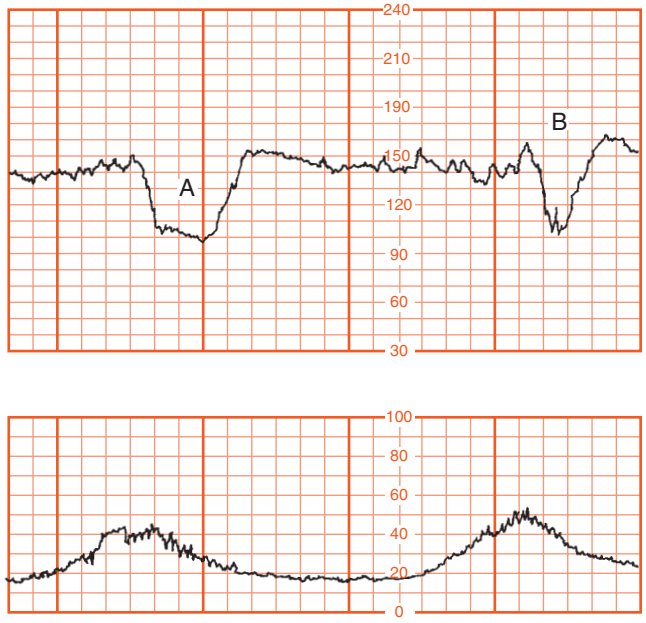

FIGURE 18-21 Varying (variable) fetal heart rate decelerations. Deceleration **(B)** exhibits "shoulders" of acceleration compared with deceleration **(A)**. (Adapted from Kunzel, 1985, with permission.)

Ball and Parer (1992) concluded that variable decelerations are mediated vagally and that the vagal response may be due to chemoreceptor or baroreceptor activity or both. Partial or complete cord occlusion produces an increase in afterload (baroreceptor) and a decrease in fetal arterial oxygen content (chemoreceptor). These both result in vagal activity leading to deceleration. In fetal monkeys, the baroreceptor reflexes appear to operate during the first 15 to 20 seconds of umbilical cord occlusion followed by decline in P_{O_2} at approximately 30 seconds, which then serves as a chemoreceptor stimulus (Mueller-Heubach and Battelli, 1982).

Thus, variable decelerations represent fetal heart rate reflexes that reflect either blood pressure changes due to interruption of umbilical flow or changes in oxygenation. It is likely that most fetuses have experienced brief but recurrent periods of hypoxia due to umbilical cord compression during gestation. The frequency and inevitability of cord occlusion undoubtedly have provided the fetus with these physiological mechanisms as a means of coping. The great dilemma for the obstetrician in managing variable fetal heart rate decelerations is determining when variable decelerations are pathological. The American College of Obstetricians and Gynecologists (1995) has defined *significant* variable decelerations as those decreasing to less than 70 beats/min and lasting more than 60 seconds.

Other fetal heart rate patterns have been associated with umbilical cord compression. *Saltatory* baseline heart rate (Fig. 18-23) was first described by Hammacher and colleagues (1968) and linked to umbilical cord complications during labor. The pattern consists of rapidly recurring couplets of acceleration and deceleration causing relatively large oscillations of the baseline fetal heart rate. We also observed a relationship between cord occlusion and the saltatory pattern (Leveno and associates, 1984). In the absence of other fetal heart rate findings,

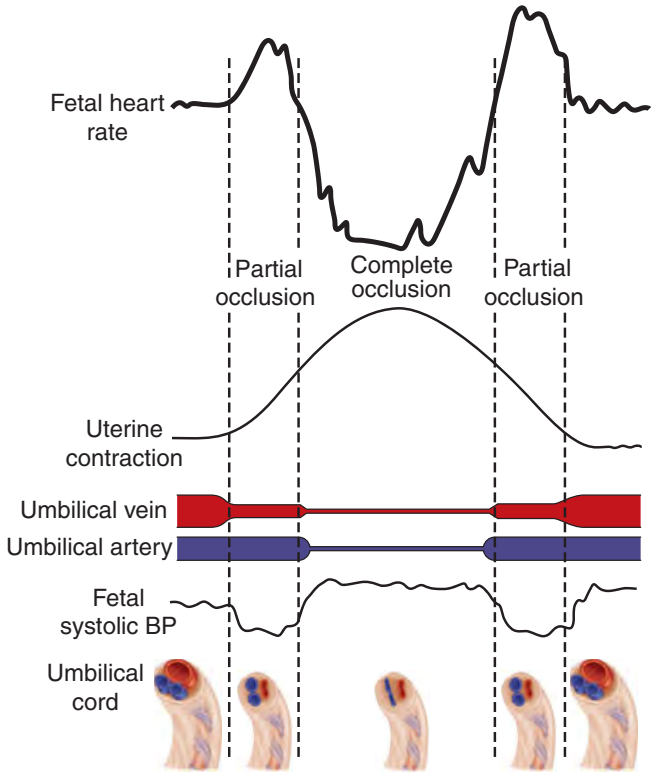

FIGURE 18-22 Schematic representation of the fetal heart rate effects with partial and complete umbilical cord occlusion. Uterine pressures generated early in a contraction cause cord compression predominantly of the thin-walled umbilical vein. The resulting decrease in fetal cardiac output leads to an initial compensatory rise in fetal heart rate. As cord compression intensifies, umbilical arteries are then also compressed. The resulting rise in fetal systolic blood pressure leads to a vagal-mediated fetal heart rate deceleration. As the contraction abates and compression is relieved first on the umbilical arteries, elevated fetal systolic blood pressures drop and the deceleration resolves. A final increase in fetal heart rate is seen as a result of persistent umbilical vein occlusion. With completion of the uterine contraction and cord compression, the fetal heart rate returns to baseline. (BP = blood pressure). (Adapted from Lee and colleagues, 1975.)

these do not signal fetal compromise. *Lambda* is a pattern involving an acceleration followed by a variable deceleration with no acceleration at the end of the deceleration. This pattern typically is seen in early labor and is not ominous (Freeman and colleagues, 2003). This lambda pattern may result from mild cord compression or stretch. *Overshoot* is a variable deceleration followed by acceleration. The clinical significance of this pattern is controversial (Westgate and associates, 2001).

Prolonged Deceleration

This pattern, which is shown in Figure 18-24, is defined as an isolated deceleration lasting 2 minutes or longer but less than 10 minutes from onset to return to baseline (NICHD Research Planning Workshop, 1997). Prolonged decelerations are difficult to interpret because they are seen in many different clinical situations. Some of the more common causes include cervical examination, uterine hyperactivity, cord entanglement, and maternal supine hypotension.

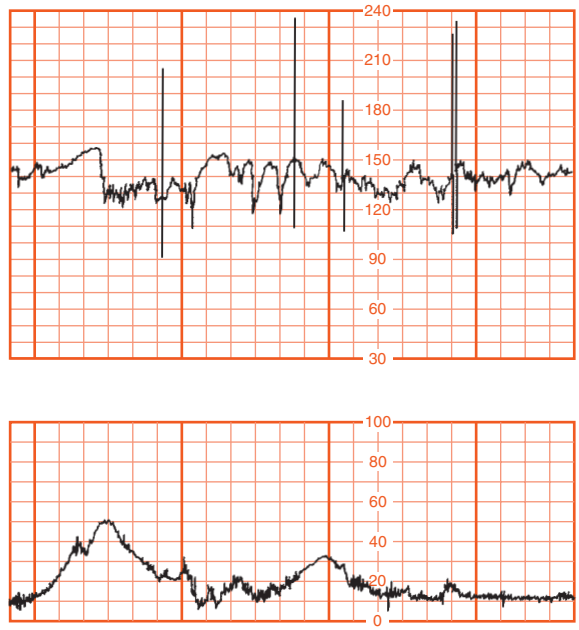

FIGURE 18-23 Saltatory baseline fetal heart rate showing rapidly recurring couplets of acceleration combined with deceleration.

Epidural, spinal, or paracervical analgesia may induce prolonged deceleration of the fetal heart rate. For example, Eberle and colleagues (1998) reported that prolonged decelerations occurred in 4 percent of normal parturients given either epidural or intrathecal labor analgesia. Hill and associates (2003) observed prolonged deceleration in 1 percent of women given epidural analgesia during labor at Parkland Hospital. Other causes of prolonged deceleration include maternal hypoperfusion or hypoxia from any cause, placental abruption, umbilical cord knots or prolapse, maternal seizures including eclampsia

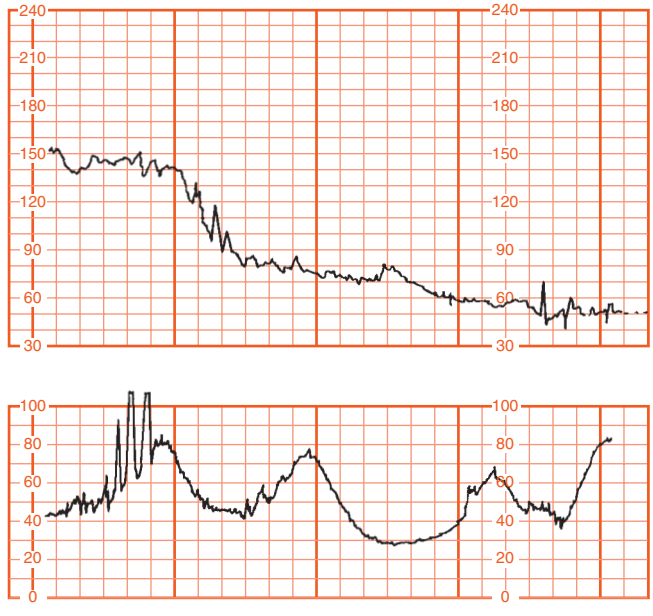

FIGURE 18-24 Prolonged fetal heart rate deceleration due to uterine hyperactivity. Approximately 3 minutes of the tracing are shown, but the fetal heart rate returned to normal after uterine hypertonus resolved. Vaginal delivery later ensued.

and epilepsy, application of a fetal scalp electrode, impending birth, or even maternal Valsalva maneuver.

The placenta is very effective in resuscitating the fetus if the original insult does not recur immediately. Occasionally, such self-limited prolonged decelerations are followed by loss of beat-to-beat variability, baseline tachycardia, and even a period of late decelerations, all of which resolve as the fetus recovers. Freeman and co-workers (2003) emphasize rightfully that the fetus may die during prolonged decelerations. Thus, management of prolonged decelerations can be extremely tenuous. Management of isolated prolonged decelerations is based upon bedside clinical judgment, which inevitably will sometimes be imperfect given the unpredictability of these decelerations.

Fetal Heart Rate Patterns During Second-Stage Labor

Decelerations are virtually ubiquitous during the second stage. In fact, Melchior and Bernard (1985) reported that only 1.4 percent of more than 7000 deliveries did not have decelerations during second-stage labor. Both cord compression and fetal head compression have been implicated as causes of decelerations and baseline bradycardia during second-stage labor. The high incidence of such patterns minimized their potential significance during the early development and interpretation of electronic monitoring. For example, Boehm (1975) described profound, prolonged fetal heart rate deceleration in 10 minutes preceding vaginal delivery of 18 healthy infants. Subsequently, Herbert and Boehm (1981) reported another 18 pregnancies with similar prolonged decelerations during second-stage labor. There was one stillbirth and one neonatal death. These experiences attest to the unpredictability of the fetal heart rate during second-stage labor.

Spong and colleagues (1998) analyzed the characteristics of second-stage variable fetal heart rate decelerations in 250 deliveries and found that as the total number of decelerations to less than 70 beats/min increased, the 5-minute Apgar score decreased. Put another way, the longer a fetus was exposed to variable decelerations, the lower the Apgar score at 5 minutes.

Picquard and co-workers (1988) analyzed heart rate patterns during second-stage labor in 234 women in an attempt to identify specific patterns to diagnose fetal compromise. Loss of beat-to-beat variability and baseline fetal heart rate less than 90 beats/min were predictive of fetal acidemia. Krebs and associates (1981) also found that persistent or progressive baseline bradycardia and baseline tachycardia were associated with low Apgar scores. Gull and colleagues (1996) observed that abrupt fetal heart rate deceleration to less than 100 beats/min, and associated with loss of beat-to-beat variability for 4 minutes or longer, was predictive of fetal acidemia. Thus, abnormal baseline heart rate—either bradycardia or tachycardia, absent beat-to-beat variability, or both—in the presence of second-stage decelerations, is associated with increased but not inevitable fetal compromise (Fig. 18-25).

Admission Fetal Monitoring in Low-Risk Pregnancies

In this application of electronic fetal monitoring, women with low-risk pregnancies are monitored for a short time on admission for labor, and continuous monitoring is used only if abnormalities of the fetal heart rate are subsequently identified. Mires and colleagues (2001) randomly assigned 3752 low-risk women in spontaneous labor at the time of admission to either auscultation of the fetal heart rate using Doppler during and immediately after at least one contraction or to 20 minutes of

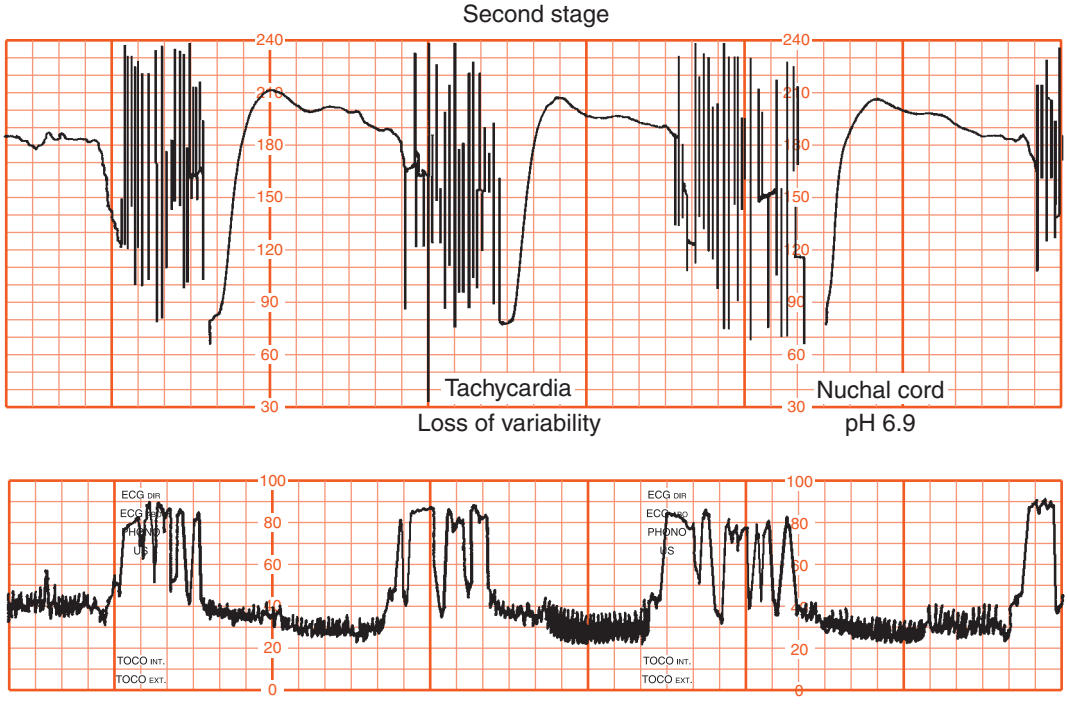

FIGURE 18-25 Cord compression fetal heart rate decelerations in second-stage labor associated with tachycardia and loss of variability. The umbilical cord arterial pH was 6.9.

electronic fetal monitoring. Use of admission electronic fetal monitoring did not improve infant outcome. Moreover, its use resulted in increased interventions, including operative delivery. Impey and associates (2003) performed a similar study in 8588 low-risk women and also found no improvement in infant outcome. More than half of the women enrolled in these studies, whether they received admission electronic monitoring or auscultation, eventually required continuous monitoring for diagnosed abnormalities in the fetal heart rate.

Complications of Electronic Fetal Monitoring

Injury to the fetal scalp or breech by the electrode is rarely a major problem, although application at some other site—such as the eye in case of a face presentation—can prove serious. Rarely, a fetal vessel in the placenta may be ruptured by catheter placement (Trudinger and Pryse-Davies, 1978). Severe cord compression has been described from entanglement with the catheter. Penetration of the placenta, causing hemorrhage and possibly uterine perforation during catheter insertion, has led to serious morbidity, as well as spurious recordings that resulted in inappropriate management.

Both the fetus and the mother may be at increased risk of *infection* as the consequence of internal monitoring. Scalp wounds from the electrode may become infected, and subsequent cranial osteomyelitis has been reported (Brook, 2005; Eggink and co-workers, 2004; McGregor and McFarren, 1989). Puerperal infection increased from 12 percent in externally monitored women to 18 percent in those in whom an internal apparatus was used (Faro and associates, 1990). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) have recommended that certain maternal infections, including human immunodeficiency virus (HIV), herpes simplex virus, hepatitis B virus, and hepatitis C virus, are relative contraindications to internal fetal heart rate monitoring.

OTHER INTRAPARTUM ASSESSMENT TECHNIQUES

Fetal Scalp Blood Sampling

According to the American College of Obstetricians and Gynecologists (1995), measurements of the pH in capillary scalp blood may help to identify the fetus in serious distress. However, that said, it also emphasized that neither normal nor abnormal scalp pH results have been shown to be predictive of infant outcome. The College also indicated that the procedure is now used uncommonly.

Technique

An illuminated endoscope is inserted through the dilated cervix after membrane rupture so as to press firmly against the fetal scalp (Fig. 18-26). The skin is wiped clean with a cotton swab and coated with a silicone gel to cause the blood to accumulate as discrete globules. An incision is made through the skin to a depth of 2 mm with a special blade on a long handle. As a drop of blood forms on the surface, it is immediately collected into a heparinized glass capillary tube. The pH of the blood is measured promptly.

FIGURE 18-26 The technique of fetal scalp sampling using an amnioscope. The end of the endoscope is displaced from the fetal vertex approximately 2 cm to show the disposable blade against the fetal scalp before incision. (Adapted from Hamilton and McKeown, 1974.)

Interpretation

The pH of fetal capillary scalp blood is usually lower than that of umbilical venous blood and approaches that of umbilical arterial blood. Zalar and Quilligan (1979) recommended the following protocol to try to confirm fetal distress. If the pH is greater than 7.25, labor is observed. If the pH is between 7.20 and 7.25, the pH measurement is repeated within 30 minutes. If the pH is less than 7.20, another scalp blood sample is collected immediately, and the mother is taken to an operating room and prepared for surgery. Delivery is performed promptly if the low pH is confirmed. Otherwise, labor is allowed to continue, and scalp blood samples are repeated periodically.

The only benefits reported for scalp pH testing are fewer cesarean deliveries for fetal distress (Young and co-workers, 1980b). Goodwin and associates (1994), however, in a study of 112,000 deliveries, showed a decrease in the scalp pH sampling rate from approximately 1.8 percent in the mid-1980s to 0.03 percent by 1992 with no increased delivery rate for fetal distress. They concluded that scalp pH sampling was unnecessary. Kruger and colleagues (1999) have advocated the use of fetal scalp blood lactate concentration as an adjunct to pH. Wiberg-Itzel and colleagues (2008) randomized 1496 fetuses to scalp blood pH analysis and 1496 to scalp blood lactate analysis. They found either to be equivalent in predicting fetal acidemia. The advantage of lactate measurement was that a smaller amount of blood was needed, which led to a lower procedure failure rate compared with scalp sampling for pH.

Scalp Stimulation

Clark and associates (1984) have suggested that scalp stimulation is an alternative to scalp blood sampling. This proposal was based on the observation that acceleration of the heart rate in response to pinching of the scalp with an Allis clamp just prior to obtaining blood was invariably associated with a normal pH. Conversely, failure to provoke acceleration was not uniformly predictive of fetal acidemia. Later, Elimian and associates (1997) reported that of 58 cases in which the fetal heart rate accelerated 10 beats/min or more after 15 seconds of gentle digital stroking of the scalp, 100 percent had a scalp pH of 7.20 or greater. Without an acceleration, however, only 30 percent had a scalp pH less than 7.20.

Vibroacoustic Stimulation

Fetal heart rate acceleration in response to vibroacoustic stimulation has been recommended as a substitute for scalp sampling (Edersheim and colleagues, 1987). The technique uses an electronic artificial larynx placed approximately 1 centimeter from or directly onto the maternal abdomen (see Chap. 15, p. 340). Response to vibroacoustic stimulation is considered normal if a fetal heart rate acceleration of at least 15 beats/min for at least 15 seconds occurs within 15 seconds after the stimulation and with prolonged fetal movements (Sherer, 1994). Lin and colleagues (2001) prospectively studied vibroacoustic stimulation in 113 women in labor with either moderate to severe variable or late fetal heart rate decelerations. They concluded that this technique is an effective predictor of fetal acidosis in the setting of variable decelerations. However, the predictability for fetal acidosis in the setting of late decelerations is limited. Other investigators have reported that although vibroacoustic stimulation in second-stage labor is associated with fetal heart rate reactivity, the quality of the response did not predict neonatal outcome or enhance labor management (Anyaegbunam and associates, 1994).

Skupski and co-workers (2002) performed a meta-analysis of reports on intrapartum fetal stimulation tests published between 1966 and 2000. Four types of fetal stimulation were analyzed and included scalp puncture for pH testing, Allis clamp pinching of the fetal scalp, vibroacoustic stimulation, and digital stroking of the scalp. Results were similar for all four methods. These investigators concluded that intrapartum stimulation tests were useful to exclude fetal acidemia. However, they cautioned that these tests are "less than perfect."

Fetal Pulse Oximetry

Using technology similar to that of adult pulse oximetry, instrumentation has been developed that may allow assessment of fetal oxyhemoglobin saturation once membranes are ruptured. A unique padlike sensor such as shown in Figure 18-27 is inserted through the cervix and positioned against the fetal face, where it is held in place by the uterine wall. Vintzileos and associates (2005) described the use of a transabdominal fetal pulse oximeter in a preliminary study of six women. As reviewed by Yam and co-workers (2000), the transcervical device has been used extensively by many investigators and has been reported to reliably register fetal oxygen saturation in 70 to 95 percent of women throughout 50 to 88 percent of their labors. The lower limit for normal fetal oxygen saturation is generally considered to be 30 percent by most investigators (Gorenberg and colleagues, 2003; Stiller and associates, 2002). As shown in Figure 18-28, however, fetal oxygen saturation normally varies greatly when measured in umbilical artery blood (Arikan and colleagues, 2000). Bloom and associates (1999) reported that brief, transient fetal oxygen saturations below 30 percent were common during labor because such values were observed in 53 percent of fetuses with normal outcomes. Saturation values below 30 percent, however, when persistent for 2 minutes or longer, were associated with an increased risk of potential fetal compromise.

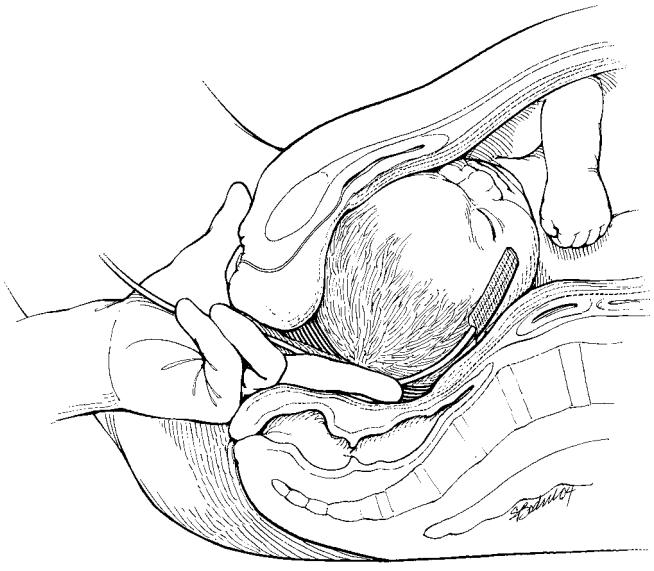

FIGURE 18-27 Schematic diagram of fetal pulse oximeter sensor placement.

Garite and colleagues (2000) randomly assigned 1010 women with term pregnancies and in whom predefined abnormal fetal heart rate patterns developed to either conventional fetal monitoring alone or fetal monitoring plus continuous fetal pulse oximetry. Cesarean delivery for fetal distress was performed when pulse oximetry values remained less than 30 percent for the entire interval between two contractions or when the fetal heart rate patterns met predefined guidelines. The use of fetal pulse oximetry significantly reduced the rate of cesarean delivery for nonreassuring fetal status from 10.2 to 4.5 percent. Alternatively, the cesarean delivery rate for dystocia increased significantly from 9 to 19 percent when pulse oximetry was used. There were no neonatal benefits or adverse effects associated with fetal pulse oximetry. Based on these observations, the Obstetrics and Gynecology Devices Panel of the Medical Devices Advisory Committee of the Food and Drug Administration (FDA) in 2000 approved marketing of the Nellcor N-400 Fetal Oxygen Monitoring System. Since then, another three randomized trials of fetal pulse oximetry have been reported:

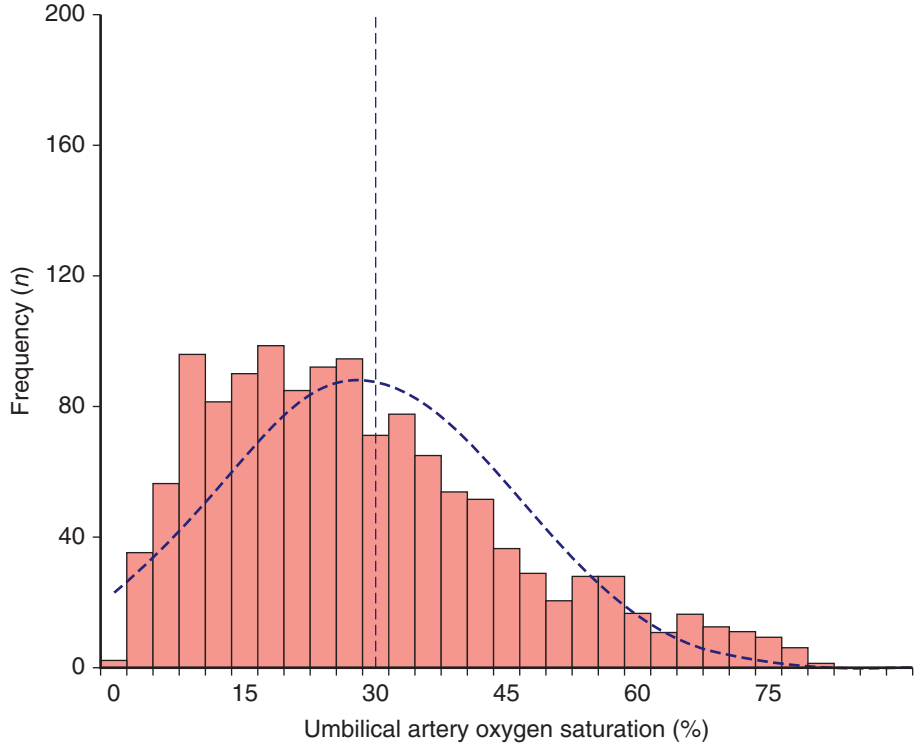

FIGURE 18-28 Frequency distribution of umbilical artery oxygen saturation values in 1281 vigorous newborn infants. Dotted line indicates normal distribution. (Reproduced from *BJOG*, Vol. 107, Issue 8, GM Arikan, HS Scholz, E Petru, MCH Haeusler, J Haas, and PAM Weiss, Cord blood oxygen saturation in vigorous infants at birth: What is normal? 987–994, 2000, with the permission of the Royal College of Obstetricians and Gynaecologists.)

1. Klauser and colleagues (2005) randomly assigned 360 women with nonreassuring fetal heart rate patterns to standard fetal monitoring plus fetal pulse oximetry or to standard monitoring alone and found no benefits for oximetry
2. East and associates (2006) from Australia randomized 600 women with nonreassuring fetal heart rate patterns to standard monitoring either alone or with added fetal pulse oximetry. These investigators reported that addition of oximetry significantly reduced cesarean deliveries for a nonreassuring fetal heart rate pattern. They further reported, however, that neonatal outcomes were not different between the study groups
3. Bloom and co-workers (2006) reported the largest trial, performed by the Maternal-Fetal Units Network. A total of 5341 women in labor at term underwent placement of the fetal oximetry sensor, but the information was randomly withheld from care providers. Unlike the earlier studies, participants were not required to have nonreassuring fetal heart rate patterns. Sensor application was generally successful and fetal oxygen saturation values were registered 75 percent of the time. Knowledge of fetal oxygen saturation did not change the rates of cesarean delivery in the overall population or in the subgroup of 2168 women who had nonreassuring fetal heart rate patterns. Moreover, neonatal outcomes were not improved by knowledge of fetal oxygen saturation status.

Because of these findings, in 2005, the manufacturer discontinued sale of the fetal oximeter system in the United States.

Fetal Electrocardiography

Because as fetal hypoxia worsens, there are changes in the T-wave and in the ST segment of the fetal ECG, several investigators have assessed the value of analyzing these parameters as an adjunct to conventional fetal monitoring. The technique requires internal monitoring of the fetal heart rate and special equipment to process the fetal ECG. The rationale behind this technology is based on the observation that the mature fetus exposed to hypoxemia develops an elevated ST segment with a progressive rise in T-wave height that can be expressed as a T:QRS ratio (**Fig. 18-29**). It is postulated that increasing T:QRS ratios reflect fetal cardiac ability to adapt to hypoxia and appears before neurological damage. Progression of hypoxia results in an increasingly negative ST-segment deflection such that it appears as a biphasic waveform (**Fig. 18-30**). In 2005, the manufacturer—Neoventa Medical—received FDA approval for their ST analysis system, named STAN system (Food and Drug Administration, 2009). Westgate and co-workers (1993) studied the benefits of monitoring ST-segment changes in a randomized trial of 2400 pregnancies. Infant outcomes were not improved compared with those in whom conventional fetal monitoring alone was used. However, there was a reduction in the cesarean delivery rate for fetal distress.

In another randomized trial of 4966 Swedish women, Amer-Wåhlin and colleagues (2001, 2007) found that the addition of ST analysis to conventional fetal monitoring significantly reduced cesarean delivery rates for fetal distress as well as metabolic

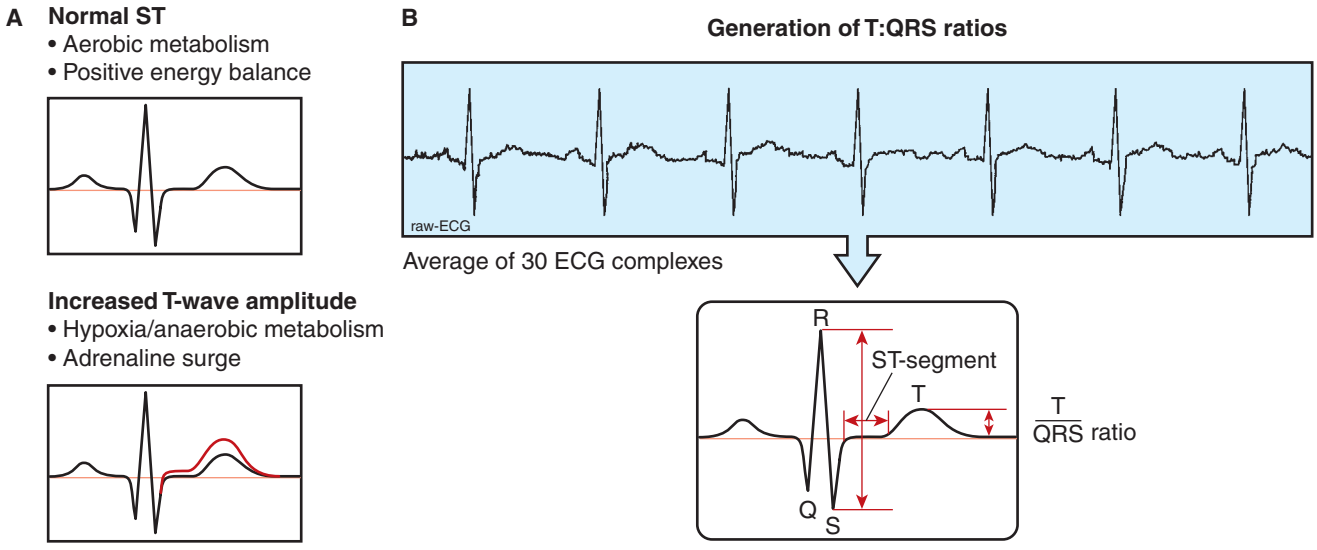

FIGURE 18-29 A. ST segment changes in normal and hypoxic conditions. **B.** Generation of T:QRS ratios. All rights reserved.)

acidemia in umbilical artery blood. Subsequently, experience was reported with clinical application of STAN monitoring at a London hospital (Doria and associates, 2007). Introduction of STAN as a clinical practice did not change the incidence of operative delivery or neonatal encephalopathy. In another study, ST data were collected from all fetuses (Norén and co-workers, 2003). There were 29 infants with adverse outcomes that included death in 3, neonatal encephalopathy in 7, or metabolic acidemia in 19. Of these, 22 had abnormal ST waveforms. A serious confounding factor in interpretation of this study is the long intervals of abnormal fetal heart rate patterns before intervention. For example, the median interval before delivery—during which time the fetal heart rate pattern was significantly abnormal—was almost 3 hours in the infants with encephalopathy. When American obstetricians were shown these very same fetal monitoring tracings, they more often would have intervened compared with their European counterparts (Ross and colleagues, 2004). It must be considered that ST abnormalities might occur late in the course of fetal compromise. Neilson (2006) reviewed the Cochrane Database to assess fetal ECG analysis during labor. There were 8872 women in which such monitoring was performed. He concluded that fetal ST segment waveform analysis was perhaps useful in preventing fetal acidosis and neonatal encephalopathy when standard fetal heart rate (FHR) monitoring suggested abnormal patterns. Although no randomized trials have yet been performed in the United States, the Maternal-Fetal Medicine Units Network has one under development.

Intrapartum Doppler Velocimetry

Doppler analysis of the umbilical artery has been studied as another potential adjunct to conventional fetal monitoring. Further described in Chapter 16 (p. 363), abnormal Doppler waveforms may signify pathological umbilical-placental vessel resistance. From their review, Farrell and co-workers (1999) concluded that this technique was a poor predictor of adverse perinatal outcomes. They concluded that Doppler velocimetry had little, if any, role in fetal surveillance during labor.

FETAL DISTRESS

The terms *fetal distress* and *birth asphyxia* are too broad and vague to be applied with any precision to clinical situations (American College of Obstetricians and Gynecologists, 2004). Uncertainty about the diagnosis based on interpretation of fetal heart rate patterns has given rise to descriptions such as *reassuring* or *nonreassuring.* The term "reassuring" suggests a restoration of confidence by a particular pattern, whereas "nonreassuring" suggests inability to remove doubt. These patterns during labor are dynamic such that they can rapidly change from reassuring to nonreassuring and vice versa. In this situation, obstetricians experience surges of both confidence and doubt. Put another way, most diagnoses of fetal distress using heart rate patterns occur when obstetricians lose confidence or cannot assuage doubts about fetal condition. *These assessments are subjective clinical judgments inevitably subject to imperfection and must be recognized as such.*

Pathophysiology

Why is the diagnosis of fetal distress based on heart rate patterns so tenuous? One explanation is that these patterns are more a reflection of fetal physiology than of pathology. Physiological control of heart rate includes a variety of interconnected mechanisms that depend on blood flow as well as oxygenation. Moreover, the activity of these control mechanisms is influenced by the preexisting state of fetal oxygenation, for example, as seen with chronic placental insufficiency. Importantly, the fetus is tethered by an umbilical cord, whereby blood flow is constantly in jeopardy. Moreover, normal labor is a process of increasing acidemia (Rogers and colleagues, 1998). Thus, normal labor is a process of repeated fetal hypoxic events resulting inevitably in acidemia. Put another way, and assuming that "asphyxia" can be defined as hypoxia leading to acidemia, normal parturition is an asphyxiating event for the fetus.

Diagnosis

Because of the above uncertainties, it follows that identification of "fetal distress" based upon fetal heart rate patterns is imprecise and controversial. It is well known that experts in interpretation of these patterns often disagree with each other. In fact, Parer (1997), a strong advocate of electronic fetal heart rate monitoring and an organizer of the 1997 NICHD fetal monitoring workshop, lightheartedly compared the experts in attendance with marine iguanas of the Galapagos Islands, to wit: "all on the same beach but facing different directions and spitting at one another constantly!"

Ayres-de-Campos and colleagues (1999) investigated interobserver agreement of interpretation of fetal heart rate patterns and found that agreement—or conversely, disagreement—was related to whether the pattern was normal, suspicious, or pathological. Specifically, experts agreed on 62 percent of normal patterns, 42 percent of suspicious patterns, and only 25 percent of pathological patterns. Keith and co-workers (1995) asked each of 17 experts to review 50 tracings on two occasions, at least 1 month apart. About 20 percent changed their own interpretations, and approximately 25 percent did not agree with the interpretations of their colleagues. And although Murphy and colleagues (2003) concluded that at least part of the interpretation problem is due to a lack of formalized education in American training programs, this is obviously only a small modifier. Put another way, how can the teacher enlighten the student if the teacher is uncertain?

Evaluation of Classification Systems

Research efforts have been designed to test the utility of well-defined fetal heart rate classification systems. Berkus and associates (1999) retrospectively analyzed fetal heart rate patterns during the last 30 minutes of labor in 1859 term pregnancies. The study was designed to determine if specific patterns or combinations of patterns predicted neonatal outcome. Indisputably normal fetal heart rate patterns were recorded within 30 minutes of delivery in only 26 percent of cases. Prolonged bradycardia or tachycardia or fetal heart rate patterns that combined the absence of accelerations with severe variable or late decelerations were associated with an increased incidence of adverse infant outcome. Low and colleagues (1999) analyzed fetal heart rate patterns of term infants born with significant metabolic acidemia—defined as an umbilical artery base deficit > 16 mmol/L. Only 71 of 23,000 fetuses had acidemia this severe, and although patterns with absent baseline variability were the most specific, they were identified in only 17 percent of the 71 acidemic fetuses.

Dellinger and co-workers (2000) analyzed intrapartum fetal heart rate patterns in 898 pregnancies using a classification system of their own design. Fetal heart rate patterns during the hour before delivery were classified as "normal," "stress," or "distress." Fetal "distress" was diagnosed in 1 percent of tracings, 70 percent were classified as "normal," and a third were "intermediate" patterns. The fetal "distress" group contained patterns with zero variability *plus* late or moderate-to-severe variable decelerations or with baseline rates < 110 beats/min for 5 minutes or longer. Outcomes such as cesarean delivery, fetal acidemia, and admission to the intensive care nursery were significantly related to the fetal heart rate pattern. These investigators concluded that their classification system accurately predicted normal outcomes for fetuses as well as discriminating true fetal distress. Others have used computer programs in an effort to improve interpretation of fetal heart rate patterns, but with variable results (Agrawal, 2003; Bellver, 2004; Devoe, 2000; Reddy, 2009, and all their colleagues). Most recently, Parer and Ikeda (2007) have developed a framework for standardized management of intrapartum fetal heart rate patterns. They identified 134 patterns and color-coded each pattern. Those with no threat of fetal acidemia were coded green, and no intervention was required. Those with a severe threat of acidemia were coded red, and rapid delivery was recommended. The authors emphasized that their proposed framework required clinical testing before it could be concluded to be effective.

National Institutes of Health Workshops on Definitions and Interpretations

The National Institute of Child Health and Human Development (1997) held a succession of workshops in 1995 and 1996 to develop standardized and unambiguous definitions of FHR tracings and published recommendations for interpreting FHR patterns. As described by Spong (2008), the goal of these definitions was to allow FHR patterns to be more precisely interpreted, and these definitions were adopted by the American College of Obstetricians and Gynecologists (2005) as shown in Table 18-1. In 2008, the NICHD reconvened a second workshop to reevaluate the 1997 recommendations and to clarify terminology (Macones and co-workers, 2008). The major changes included categorizations of FHR interpretations into a three-tier system shown in Table 18-2. The new terminology for defining uterine contractions is described subsequently in the section on surveillance of uterine activity (p. 437).

Status of Fetal Heart Rate Pattern Interpretation

After almost 40 years of experience with interpretation of fetal heart rate patterns, evidence is finally emerging that some combinations of fetal heart rate characteristics can be meaningfully used to identify normal and severely abnormal fetuses. As

TABLE 18-2. Three-Tier Fetal Heart Interpretation System Recommended by the 2008 NICHD Workshop on Electronic Fetal Monitoring

Category I—Normal

Include all of the following:

- Baseline rate: 110–160 bpm
- Baseline FHR variability: moderate
- Late or variable decelerations: absent
- Early decelerations: present or absent
- Accelerations: present or absent

Category II—Indeterminate

Include all FHR tracings not categorized as Category I or III. Category II tracings may represent an appreciable fraction of those encountered in clinical care. Examples include any of the following:

Baseline rate

- Bradycardia not accompanied by absent baseline variability
- Tachycardia

Baseline FHR variability

- Minimal baseline variability
- Absent baseline variability not accompanied by recurrent decelerations
- Marked baseline variability

Accelerations

- Absence of induced accelerations after fetal stimulation

Periodic or episodic decelerations

- Recurrent variable decelerations accompanied by minimal or moderate baseline variability
- Prolonged deceleration ≥ 2 minutes but < 10 minutes
- Recurrent late decelerations with moderate baseline variability
- Variable decelerations with other characteristics, such as slow return to baseline, "overshoots," or "shoulders"

Category III—Abnormal

Include either:

- Absent baseline FHR variability and any of the following:
  Recurrent late decelerations
  Recurrent variable decelerations
  Bradycardia
- Sinusoidal pattern

bpm = beats per minute; FHR = fetal heart rate; NICHD = National Institute of Child Health and Human Development.
From Macones and colleagues (2008), with permission.

shown in Tables 18-1 and 18-2, true fetal distress patterns appear to be those in which beat-to-beat variability is zero in conjunction with severe decelerations or persistent baseline rate changes, or both. Fortunately, such fetal distress is rare. One explanation for the persistent failure to scientifically establish the benefits of fetal heart rate monitoring is the rarity of such fetal distress, effectively precluding statistically significant results from clinical trials (Hornbuckle and colleagues, 2000).

Meconium in the Amnionic Fluid

Obstetrical teaching throughout the past century has included the concept that meconium passage is a potential warning of fetal asphyxia. In 1903, J. Whitridge Williams observed and attributed meconium passage to "relaxation of the sphincter ani muscle induced by faulty aeration of the (fetal) blood." Obstetricians, however, have also long realized that the detection of meconium during labor is problematic in the prediction of fetal distress or asphyxia. In their review, Katz and Bowes (1992) emphasized the prognostic uncertainty of meconium by referring to the topic as a "murky subject." Indeed, although 12 to 22 percent of labors are complicated by meconium, only a few are linked to infant mortality. In an investigation from Parkland Hospital, meconium was found to be a "low-risk" obstetrical hazard because the perinatal mortality rate attributable to meconium was 1 death per 1000 live births (Nathan and co-workers, 1994).

Three theories have been suggested to explain fetal passage of meconium and, in part, may explain the tenuous connection between its detection and infant mortality. The pathological explanation proposes that fetuses pass meconium in response to hypoxia and that meconium therefore signals fetal compromise (Walker, 1953). Alternatively, in utero passage of meconium may represent normal gastrointestinal tract maturation under neural control (Mathews and Warshaw, 1979). Third, meconium passage could follow vagal stimulation from common but transient umbilical cord entrapment and resultant increased peristalsis (Hon and colleagues, 1961). Thus, meconium release also could represent physiological processes.

Ramin and associates (1996) studied almost 8000 pregnancies with meconium-stained amnionic fluid delivered at Parkland Hospital. Meconium aspiration syndrome was significantly associated with fetal acidemia at birth. Other significant correlates of aspiration included cesarean delivery, forceps to expedite delivery, intrapartum heart rate abnormalities, depressed Apgar scores, and need for assisted ventilation at delivery. Analysis of the type of fetal acidemia based on umbilical blood gases suggested that the fetal compromise associated with meconium aspiration syndrome was an acute event, because most acidemic fetuses had abnormally increased P_{CO_2} values rather than a pure metabolic acidemia.

Dawes and co-workers (1972) observed that such hypercarbia in fetal lambs induces gasping and resultant increased amnionic fluid inhalation. Jovanovic and Nguyen (1989) observed that meconium gasped into the fetal lungs caused aspiration syndrome only in asphyxiated animals. Ramin and co-workers (1996) hypothesized that the pathophysiology of meconium aspiration syndrome includes, but is not limited to, fetal hypercarbia, which stimulates fetal respiration leading to aspiration of meconium into the alveoli. Lung parenchymal injury is secondary to acidemia-induced alveolar cell damage. In this pathophysiological scenario, meconium in amnionic fluid is a fetal environmental hazard rather

than a marker of preexistent compromise. This proposed pathophysiological sequence is not all-inclusive, because it does not account for approximately half of the cases of meconium aspiration syndrome in which the fetus was not acidemic at birth.

From the foregoing, it was concluded that the high incidence of meconium observed in the amnionic fluid during labor often represents fetal passage of gastrointestinal contents in conjunction with normal physiological processes. Although normal, such meconium becomes an environmental hazard when fetal acidemia supervenes. Importantly, such acidemia occurs acutely, and therefore meconium aspiration is unpredictable and likely unpreventable. Moreover, Greenwood and colleagues (2003) showed that clear amnionic fluid was also a poor predictor. In a prospective study of 8394 women with clear amnionic fluid, they found that clear fluid was an unreliable sign of fetal well-being.

There is accumulating evidence that many infants with meconium aspiration syndrome have suffered chronic hypoxia before birth (Ghidini and Spong, 2001). For example, Blackwell and associates (2001) found that 60 percent of infants diagnosed as having meconium aspiration syndrome had umbilical artery blood pH $\geq$ 7.20, suggesting that the syndrome was unrelated to the neonatal condition at delivery. Similarly, markers of chronic hypoxia, such as fetal erythropoietin levels and nucleated red blood cell counts in newborn infants, suggest that chronic hypoxia is involved in many cases of meconium aspiration syndrome (Dollberg and colleagues, 2001; Jazayeri and colleagues, 2000).

Routine obstetrical management of a newborn with meconium-stained amnionic fluid has generally included intrapartum suctioning of the oropharynx and nasopharynx on the perineum after delivery of the head, but before delivery of the shoulder. The new guidelines from the American College of Obstetricians and Gynecologists (2007), however, recommend that such infants no longer routinely receive intrapartum suctioning because it does not prevent meconium aspiration syndrome (Chap. 28, p. 628). If the infant is depressed, the trachea is intubated, and meconium suctioned from beneath the glottis. If the newborn is vigorous, defined as having strong respiratory efforts, good muscle tone, and a heart rate > 100 bpm, then tracheal suction is not necessary and may injure the vocal cords.

Management Options

The principal management options for significantly variable fetal heart rate patterns consist of correcting any fetal insult, if possible. Measures suggested by the American College of Obstetricians and Gynecologists (2005) are listed in **Table 18-3**. Moving the mother to the lateral position, correcting maternal hypotension caused by regional analgesia, and discontinuing oxytocin serve to improve uteroplacental perfusion. Examination is done to exclude prolapsed cord or impending delivery. Simpson and James (2005) assessed benefits of three maneuvers in 52 women with fetal O_2 saturation sensors already in place. They used intravenous hydration—500 to 1000 mL of lactated Ringers solutions given over 20 minutes; lateral versus supine position; and using a nonrebreather mask administered supplemental oxygen at 10 L/min. Each of these maneuvers significantly increased fetal oxygen saturation levels, although the increments were small.

TABLE 18-3. Initial Evaluation and Treatment of Nonreassuring Fetal Heart Rate Patterns

- Discontinuation of any labor stimulating agent Cervical examination to assess for umbilical cord prolapse or rapid cervical dilation or descent of the fetal head
- Changing maternal position to left or right lateral recumbent position, reducing compression of the vena cava and improving uteroplacental blood flow
- Monitoring maternal blood pressure level for evidence of hypotension, especially in those with regional anesthesia—if present, treatment with ephedrine or phenylephrine may be warranted
- Assessment of patient for uterine hyperstimulation by evaluating uterine contraction frequency and duration

From American College of Obstetricians and Gynecologists, *Intrapartum Fetal Heart Rate Monitoring,* ACOG Practice Bulletin 70, Washington, DC: ACOG, 2005, with permission.

Tocolysis

A single intravenous or subcutaneous injection of 0.25 mg of terbutaline sulfate given to relax the uterus has been described as a temporizing maneuver in the management of nonreassuring fetal heart rate patterns during labor. The rationale is that inhibition of uterine contractions might improve fetal oxygenation, thus achieving in utero resuscitation. Cook and Spinnato (1994) described their experience with terbutaline tocolysis for fetal resuscitation in 368 pregnancies over a 10-year period. Such resuscitation improved fetal scalp blood pH values, although all fetuses underwent cesarean delivery. These investigators concluded that although the studies were small and rarely randomized, most reported favorable results with terbutaline tocolysis for nonreassuring patterns. Small intravenous doses of nitroglycerin—60 to 180 μg—also have been reported to be beneficial (Mercier and colleagues, 1997).

Amnioinfusion

Gabbe and co-workers (1976) showed in monkeys that removal of amnionic fluid produced variable decelerations and that replenishment of fluid with saline relieved the decelerations. Miyazaki and Taylor (1983) infused saline through an intrauterine pressure catheter in laboring women who had either variable decelerations or prolonged decelerations attributed to cord entrapment. Such therapy improved the heart rate pattern in half of the women studied. Later, Miyazaki and Nevarez (1985) randomly assigned 96 nulliparous women in labor with cord compression patterns and found that those who were treated with amnioinfusion required cesarean delivery for fetal distress less often.

Based on many of these early reports, transvaginal amnioinfusion has been extended into three clinical areas:

1. Treatment of variable or prolonged decelerations
2. Prophylaxis for women with oligohydramnios, as with prolonged ruptured membranes
3. Attempts to dilute or wash out thick meconium (see Chap. 21, p. 497).

Many different amnioinfusion protocols have been reported, but most include a 500- to 800-mL bolus of warmed normal saline followed by a continuous infusion of approximately 3 mL per minute (Owen and co-workers, 1990; Pressman and Blakemore, 1996). In another study, Rinehart and colleagues (2000) randomly gave either 500-mL boluses of normal saline at room temperature alone or 500-mL boluses plus continuous infusion of 3 mL per minute. Their study included 65 women with variable decelerations, and the investigators found neither method to be superior. Wenstrom and associates (1995) surveyed use of amnioinfusion in teaching hospitals in the United States. The procedure was used in 96 percent of the 186 centers surveyed, and it was estimated that 3 to 4 percent of all women delivered at these centers received such infusion. Potential complications of amnioinfusion are summarized in Table 18-4.

Prophylactic Amnioinfusion for Variable Decelerations. Hofmeyr (1998) used the Cochrane Database to specifically analyze the effects of amnioinfusion in the management of fetal heart rate patterns associated with umbilical cord compression. There were 14 suitable studies identified, most with fewer than 200 participants. It was concluded that amnioinfusion appeared to be useful in reducing the occurrence of variable decelerations, improving neonatal outcome, and reducing cesarean delivery rates for "fetal distress." Based largely on this review, the American College of Obstetricians and Gynecologists (2005) recommends consideration of amnioinfusion with persistent variable decelerations.

TABLE 18-4. Complications Associated with Amnioinfusion from a Survey of 186 Obstetrical Centers

Complication	Centers Reporting No. (%)
Uterine hypertonus	27 (14)
Abnormal fetal heart rate tracing	17 (9)
Chorioamnionitis	7 (4)
Cord prolapse	5 (2)
Uterine rupture	4 (2)
Maternal cardiac or respiratory compromise	3 (2)
Placental abruption	2 (1)
Maternal death	2 (1)

Prophylactic Amnioinfusion for Oligohydramnios. Amnioinfusion in women with oligohydramnios has been used prophylactically in an effort to avoid intrapartum fetal heart rate patterns from cord occlusion. Nageotte and co-workers (1991) found that such amnioinfusion resulted in significantly decreased frequency and severity of variable decelerations in labor. There was no improvement, however, in the cesarean delivery rate or condition of term infants. In a randomized investigation, Macri and colleagues (1992) studied prophylactic amnioinfusion in 170 term and postterm pregnancies complicated by both thick meconium and oligohydramnios. Amnioinfusion significantly reduced cesarean delivery rates for fetal distress as well as meconium aspiration syndrome. In contrast, Ogundipe and associates (1994) randomly assigned 116 term pregnancies with an amnionic fluid index of < 5 cm to receive prophylactic amnioinfusion or standard obstetrical care. There were no significant differences in overall cesarean delivery rates, delivery rates for fetal distress, or umbilical gas studies.

Amnioinfusion for Meconium-Stained Amnionic Fluid. Pierce and associates (2000) summarized the results of 13 prospective trials of intrapartum amnioinfusion in 1924 women with moderate to thick meconium-stained fluid. Infants born to women treated by amnioinfusion were significantly less likely to have meconium below the vocal cords and were less likely to develop meconium aspiration syndrome than infants born to women not undergoing amnioinfusion. The cesarean delivery rate was also lower in the amnioinfusion group. Similar results were reported by Rathore and colleagues (2002). In contrast, a number of investigators were not supportive of amnioinfusion for meconium staining. For example, Usta and associates (1995) reported that amnioinfusion was not feasible in half of women with moderate or thick meconium who were randomized to this treatment. These investigators were unable to demonstrate any improvement in neonatal outcomes. Spong and co-workers (1994) also concluded that although prophylactic amnioinfusion did dilute meconium, it did not improve perinatal outcome. Lastly, Fraser and colleagues (2005) randomized amnioinfusion in 1998 women with thick meconium staining of the amnionic fluid in labor and found no benefits. Because of these findings, the American College of Obstetricians and Gynecologists (2006a) does not recommend amnioinfusion to dilute meconium-stained amnionic fluid.

Xu and co-workers (2007) recently performed a systematic review of randomized controlled trials done to evaluate benefits of amnioinfusion for women in labor complicated by meconium-stained amnionic fluid. They separated the reporting centers based on availability or nonavailability of continuous electronic fetal monitoring—standard versus limited intrapartum surveillance, respectively (Table 18-5). Importantly, amnioinfusion did not decrease the incidence of meconium-aspiration syndrome in the standard surveillance group. It did, however, in the group with limited surveillance—2.4 versus 10 percent for amnioinfusion versus controls—RR = 0.25 (0.13–0.47). These reviewers concluded that amnioinfusion in areas with limited resources may be used to lower the incidence of meconium-aspiration syndrome.

TABLE 18-5. Results of Randomized Controlled Trials of Amnioinfusion versus Standard Intrapartum Surveillance of Women in Labor with Meconium-Stained Amniotic Fluid

	Treatment Group		
Outcome	Amnioinfusion No. (%)	Control No. (%)	RR (95% CI)
Meconium-aspiration syndrome	55/1576 (3.5)	64/1062 (6.0)	0.59 (0.28–1.25)
Meconium beneath cords	83/1538 (5.4)	210/1564[a] (13.4)	0.29 (0.14–0.57)
5-minute Apgar < 7	36/1425 (2.5)	46/1443 (3.2)	0.9 (0.58–1.41)
Neonatal pH < 7.2	188/903 (20.8)	226/885[a] (25.5)	0.62 (0.40–0.96)
Cesarean delivery	471/1586 (29.7)	474/1598 (29.7)	0.89 (0.73–1.10)

[a]Comparison between treatment groups is significant ($p < .05$).

Fetal Heart Rate Patterns and Brain Damage

Attempts to correlate fetal heart rate patterns with brain damage have been based primarily on studies of infants identified as a result of medicolegal actions. For example, Rosen and Dickinson (1992) analyzed intrapartum fetal heart rate patterns in 55 such cases and found no specific pattern that correlated with neurological injury. Phelan and Ahn (1994) reported that among 48 fetuses later found to be neurologically impaired, a persistent nonreactive fetal heart rate tracing was already present at the time of admission in 70 percent. They concluded that fetal neurological injury occurred predominately prior to arrival to the hospital. When they looked retrospectively at heart rate patterns in 209 brain-damaged infants, they concluded that there was not a single unique pattern associated with fetal neurological injury (Ahn and co-workers, 1996). Identical results were reported by Williams and Galerneau (2004), who also found that neonatal seizures due to hypoxic ischemic encephalopathy were related to nonspecific abnormal fetal heart rate patterns only when the patterns had been present for an average of 72 minutes. Most recently, Graham and associates (2006) reviewed the world literature published between 1966 and 2006 on the effect of fetal heart rate monitoring to prevent perinatal brain injury and found no benefit.

Experimental Evidence

Fetal heart rate patterns necessary for perinatal brain damage have been studied in experimental animals. Myers (1972) described the effects of complete and partial asphyxia in rhesus monkeys in studies of brain damage due to perinatal asphyxia. Complete asphyxia was produced by total occlusion of umbilical blood flow that led to prolonged deceleration (Fig. 18-31). Fetal arterial pH did not reach 7.0 until about 8 minutes after complete cessation of oxygenation and umbilical flow. At least 10 minutes of such prolonged deceleration was required before there was evidence of brain damage in surviving fetuses.

Myers (1972) also produced partial asphyxia in rhesus monkeys by impeding maternal aortic blood flow. This resulted in late decelerations due to uterine and placental hypoperfusion. He observed that several hours of these late decelerations did not damage the fetal brain unless the pH fell below 7.0. Indeed, Adamsons and Myers (1977) reported subsequently that late

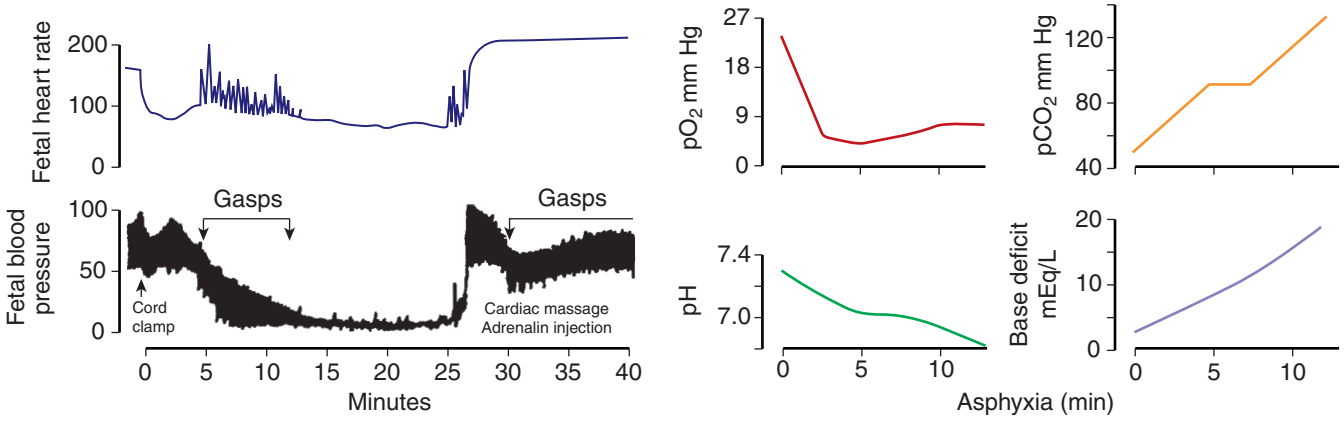

FIGURE 18-31 Prolonged deceleration in a rhesus monkey shown with blood pressure and biochemical changes during total occlusion of umbilical cord blood flow. (Adapted from Myers, 1972.)

decelerations were a marker of partial asphyxia long before brain damage occurred.

The most common fetal heart rate pattern during labor—due to umbilical cord occlusion—requires considerable time to significantly affect the fetus in experimental animals. Clapp and colleagues (1988) partially occluded the umbilical cord for 1 minute every 3 minutes in fetal sheep. Rocha and colleagues (2004) totally occluded the umbilical cord for 90 seconds every 30 minutes for 3 to 5 hours a day for 4 days without producing necrotic brain cell injury. The results from experiments such as these suggest that the effects of umbilical cord entrapment depend on the degree of occlusion—partial versus total, the duration of individual occlusions, and the frequency of such occlusions.

Human Evidence. The contribution of intrapartum events to subsequent neurological handicaps has been greatly overestimated as discussed in further detail in Chapter 29 (p. 612). Nelson and Grether (1998) performed a population-based study of children with disabling spastic cerebral palsy in which they compared intrapartum records of these children with matched controls. Intrapartum fetal heart rate abnormalities did not distinguish between children with cerebral palsy and normal controls. Badawi and colleagues (1998) performed a case-control population-based study of infants with cerebral palsy in Western Australia. Only 5 percent of the brain-damaged infants had intrapartum factors. This fact led them to conclude that most cerebral palsy is unrelated to labor events. Shown in Table 18-6 are some of the other pathologies associated with cerebral palsy.

Low and co-workers (1989) divided perinatal brain damage found following an asphyxial event into three categories based on microscopic findings:

1. From 18 to 48 hours—neuronal necrosis with pyknosis or lysis of the nucleus in shriveled eosinophilic cells
2. From 48 to 72 hours—more intense neuronal necrosis with macrophage response
3. More than 3 days—all the preceding plus astrocytic response with gliosis and in some, early cavitation.

TABLE 18-6. Some Major, Nonintrapartum Pathologies Associated with Cerebral Palsy

- Preterm delivery
- Placental hemorrhage—previa, abruption
- Multifetal pregnancy
- Genetic disorders and anomalies
- Fetal infection—e.g., cytomegalovirus, toxoplasmosis, funisitis, villitis
- Fetal-growth restriction
- Maternal disease—e.g., diabetes, hypertension, viral illness
- Placental infarction, thrombosis
- Tight nuchal cord
- Childhood causes
- Fetal anemia—e.g., hemorrhage, anti-D isoimmunization

Adapted from Strijbis and colleagues (2006).

Abnormal brain histopathology was not observed with acute, lethal asphyxia. Moreover, 43 percent of brain damage episodes occurred prior to labor, and 25 percent were in the neonatal period. In another investigation, Low and associates (1984) estimated that more than 1 hour of fetal hypoxia associated with profound metabolic acidemia—pH less than 7.0—was required before neurological abnormalities could be diagnosed at age 6 to 12 months. Low and co-workers (1988) identified 37 term infants with profound metabolic acidemia at birth, followed them for 1 year, and found major neurological deficits in 13 percent. Minor deficits were diagnosed in 10 infants, and the remaining 60 percent were normal. These investigators further observed that intrapartum fetal asphyxia with metabolic acidemia at delivery in both the term and preterm fetus was marked by severe complications not only of the central nervous system, but also of the respiratory and renal systems (Low and colleagues, 1994, 1995).

Clearly, for brain damage to occur, the fetus must be exposed to much more than a brief period of hypoxia. Moreover, the hypoxia must cause profound, just barely sublethal metabolic acidemia. The American College of Obstetricians and Gynecologists (2006b) specifies that such hypoxic-ischemic encephalopathy will show other signs of damage to include: (1) metabolic acidosis in umbilical cord artery blood—pH < 7 and base deficit ≥ 12 mmol/L; (2) Apgar scores 0–3 beyond 5 minutes, and (3) neurological sequelae—seizures, coma, hypotonia, and one or more of cardiovascular, gastrointestinal, hematological, pulmonary, hepatic, or renal system dysfunction. Accordingly, the American College of Obstetricians and Gynecologists (2006b) recommends umbilical cord gases be obtained whenever there is cesarean delivery for fetal compromise, a low 5-minute Apgar score, severe fetal-growth restriction, an abnormal fetal heart rate tracing, maternal thyroid disease, or multifetal gestation. Fetal heart rate patterns consistent with these sublethal conditions are fortunately rare.

These observations strengthen the position of the American College of Obstetricians and Gynecologists (2006b) on the criteria necessary to consider birth asphyxia as a cause of cerebral palsy as discussed in detail in Chapter 29 (p. 612). These include cord blood evidence of metabolic acidosis and early onset of severe or moderate encephalopathy. Importantly, spastic quadriplegia and, less commonly, dyskinetic cerebral palsy are the only types of cerebral palsy associated with acute hypoxic intrapartum events. Unilateral brain lesions—hemiplegia or diplegia—are not a result of intrapartum hypoxia.

Benefits of Electronic Fetal Heart Rate Monitoring

There are several fallacious assumptions behind expectations of improved perinatal outcome with electronic monitoring. One assumption is that fetal distress is a slowly developing phenomenon

and that electronic monitoring makes possible early detection of the compromised fetus. This assumption is illogical; that is, how can all fetuses die slowly? Another presumption is that all fetal damage develops in the hospital. Within the past 20 years, attention has been focused on the reality that most damaged fetuses suffered insults before arrival at labor units. The very term *fetal monitor* implies that this inanimate technology in some fashion "monitors." The assumption is made that if a dead or damaged infant is delivered, the tracing strip must provide some clue, because this device was monitoring fetal condition. All of these assumptions led to great expectations and fostered the belief that all dead or damaged neonates were preventable. Parer and King (2000) reviewed reasons why fetal heart rate monitoring did not live up to its expectations. These unwarranted expectations have greatly fueled litigation in obstetrics. Indeed, Symonds (1994) reported that 70 percent of all liability claims related to fetal brain damage are based on reputed abnormalities seen in the electronic fetal monitor tracing.

By the end of the 1970s, questions about the efficacy, safety, and costs of electronic monitoring were being voiced from the Office of Technology Assessment, the United States Congress, and the Centers for Disease Control and Prevention. Banta and Thacker (2002) reviewed 25 years of the controversy on the benefits, or lack thereof, of electronic fetal monitoring. Parer (2003) points out that the controversy continues and that ". . . to justify our continued use of EFM, we need to clean up our house. We must come to some agreement on a national level about interpretation and management."

Parkland Hospital Experience: Selective versus Universal Monitoring

In July 1982, an investigation began at Parkland Hospital to ascertain whether all women in labor should undergo electronic monitoring (Leveno and co-workers, 1986). In alternating months, universal electronic monitoring was rotated with selective heart rate monitoring, which was the prevailing practice. During the 3-year investigation, 17,410 labors were managed using universal electronic monitoring. No significant differences were found in any perinatal outcomes. There was a significantly small increase in the cesarean delivery rate for fetal distress associated with universal monitoring. Thus, increased application of electronic monitoring at Parkland Hospital did not improve perinatal results, but it increased the frequency of cesarean delivery for fetal distress.

Summary of Randomized Studies. Thacker and associates (1995) identified 12 randomized clinical trials of electronic fetal monitoring from 1966 to 1994. There were 58,624 total pregnancies included in these studies. These authors concluded that the benefits once claimed for electronic monitoring are clearly more modest than were believed and appear to be primarily in the prevention of neonatal seizures. Long-term implications of this outcome, however, appear less serious than once believed. Abnormal neurological consequences were not consistently higher among children monitored by auscultation compared with electronic methods. The authors concurred with the position of the American College of Obstetricians and Gynecologists (1995) on intrapartum fetal surveillance.

Current Recommendations

The methods most commonly used for intrapartum fetal heart rate monitoring include auscultation with a fetal stethoscope or a Doppler ultrasound device, or continuous electronic monitoring of the heart rate and uterine contractions. No scientific evidence has identified the most effective method, including the frequency or duration of fetal surveillance that ensures optimum results. Summarized in Table 18-7 are the current recommendations of the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007). Intermittent auscultation or continuous electronic monitoring is considered an acceptable method of intrapartum surveillance

TABLE 18-7. Guidelines for Methods of Intrapartum Fetal Heart Rate Monitoring

Surveillance	Low-Risk Pregnancies	High-Risk Pregnancies
Acceptable methods		
Intermittent auscultation	Yes	Yes[a]
Continuous electronic monitoring (internal or external)	Yes	Yes[b]
Evaluation intervals		
First-stage labor (active)	30 min	15 min[a,b]
Second-stage labor	15 min	5 min[a,c]

[a]Preferably before, during, and after a uterine contraction.
[b]Includes tracing evaluation and charting at least every 15 minutes.
[C]Tracing should be evaluated at least every 5 minutes.
From the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007).

in both low- and high-risk pregnancies. The recommended interval between checking the heart rate, however, is longer in the uncomplicated pregnancy. When auscultation is used, it is recommended that it be performed after a contraction and for 60 seconds. It also is recommended that a 1-to-1 nurse–patient ratio be used if auscultation is employed.

INTRAPARTUM SURVEILLANCE OF UTERINE ACTIVITY

Analysis of electronically measured uterine activity permits some generalities concerning the relationship of certain contraction patterns to labor outcome. There is considerable normal variation, however, and caution must be exercised before judging true labor or its absence solely from study of a monitor tracing. Uterine muscle efficiency to effect delivery varies greatly. To use an analogy, 100-meter sprinters all have the same muscle groups yet cross the finish line at different times.

Internal Uterine Pressure Monitoring

Amnionic fluid pressure is measured between and during contractions by a fluid-filled plastic catheter with its distal tip located above the presenting part (Fig. 18-32). The catheter is connected to a strain-gauge pressure sensor adjusted to the same level as the catheter tip in the uterus. The amplified electrical signal produced in the strain gauge by variation in pressure within the fluid system is recorded on a calibrated moving paper strip simultaneously with the fetal heart rate recording. Intrauterine pressure catheters are now available that have the pressure sensor in the catheter tip, which obviates the need for the fluid column.

External Monitoring

Uterine contractions can be measured by a displacement transducer in which the transducer button, or "plunger," is held against the abdominal wall. As the uterus contracts, the button moves in proportion to the strength of the contraction. This movement is converted into a measurable electrical signal that indicates the *relative* intensity of the contraction—it does not give an accurate measure of intensity. However, external monitoring can give a good indication of the onset, peak, and end of the contraction.

Patterns of Uterine Activity

Caldeyro-Barcia and Poseiro (1960), from Montevideo, Uruguay, were pioneers who have done much to elucidate the patterns of spontaneous uterine activity throughout pregnancy. Contractile waves of uterine activity were usually measured using intra-amnionic pressure catheters. But early in their studies, as many as four simultaneous intramyometrial microballoons were also used to record uterine pressure. These investigators also introduced the concept of *Montevideo units* to define uterine activity (see Chap. 20, p. 467). By this definition, uterine performance is the product of the intensity—increased uterine pressure above baseline tone—of a contraction in mm Hg multiplied by contraction frequency per 10 minutes. For example, three contractions in 10 minutes, each of 50 mm Hg intensity, would equal 150 Montevideo units.

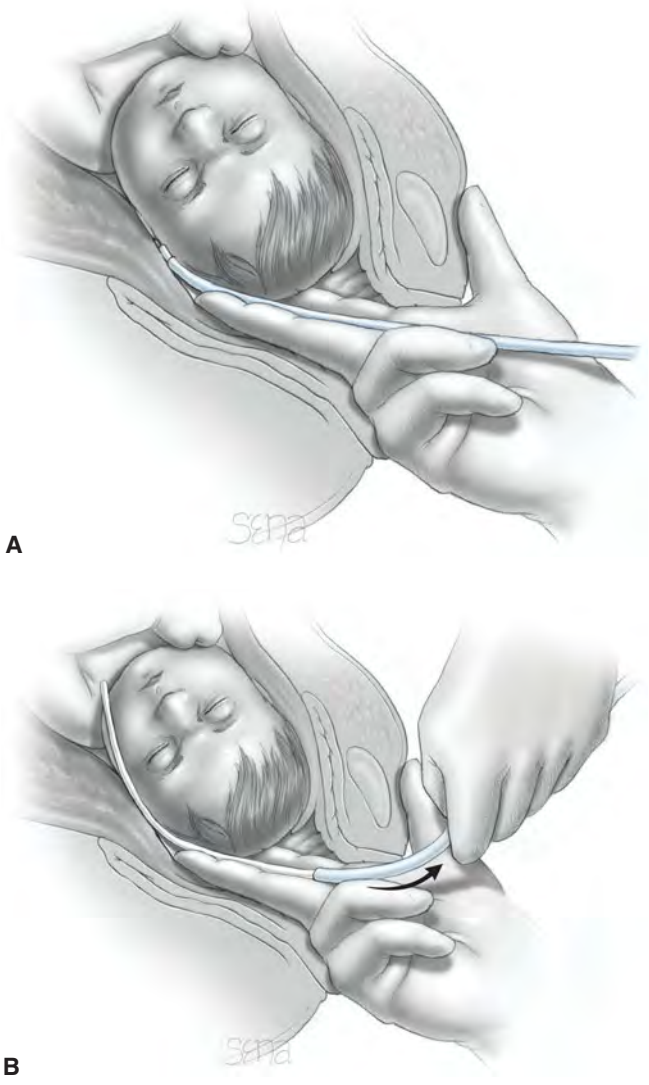

FIGURE 18-32 Placement of an intrauterine pressure catheter to monitor contractions and their pressures. **A.** The white catheter, contained within the blue introducer, is inserted into the birth canal and placed along one side of the fetal head. **B.** The catheter is then gently advanced into the uterus, and the introducer is withdrawn.

During the first 30 weeks, uterine activity is comparatively quiescent. Contractions are seldom greater than 20 mm Hg, and these have been equated with those first described in 1872 by John Braxton Hicks. Uterine activity increases gradually after 30 weeks, and it is noteworthy that these *Braxton Hicks contractions* also increase in intensity and frequency. Further increases in uterine activity are typical of the last weeks of pregnancy, termed *prelabor*. During this phase, the cervix ripens (see Chap. 6, p. 138).

According to Caldeyro-Barcia and Poseiro (1960), clinical labor usually commences when uterine activity reaches values between 80 and 120 Montevideo units. This translates into approximately three contractions of 40 mm Hg every 10 minutes.

Importantly, there is no clear-cut division between prelabor and labor, but rather a gradual and progressive transition.

During first-stage labor, uterine contractions increase progressively in intensity from approximately 25 mm Hg at commencement of labor to 50 mm Hg at the end. At the same time, frequency increases from three to five contractions per 10 minutes, and uterine baseline tone from 8 to 12 mm Hg. Uterine activity further increases during second-stage labor, aided by maternal pushing. Indeed, contractions of 80 to 100 mm Hg are typical and occur as frequently as five to six per 10 minutes. Interestingly, the duration of uterine contractions—60 to 80 seconds—does not increase appreciably from early active labor through the second stage (Bakker and associates, 2007; Pontonnier and colleagues, 1975). Presumably, this duration constancy serves fetal respiratory gas exchange. During a uterine contraction, the intervillous space, where respiratory gas exchange occurs, becomes isolated. This leads to functional fetal "breath holding," which has a 60- to 80-second limit that remains relatively constant.

Caldeyro-Barcia and Poseiro (1960) also observed empirically that uterine contractions are clinically palpable only after their intensity exceeds 10 mm Hg. Moreover, until the intensity of contractions reaches 40 mm Hg, the uterine wall can readily be depressed by the finger. At greater intensity, the uterine wall then becomes so hard that it resists easy depression. Uterine contractions usually are not associated with pain until their intensity exceeds 15 mm Hg, presumably because this is the minimum pressure required for distending the lower uterine segment and cervix. It follows that Braxton Hicks contractions exceeding 15 mm Hg may be perceived as uncomfortable because distension of the uterus, cervix, and birth canal is generally thought to elicit discomfort.

Hendricks (1968) observed that "the clinician makes great demands upon the uterus." The uterus is expected to remain well relaxed during pregnancy, to contract effectively but intermittently during labor, and then to remain in a state of almost constant contraction for several hours postpartum. **Figure 18-33** demonstrates an example of normal uterine activity during labor. Uterine activity progressively and gradually increases from prelabor through late labor. Interestingly, as shown in Figure 18-33, uterine contractions after birth are identical to those resulting in delivery of the infant. It is therefore not surprising that the uterus that performs poorly before delivery is also prone to atony and puerperal hemorrhage.

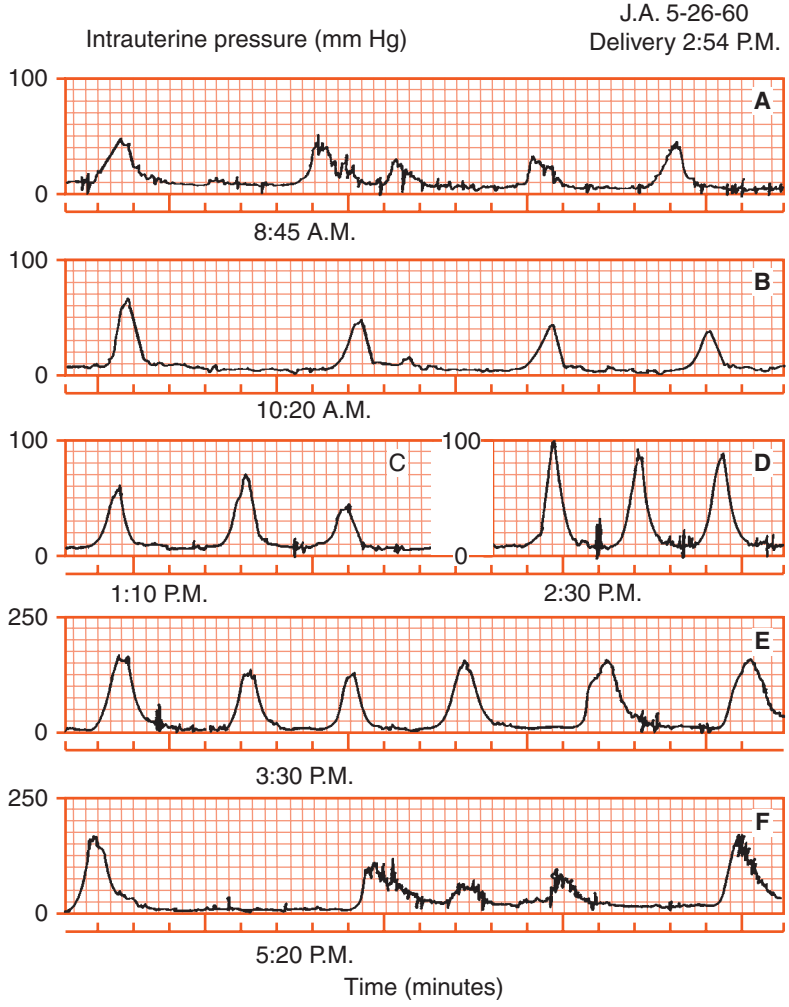

FIGURE 18-33 Intrauterine pressure recorded through a single catheter. **A.** Prelabor. **B.** Early labor. **C.** Active labor. **D.** Late labor. **E.** Spontaneous activity ½ hour postpartum. **F.** Spontaneous activity 2½ hours postpartum. (Adapted from Hendricks, 1968, with permission.)

Origin and Propagation of Contractions

The uterus has not been studied extensively in terms of its nonhormonal physiological mechanisms of function. The normal contractile wave of labor originates near the uterine end of one of the fallopian tubes. Thus, these areas act as "pacemakers" (Fig. 18-34). The right pacemaker usually predominates over the left and starts most contractile waves. Contractions spread from the pacemaker area throughout the uterus at 2 cm/sec, depolarizing the whole organ within 15 seconds. This depolarization wave propagates downward toward the cervix. Intensity is greatest in the fundus, and it diminishes in the lower uterus. This phenomenon is thought to reflect reductions in myometrial thickness from the fundus to the cervix. Presumably, this descending gradient of pressure serves to direct fetal descent toward the cervix as well as to efface the cervix. Importantly, all parts of the uterus are synchronized and reach their peak pressure almost simultaneously, giving rise to the curvilinear waveform shown in Figure 18-34. Young and Zhang (2004) have shown that the initiation of each contraction is triggered by a tissue-level bioelectric event.

The pacemaker theory also serves to explain the varying intensity of adjacent coupled contractions shown in panels A and B of Figure 18-33. Such coupling was termed *incoordination* by Caldeyro-Barcia and Poseiro (1960). A contractile wave begins in one cornual-region pacemaker, but does not synchronously depolarize the entire uterus. As a result, another contraction begins in the contralateral pacemaker and produces the second contractile wave of the couplet. These small contractions alternating with larger ones appear to be typical of early labor. Indeed, labor may progress with such uterine activity, albeit at a slower pace. These authors also observed that labor would progress slowly if regular contractions were hypotonic—that is, contractions with intensity less than 25 mm Hg or frequency less than 2 per 10 minutes. Similar observations were made by Seitchik (1981) in a computer-aided analysis comparing women in active labor with those in arrested labor. Normal labor was characterized by a minimum of three contractions that averaged greater than 25 mm Hg and less than 4-minute intervals between contractions. A lesser amount of uterine activity was associated with arrest of active labor. Prospective diagnosis of hypotonic labor cannot be reliably based simply on a few uterine pressures.

Hauth and co-workers (1986) quantified uterine contraction pressures in 109 women at term who received oxytocin for

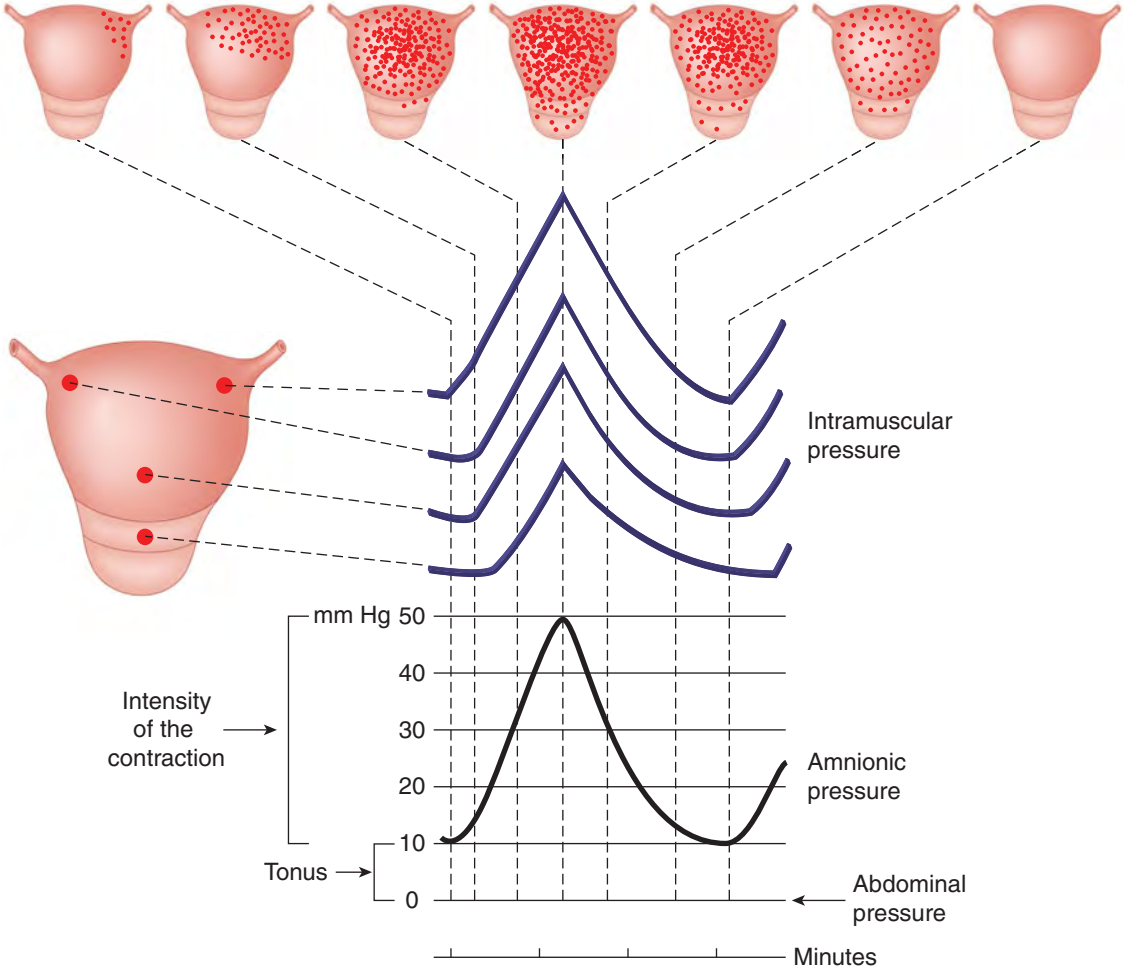

FIGURE 18-34 Schematic representation of the normal contractile wave of labor. Large uterus on the left shows the four points at which intramyometrial pressure was recorded with microballoons. Four corresponding pressure tracings are shown in relation to each other by shading on the small uteri at top. (Adapted from Caldeyro-Barcia and Poseiro, 1960.)

labor induction or augmentation. Most of these women achieved 200 to 225 Montevideo units, and 40 percent had up to 300 units to effect delivery. The authors suggested that these levels of uterine activity should be sought before consideration of cesarean delivery for presumed dystocia.

LOCAL INFILTRATION FOR CESAREAN DELIVERY 458
GENERAL ANESTHESIA 459

Obstetrical anesthesia presents unique challenges. Labor begins without warning, and anesthesia may be required within minutes of a full meal. Vomiting with aspiration of gastric contents is a constant threat. The usual physiological adaptations of pregnancy require special consideration, especially with disorders such as preeclampsia, placental abruption, or sepsis syndrome.

Of all anesthesia-related deaths in the U.S. from 1995 to 2005, 3.6 percent were in pregnant women (Li and co-workers, 2009). Anesthesia complications caused 1.6 percent of pregnancy-related maternal deaths in the United States from 1991 through 1997 (Berg and co-workers, 2003). Of the 855 pregnancy-associated deaths described by Mhyre and colleagues (2007), anesthesia was related to 2.3 percent. Data from the Pregnancy Mortality Surveillance Program of the Centers for Disease Control and Prevention indicate that anesthesia-related maternal mortality rates have declined significantly (Chang and colleagues, 2003). Supportive of this, Deneux-Tharaux and colleagues (2005) reported that there were no maternal deaths from anesthetic complications in Massachusetts and North Carolina during 1999 and 2000. Finally, Kuklina and co-workers (2009) reviewed obstetrical morbidity in the U.S. and reported a decrease in severe anesthesia complications—2 per 1000 in 1999 compared with 1.1 per 1000 in 2005.

Several factors have contributed to improved safety of obstetrical anesthesia. Hawkins and colleagues (1997b) and D'Angelo (2007) concluded that the most significant factor is the increased use of regional analgesia. Increased availability of in-house anesthesia coverage almost certainly is another important reason (Hawkins and associates, 1997a, b; Nagaya and associates, 2000).

GENERAL PRINCIPLES

Obstetrical Anesthesia Services

The American College of Obstetricians and Gynecologists (2002) reaffirmed its joint position with the American Society of Anesthesiologists that a woman's request for labor pain relief is sufficient medical indication for its provision. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) have specified that it is the responsibility of the obstetrician or certified nurse-midwife, in consultation with an anesthesiologist, if appropriate, to formulate a suitable plan for pain relief. Identification of any of the risk factors shown in **Table 19-1** should prompt consultation with anesthesia personnel to permit a joint management plan. This plan should include strategies to minimize the need for emergency anesthesia in women for whom such anesthesia would be especially hazardous. To help guide these decisions, the American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (2007) has recently updated its Practice Guidelines.

Goals for optimizing obstetrical anesthesia services have been jointly established by the American College of Obstetricians and Gynecologists and the American Society of Anesthesiologists (2004, 2009):

TABLE 19-1. Maternal Risk Factors That Should Prompt Anesthesia Consultation

- Marked obesity
- Severe edema or anatomical abnormalities of the face, neck, or spine, including trauma or surgery
- Abnormal dentition, small mandible, or difficulty opening the mouth
- Extremely short stature, short neck, or arthritis of the neck
- Goiter
- Serious maternal medical problems, such as cardiac, pulmonary, or neurological disease
- Bleeding disorders
- Severe preeclampsia
- Previous history of anesthetic complications
- Obstetrical complications likely to lead to operative delivery—examples include placenta previa or higher-order multifetal gestation

From the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2007, with permission.

1. Availability of a licensed practitioner who is credentialed to administer an appropriate anesthetic whenever necessary and to maintain support of vital functions in an obstetrical emergency.
2. Availability of anesthesia personnel to permit the start of a cesarean delivery within 30 minutes of the decision to perform the procedure.
3. Anesthesia personnel immediately available to perform an emergency cesarean delivery during the active labor of a woman attempting vaginal birth after cesarean (see Chap. 26, p. 571).
4. Appointment of a qualified anesthesiologist to be responsible for all anesthetics administered.
5. Availability of a qualified physician with obstetrical privileges to perform operative vaginal or cesarean delivery during administration of anesthesia.
6. Availability of equipment, facilities, and support personnel equal to that provided in the surgical suite.
7. Immediate availability of personnel, other than the surgical team, to assume responsibility for resuscitation of a depressed newborn (see Chap. 28, p. 591).

To meet these goals, 24-hour in-house anesthesia coverage is usually necessary. Providing such services in smaller facilities is more challenging—a problem underscored by the fact that approximately one third of all hospitals providing obstetrical care have fewer than 500 deliveries per year (American College of Obstetricians and Gynecologists, 2009).

Bell and colleagues (2000) calculated the financial burden that may be incurred when trying to provide "24/7" obstetrical anesthesia coverage. Given the average indemnity and Medicaid reimbursement for labor epidural analgesia, they concluded that such coverage could not operate profitably at their tertiary referral institution. Compounding this burden, some third-party payers have denied reimbursement for epidural analgesia in the absence of a specific medical indication—an approach repudiated by the American College of Obstetricians and Gynecologists and the American Society of Anesthesiologists (2004).

Role of an Obstetrician

Every obstetrician should be proficient in local and pudendal analgesia that may be administered in appropriately selected circumstances. In general, however, it is preferable for an anesthesiologist or anesthetist to provide pain relief so that the obstetrician can focus attention on the laboring woman and her fetus. **General anesthesia should be administered only by those with special training.**

Principles of Pain Relief

In a scholarly review, Lowe (2002) emphasized that the experience of labor pain is a highly individual reflection of variable stimuli that are uniquely received and interpreted by each woman. These stimuli are modified by emotional, motivational, cognitive, social, and cultural circumstances. The complexity and individuality of the experience suggest that a woman and her caregivers may have a limited ability to anticipate her pain experience prior to labor. Thus, choice among a variety of methods of pain relief is desirable.

NONPHARMACOLOGICAL METHODS OF PAIN CONTROL

Fear and the unknown potentiate pain. A woman who is free from fear, and who has confidence in the obstetrical staff that cares for her, usually requires smaller amounts of analgesia. Read (1944) emphasized that the intensity of pain during labor is related in large measure to emotional tension. He urged that women be well informed about the physiology of parturition and the various hospital procedures they may experience during labor and delivery. Lamaze (1970) subsequently described his psychoprophylactic method, which emphasized childbirth as a natural physiological process. Pain often can be lessened by teaching pregnant women relaxed breathing and their labor partners psychological support techniques. These concepts have considerably reduced the use of potent analgesic, sedative, and amnestic drugs during labor and delivery.

When motivated women have been prepared for childbirth, pain and anxiety during labor have been found to be diminished significantly, and labors are even shorter (Melzack, 1984; Saisto and associates, 2001). In addition, the presence of a supportive spouse or other family member, of conscientious labor attendants, and of a considerate obstetrician who instills confidence have all been found to be of considerable benefit. In one study, Kennell and associates (1991) randomly assigned 412 nulliparous women in labor either to continuous emotional support from an experienced companion or to monitoring by an inconspicuous observer who did not interact with the laboring woman. The cesarean delivery rate was significantly lower in the continuous support group compared with that of the hands-off monitored group—8 versus 13 percent—as was the frequency of epidural analgesia for vaginal delivery—8 versus 23 percent.

TABLE 19-2. Parenteral Agents for Labor Pain

Agent	Usual Dose	Frequency	Onset	Neonatal Half-Life
Meperidine	25–50 mg (IV) 50–100 mg (IM)	Q 2–4 hr Q 1–2 hr	5 min (IV) 30–45 min (IM)	13–22.4 hr 63 hr for active metabolites
Fentanyl	50–100 μg (IV)	Q 1 hr	1 min	5.3 hr
Nalbuphine	10 mg (IV or IM)	Q 3 hr	2–3 min (IV) 15 min (IM)	4.1 hr
Butorphanol	1–2 mg (IV or IM)	Q 4 hr	1–2 (IV) 10–30 min (IM)	Not known Similar to nalbuphine in adults
Morphine	2–5 mg (IV) 10 mg (IM)	Q 4 hr	5 min (IV) 30–40 min (IM)	7.1 hr

IV = intravenously; IM = intramuscularly; Q = every.

ANALGESIA AND SEDATION DURING LABOR

When uterine contractions and cervical dilatation cause discomfort, pain relief with a narcotic such as meperidine, plus one of the tranquilizer drugs such as promethazine, is usually appropriate. With a successful program of analgesia and sedation, the mother should rest quietly between contractions. In this circumstance, discomfort usually is felt at the acme of an effective uterine contraction, but the pain is generally not unbearable. Appropriate drug selection and administration of the medications shown in Table 19-2 should safely accomplish these objectives for the great majority of women in labor.

Parenteral Agents

Meperidine and Promethazine

Meperidine, 50 to 100 mg, with promethazine, 25 mg, may be administered intramuscularly at intervals of 2 to 4 hours. A more rapid effect is achieved by giving meperidine intravenously in doses of 25 to 50 mg every 1 to 2 hours. Whereas analgesia is maximal 30 to 45 minutes after an intramuscular injection, it develops almost immediately following intravenous administration. Meperidine readily crosses the placenta, and its half-life in the newborn is approximately 13 hours or longer (American College of Obstetricians and Gynecologists, 2002). Its depressant effect in the fetus follows closely behind the peak maternal analgesic effect.

According to Bricker and Lavender (2002), meperidine is the most common opioid used worldwide for pain relief from labor. Tsui and associates (2004) found meperidine to be superior to placebo for pain relief in the first stage of labor. In a randomized investigation of epidural analgesia conducted at Parkland Hospital, patient-controlled intravenous analgesia with meperidine was found to be an inexpensive and reasonably effective method for labor analgesia (Sharma and colleagues, 1997). Women randomized to self-administered analgesia were given 50-mg meperidine with 25-mg promethazine intravenously as an initial bolus. Thereafter, an infusion pump was set to deliver 15 mg of meperidine every 10 minutes as needed until delivery. Neonatal sedation, as measured by need for naloxone treatment in the delivery room, was identified in 3 percent of newborns.

Butorphanol (Stadol)

This synthetic narcotic, given in 1- to 2-mg doses, compares favorably with 40 to 60 mg of meperidine (Quilligan and colleagues, 1980). The major side effects are somnolence, dizziness, and dysphoria. Neonatal respiratory depression is reported to be less than with meperidine, but care must be taken that the two drugs are not given contiguously because butorphanol antagonizes the narcotic effects of meperidine. Angel and colleagues (1984) and Hatjis and Meis (1986) described a sinusoidal fetal heart rate pattern following butorphanol administration (see Chap. 18, p. 419).

Fentanyl

This short-acting and potent synthetic opioid may be given in doses of 50 to 100 μg intravenously every hour. Its main disadvantage is a short duration of action, which requires frequent dosing or the use of a patient-controlled intravenous pump. Moreover, Atkinson and associates (1994) reported that butorphanol provided better initial analgesia than fentanyl and was associated with fewer requests for more medication or for epidural analgesia.

Efficacy and Safety of Parenteral Agents

Parenteral sedation is not without risks. Hawkins and colleagues (1997b) reported that 4 of 129 maternal anesthetic-related deaths were from such sedation—one from aspiration, two from inadequate ventilation, and one from overdosage. As discussed, narcotics used during labor may cause newborn respiratory depression.

Narcotic Antagonists

Naloxone is a narcotic antagonist capable of reversing respiratory depression induced by opioid narcotics. It acts by displacing the narcotic from specific receptors in the central nervous system. Withdrawal symptoms may be precipitated in recipients who are physically dependent on narcotics. For this reason, naloxone is contraindicated in a newborn of a

narcotic-addicted mother (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2007). After adequate ventilation has been established, naloxone may be given to reverse respiratory depression in a newborn infant whose mother received narcotics (see Chap. 28, p. 593).

Nitrous Oxide

A self-administered mixture of 50-percent nitrous oxide (N_2O) and oxygen provides satisfactory analgesia during labor for many women (Rosen, 2002a). Some preparations are premixed in a single cylinder (*Entonox*), and in others, a blender mixes the two gases from separate tanks (*Nitronox*). The gases are connected to a breathing circuit through a valve that opens only when the patient inspires. The use of intermittent nitrous oxide for labor pain has been reviewed by Rosen (2002a) and the following technique suggested:

1. Instruct the woman to take slow deep breaths and to begin inhaling 30 seconds before the next anticipated contraction and to cease when the contraction starts to recede
2. Remove the mask between contractions and encourage her to breathe normally. No one but the patient or knowledgeable personnel should hold the mask
3. Instruct a caregiver to remain in verbal contact with the patient
4. Provide the expectation that the pain will likely not be eliminated, but that the gas should provide some relief
5. Ensure intravenous access, pulse oximetry, and adequate scavenging of exhaled gases
6. Use with additional caution after previous opioid administration because the combination can more easily render a woman unconscious and unable to protect her airway.

REGIONAL ANALGESIA

Various nerve blocks have been developed over the years to provide pain relief during labor and delivery. They are correctly referred to as *regional analgesics.*

Sensory Innervation of the Genital Tract

Uterine Innervation

Pain during the first stage of labor is generated largely from the uterus. Visceral sensory fibers from the uterus, cervix, and upper vagina traverse through the Frankenhäuser ganglion, which lies just lateral to the cervix, and enter into the pelvic plexus and then into the middle and superior internal iliac plexuses (Fig. 19-1). From there, the fibers travel in the lumbar and lower thoracic sympathetic chains to enter the spinal cord through the white rami communicantes associated with the T10 through T12 and L1 nerves. Early in labor, the pain of uterine contractions is transmitted predominantly through the T11 and T12 nerves.

The motor pathways to the uterus leave the spinal cord at the level of T7 and T8 vertebrae. Theoretically, any method of sensory block that does not also block motor pathways to the uterus can be used for analgesia during labor.

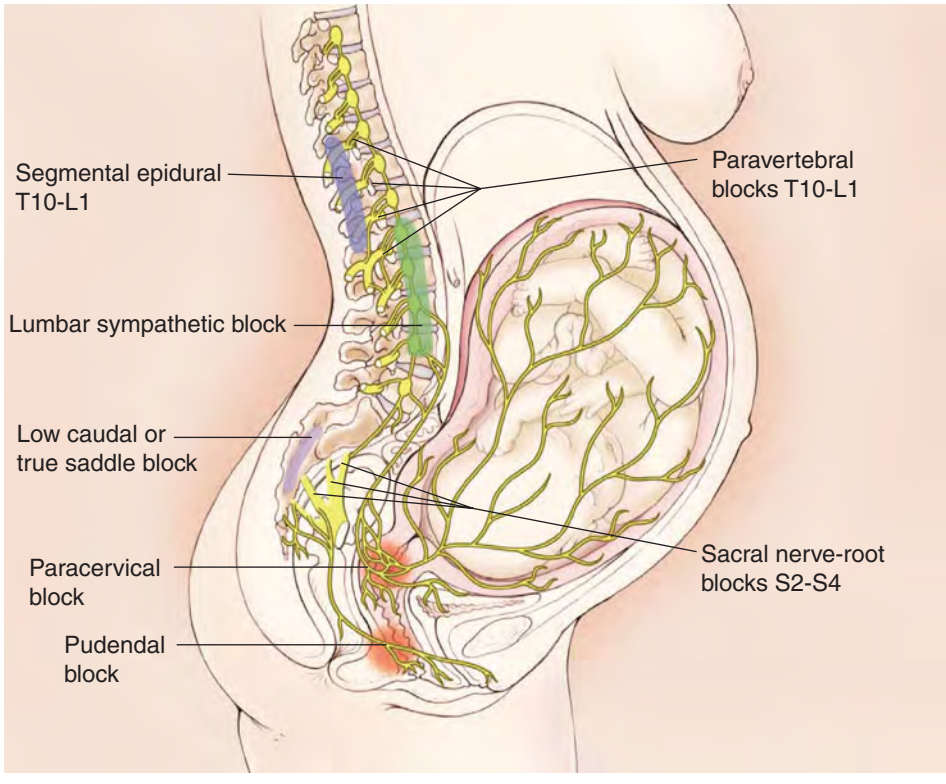

FIGURE 19-1 Pathways of labor pain. Pain stimuli from the cervix and uterus travel through the paracervical region and the pelvic and hypogastric plexus to enter the lumbar sympathetic chain. Through the white rami communicantes of the T10, T11, T12, and L1 spinal nerves, they enter the dorsal horn of the spinal cord. Blockade at different levels along this path can alleviate the visceral component of labor pain. (Adapted from Eltzschig HK, Lieberman ES, and Camann WR: Medical progress: Regional anesthesia and analgesia for labor and delivery. *N Engl J Med* 348:319, with permission. Copyright © 2003 Massachusetts Medical Society. All rights reserved.)

Lower Genital Tract Innervation

Pain with vaginal delivery arises from stimuli from the lower genital tract. These are transmitted primarily through the pudendal nerve, the peripheral branches of which provide sensory innervation to the perineum, anus, and the more medial and inferior parts of the vulva and clitoris. The pudendal nerve passes beneath the posterior surface of the sacrospinous ligament just as the ligament attaches to the ischial spine. As discussed in Chapter 2 (p. 19), sensory nerve fibers of the pudendal nerve are derived from ventral branches of the S2 through S4 nerves.

Anesthetic Agents

Some of the more commonly used local anesthetics, along with their usual concentrations, doses, and durations of action, are summarized in Table 19-3. The dose of

TABLE 19-3. Some Local Anesthetic Agents Used in Obstetrics

Plain Solutions

Anesthetic Agent	Usual Concentration (percent)	Usual Volume (mL)	Usual Dose (mg)	Onset	Average Duration (min)	Clinical Use
Amino-esters						
2-Chloroprocaine	1–2	20–30	400–600	Rapid	15–30	Local or pudendal block
	2–3	15–25	300–750		30–60	Epidural (not subarachnoid) for cesarean delivery
Tetracaine	0.2	—	4	Slow	75–150	Low spinal block/6% glucose[a]
	0.5	—	7–10		75–150	Spinal for cesarean delivery/5% glucose[a]
Amino-amides						
Lidocaine	1	20–30	200–300	Rapid	30–60	Local or pudendal block
	2	15–30	300–450		60–90	Epidural for cesarean delivery
	5	1–1.5	50–75		45–60	Spinal for cesarean or puerperal tubal ligation/7.5% glucose[a]
	5	0.5–1	25–50		30–60	Spinal for vaginal delivery/7.5% glucose[a]
Bupivacaine	0.5	15–20	50–100	Slow	90–150	Epidural for cesarean delivery
	0.25	8–10	20–25		60–90	Epidural for labor
	0.75	1–1.5	7.5–11		60–120	Spinal for cesarean delivery/8.25% glucose[a]
Ropivacaine	0.5	15–20	75–100	Slow	90–150	Epidural for cesarean delivery
	0.25	8–10	20–25		60–90	Epidural for labor

[a]Addition of glucose to local anesthetics creates a hyperbaric solution, which is heavier and denser than cerebrospinal fluid. (Courtesy of Dr. Shiv Sharma and Dr. Donald Wallace.)

each agent varies widely and is dependent on the particular nerve block and physical status of the woman. The onset, duration, and quality of analgesia can be enhanced by increasing the dose. This can be done safely only by incrementally administering small-volume boluses of the agent and by carefully monitoring early warning signs of toxicity. Administration of these agents must be followed by appropriate monitoring for adverse reactions. Equipment and personnel to manage these reactions must be immediately available.

Most often, serious toxicity follows inadvertent intravenous injection. For this reason, when epidural analgesia is initiated, dilute epinephrine is sometimes added and given as a test dose. A sudden significant rise in the maternal heart rate or blood pressure immediately after administration suggests intravenous catheter placement. Personnel using these agents must be cognizant that these agents are manufactured in more than one concentration and ampule size, which increases the potential for dosing errors. Systemic toxicity from local anesthetics typically manifests in the central nervous and cardiovascular systems.

Central Nervous System Toxicity

Early symptoms are those of *stimulation* but, as serum levels increase, *depression* follows. Symptoms may include light-headedness, dizziness, tinnitus, metallic taste, and numbness of the tongue and mouth. Patients may show bizarre behavior, slurred speech, muscle fasciculation and excitation, and ultimately, generalized convulsions, followed by loss of consciousness. The convulsions should be controlled, an airway established, and oxygen delivered. Succinylcholine abolishes the peripheral manifestations of the convulsions and allows tracheal intubation. Thiopental or diazepam act centrally to inhibit convulsions. Magnesium sulfate, administered according to the regimen for eclampsia, also controls convulsions (see Chap. 34, p. 737). Abnormal fetal heart rate patterns such as late decelerations or persistent bradycardia may develop from maternal hypoxia and lactic acidosis induced by convulsions. With arrest of convulsions, administration of oxygen, and application of other supportive measures, the fetus usually recovers more quickly in utero than following immediate cesarean delivery. Moreover, the mother is better served if delivery is forestalled until the intensity of hypoxia and metabolic acidosis has diminished.

Cardiovascular Toxicity

These manifestations generally develop later than those from cerebral toxicity, but may not develop at all because they are induced by higher serum drug levels. The notable exception is bupivacaine, which is associated with the development of neurotoxicity and cardiotoxicity at virtually identical levels (Mulroy, 2002). Because of this risk of systemic toxicity, use of 0.75-percent solution of bupivacaine for epidural injection was proscribed by the Food and Drug Administration in 1984. Similar to neurotoxicity, cardiovascular toxicity is characterized first by stimulation and then by depression. Accordingly, there is hypertension and tachycardia, which soon is followed by hypotension, cardiac arrhythmias, and impaired uteroplacental perfusion.

Hypotension is managed initially by turning the woman onto either side to avoid aortocaval compression. A crystalloid solution is infused rapidly along with intravenously administered ephedrine. Emergency cesarean delivery should be considered if maternal vital signs have not been restored within 5 minutes of cardiac arrest (see Chap. 42, p. 942). As with convulsions, however, the fetus is likely to recover more quickly in utero once maternal cardiac output is reestablished.

Pudendal Block

This block is a relatively safe and simple method of providing analgesia for spontaneous delivery. As shown in **Figure 19-2**, a tubular introducer that allows 1.0 to 1.5 cm of a 15-cm 22-gauge needle to protrude beyond its tip is used to guide the needle into position over the pudendal nerve. The end of the introducer is placed against the vaginal mucosa just beneath the tip of the ischial spine. The needle is pushed beyond the tip of the director into the mucosa and a mucosal wheal is made with 1 mL of 1-percent lidocaine solution or an equivalent dose of another local anesthetic (Table 19-3). To guard against intravascular infusion, aspiration is attempted before this and all subsequent injections. The needle is then advanced until it touches the sacrospinous ligament, which is infiltrated with 3 mL of lidocaine. The needle is advanced farther through the ligament, and as it pierces the loose areolar tissue behind the ligament, the resistance of the plunger decreases. Another 3 mL of solution is injected into this region. Next, the needle is withdrawn into the introducer, which is moved to just above the ischial spine. The needle is inserted through the mucosa and 3 more mL is deposited. The procedure is then repeated on the other side.

Within 3 to 4 minutes of injection, the successful pudendal block will allow pinching of the lower vagina and posterior vulva bilaterally without pain. If delivery occurs before the pudendal block becomes effective and an episiotomy is indicated, then the fourchette, perineum, and adjacent vagina can be infiltrated with 5 to 10 mL of 1-percent lidocaine solution directly at the site where the episiotomy is to be made. By the time of the repair, the pudendal block usually has become effective.

Pudendal block usually does not provide adequate analgesia when delivery requires extensive obstetrical manipulation. Moreover, such analgesia is usually inadequate for women in whom complete visualization of the cervix and upper vagina or manual exploration of the uterine cavity is indicated.

Complications

As previously described, intravascular injection of a local anesthetic agent may cause serious systemic toxicity. Hematoma formation from perforation of a blood vessel is most likely when there is a coagulopathy (Lee and colleagues, 2004). Rarely, severe infection may originate at the injection site. The infection may spread posterior to the hip joint, into the gluteal musculature, or into the retropsoas space (Svancarek and associates, 1977).

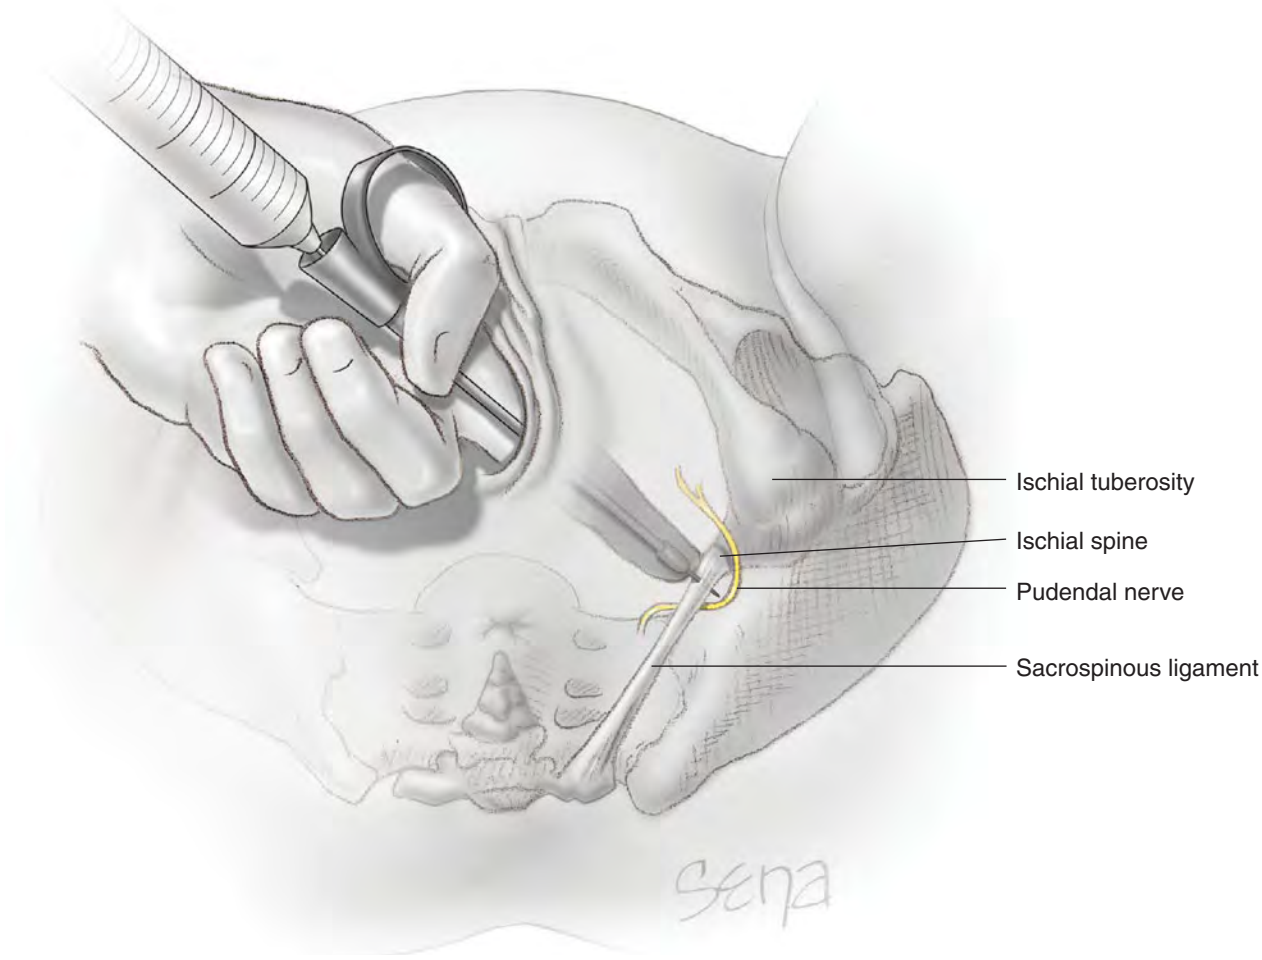

FIGURE 19-2 Local infiltration of the pudendal nerve. Transvaginal technique showing the needle extended beyond the needle guard and passing through the sacrospinous ligament to reach the pudendal nerve.

Paracervical Block

This block usually provides satisfactory pain relief during the first stage of labor. We do not use it routinely in our institutions. Because the pudendal nerves are not blocked, however, additional analgesia is required for delivery. For paracervical blockade, usually lidocaine or chloroprocaine, 5 to 10 mL of a 1-percent solution, is injected into the cervix laterally at 3 and 9 o'clock. Bupivacaine is contraindicated because of an increased risk of cardiotoxicity (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2007; Rosen, 2002b). Because these anesthetics are relatively short acting, paracervical block may have to be repeated during labor.

Complications

Fetal bradycardia is a worrisome complication that occurs in approximately 15 percent of paracervical blocks (Rosen, 2002b). Bradycardia usually develops within 10 minutes and may last up to 30 minutes. Doppler studies have shown an increase in the pulsatility index of the uterine arteries following paracervical blockade (see Chap. 16, p. 364). These observations support the hypothesis of drug-induced arterial vasospasm as a cause of fetal bradycardia (Manninen and co-workers, 2000). For these reasons, paracervical block should not be used in situations of potential fetal compromise.

Spinal (Subarachnoid) Block

Introduction of a local anesthetic into the subarachnoid space to effect analgesia has long been used for delivery. Advantages include a short procedure time, rapid onset of blockade, and high success rate. Because of the smaller subarachnoid space during pregnancy, likely the consequence of engorgement of the internal vertebral venous plexus, the same amount of anesthetic agent in the same volume of solution produces a much higher blockade in parturients than in nonpregnant women.

Vaginal Delivery

Low spinal block can be used for forceps or vacuum delivery. The level of analgesia should extend to the T10 dermatome, which corresponds to the level of the umbilicus. Blockade to this level provides excellent relief from the pain of uterine contractions (see Fig. 19-1).

Several local anesthetic agents have been used for spinal analgesia. Addition of glucose to any of these agents creates a hyperbaric solution, which is heavier and denser than cerebrospinal

fluid. A sitting position causes a hyperbaric solution to settle caudally, whereas a lateral position will have a greater effect on the dependent side. Lidocaine given in a hyperbaric solution produces excellent analgesia and has the advantage of a rapid onset and relatively short duration. Bupivacaine in an 8.25-percent dextrose solution provides satisfactory anesthesia to the lower vagina and the perineum for more than 1 hour. Neither is administered until the cervix is fully dilated and all other criteria for safe forceps delivery have been fulfilled (see Chap. 23, p. 513). Preanalgesic intravenous hydration with 1 L of crystalloid solution will prevent or minimize hypotension in many cases.

Cesarean Delivery

A level of sensory blockade extending to the T4 dermatome is desired for cesarean delivery (see **Fig. 19-3**). Depending on maternal size, 10 to 12 mg of bupivacaine in a hyperbaric solution or 50 to 75 mg of lidocaine hyperbaric solution are administered. The addition of 20 to 25 mg of fentanyl increases the rapidity of blockade onset and reduces shivering. The addition of 0.2 mg of morphine improves pain control during delivery and postoperatively.

Complications of Regional Analgesia

Shown in **Table 19-4** are some of the more common complications associated with regional analgesia. The estimated incidences were derived from 19 studies published between 1987 and 2000, as well as data from the Maternal-Fetal Medicine Units (MFMU) Network, which included more than 37,000 women undergoing cesarean delivery (Bloom and colleagues, 2005). Importantly, obese women have significantly impaired ventilation and thus close clinical monitoring is imperative (von Ungern-Sternberg and associates, 2004).

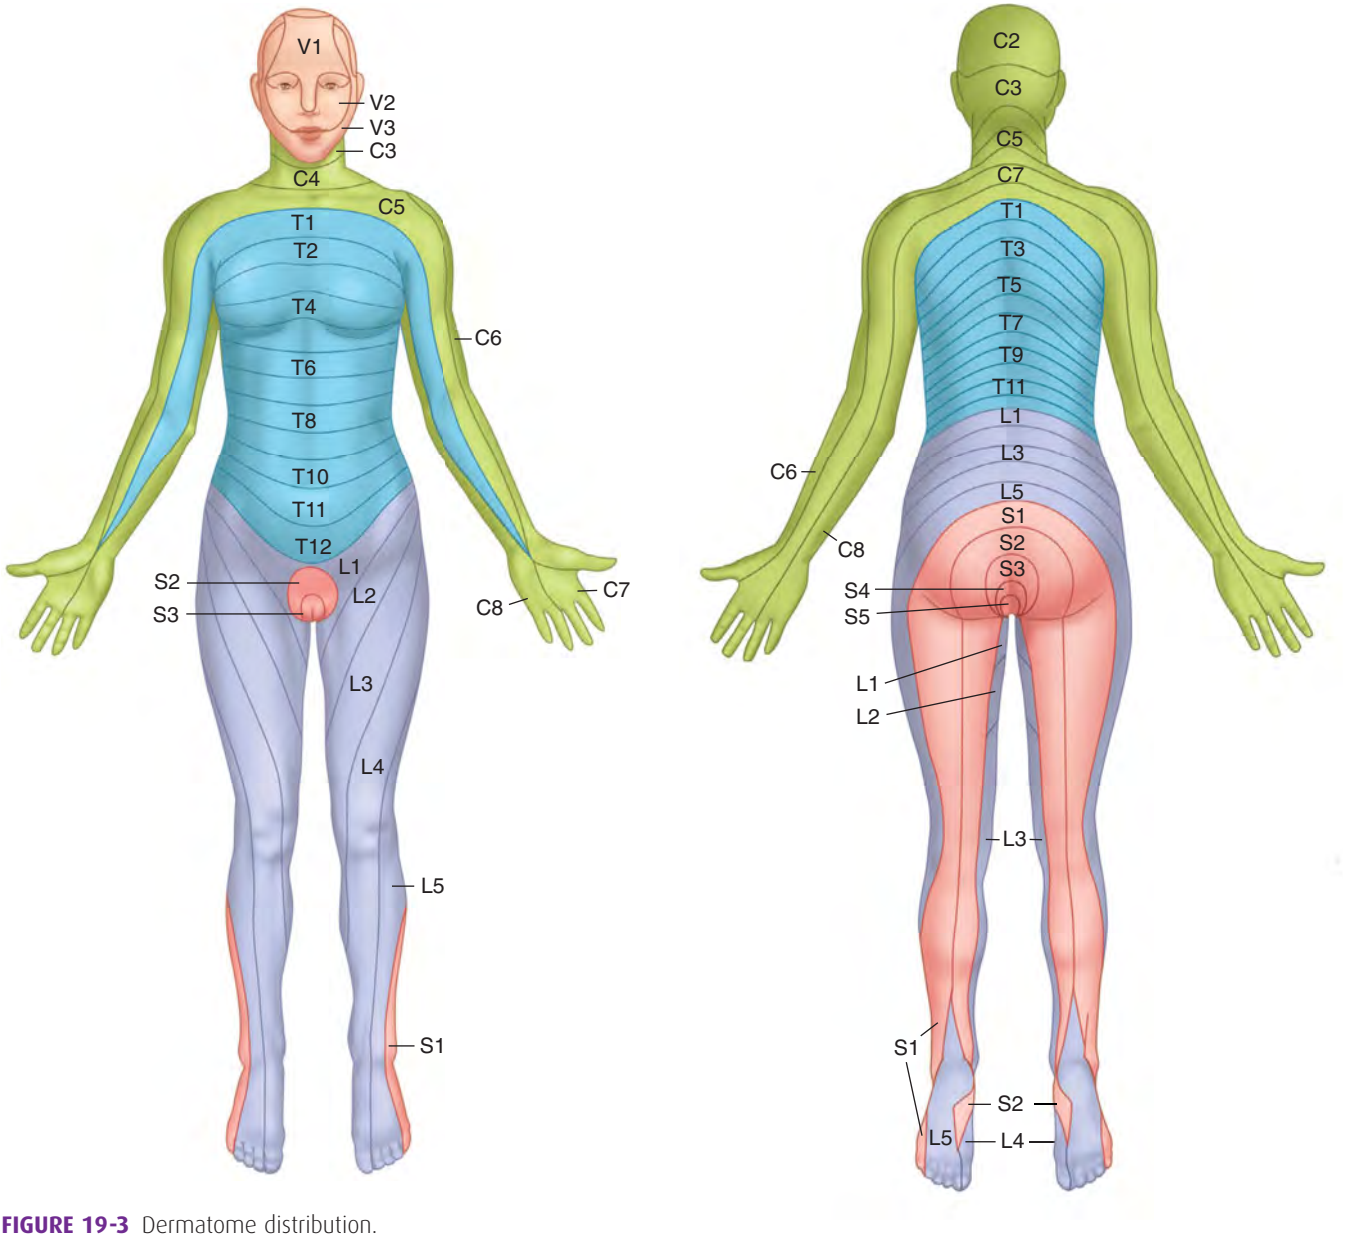

FIGURE 19-3 Dermatome distribution.

Data from the American College of Obstetricians and Gynecologists (2002) and Bloom and colleagues (2005).

Hypotension

This common complication may develop soon after injection of the local anesthetic agent. It is the consequence of vasodilatation from sympathetic blockade and is compounded by obstructed venous return due to uterine compression of the great vessels. **In the supine position, even in the absence of maternal hypotension measured in the brachial artery, placental blood flow may still be significantly reduced.** Treatment includes uterine displacement by left lateral positioning of the patient, intravenous hydration, and intravenous bolus injections of ephedrine or phenylephrine.

Ephedrine is a sympathomimetic drug that binds to alpha- and beta-receptors but also indirectly enhances norepinephrine release. It raises blood pressure by increasing heart rate and cardiac output and by variably elevating peripheral vascular resistance. In animal studies, ephedrine preserves uteroplacental blood flow during pregnancy compared with alpha$_1$-receptor agonists. For this reason, it is a preferred vasopressor for obstetric use. Phenylephrine is a pure alpha agonist and raises blood pressure solely through vasoconstriction. A meta-analysis of seven randomized trials by Lee and colleagues (2002b) suggests that the safety profiles of ephedrine and phenylephrine are comparable.

In a randomized trial at Parkland Hospital, Morgan and colleagues (2000) found that from the standpoint of umbilical artery pH at birth, epinephrine used as needed to maintain blood pressure during spinal injection was superior to prophylactic ephedrine. Mean pH in the former group was 7.26 and in the latter 7.12. Following their systematic review of 14 reports, Lee and colleagues (2002a) question whether routine prophylactic ephedrine is needed for elective cesarean delivery. Ngan Kee and associates (2004) have used prophylactic phenylephrine infusion without the fetal acidemia reported with prophylactic ephedrine use.

High Spinal Blockade

Most often, complete spinal blockade follows administration of an excessive dose of local anesthetic agent. This is certainly not always the case, because accidental total spinal block has even occurred following an epidural test dose (Palkar and associates, 1992). With complete spinal block, hypotension and apnea promptly develop and must be immediately treated to prevent cardiac arrest. In the undelivered woman: (1) the uterus is immediately displaced laterally to minimize aortocaval compression, (2) effective ventilation is established, preferably with tracheal intubation, and (3) intravenous fluids and ephedrine are given to correct hypotension.

Spinal (Postdural Puncture) Headache

Leakage of cerebrospinal fluid from the site of puncture of the meninges can lead to spinal headache. Presumably, when the woman sits or stands, the diminished volume of cerebrospinal fluid creates traction on pain-sensitive central nervous system structures. Rates of this complication can be reduced by using a small-gauge spinal needle and avoiding multiple punctures. In a prospective, randomized study of five different spinal needles, Vallejo and colleagues (2000) concluded that Sprotte and Whitacre needles had the lowest risks of postdural puncture headaches. In a recent study by Sprigge and Harper (2008), the incidence of postdural puncture headache was 1 percent in more than 5000 women undergoing spinal analgesia.

There is no good evidence that placing a woman absolutely flat on her back for several hours is effective in preventing headache. Vigorous hydration may be of value, but compelling evidence to support its use is also lacking. The administration of

caffeine, a cerebral vasoconstrictor, has been shown in randomized studies to afford temporary relief (Sechzer and Abel, 1978; Camann and colleagues, 1990).

With severe headache, an *epidural blood patch* is most effective. A few milliliters of autologous blood are obtained aseptically by venipuncture into a tube *without anticoagulant.* This blood is injected into the epidural space at the site of the dural puncture. Relief is immediate and complications uncommon. In a randomized trial of 64 women, Scavone and colleagues (2004) found that prophylactic blood patch did not decrease either the incidence of postdural puncture headache or the need for a subsequent therapeutic blood patch.

If a headache does not have the pathognomonic postural characteristics or persists despite treatment with a blood patch, other diagnoses should be considered. For example, Chisholm and Campbell (2001) described a case of superior sagittal sinus thrombosis that manifested as a postural headache. Chan and Paech (2004) have described persistent cerebrospinal fluid leak in three women. Smarkusky and colleagues (2006) described pneumocephalus, which caused immediate cephalgia. Finally, Dawley and Hendrix (2009) reported an intracranial subdural hematoma after spinal anesthesia.

Convulsions. In rare instances, postdural puncture cephalgia is associated with temporary blindness and convulsions. Shearer and colleagues (1995) described eight such cases associated with 19,000 regional analgesic procedures. It is presumed that these too are caused by cerebrospinal fluid hypotension. Immediate treatment of seizures and blood patch was effective in all cases.

Bladder Dysfunction

With spinal analgesia, bladder sensation is likely to be obtunded and bladder emptying impaired for several hours after delivery. As a consequence, bladder distension is a frequent postpartum complication, especially if appreciable volumes of intravenous fluid are given.

Oxytocics and Hypertension

Paradoxically, hypertension from ergonovine or methylergonovine injections following delivery is more common in women who have received a spinal or epidural block.

Arachnoiditis and Meningitis

Local anesthetics are no longer preserved in alcohol, formalin, or other toxic solutes, and disposable equipment is used by most. These practices, coupled with aseptic technique, have made meningitis and arachnoiditis rare but have not eliminated them (Harding, 1994; Newton, 1994; Sandkovsky, 2009, and all their associates).

Contraindications to Spinal Analgesia

Shown in Table 19-5 are the absolute contraindications to regional analgesia according to the American College of Obstetricians and Gynecologists (2002). Obstetrical complications that are associated with maternal hypovolemia and hypotension—for example, severe hemorrhage—are contraindications to the use of spinal blockade. The additive cardiovascular effects of spinal blockade in the presence of acute blood loss in nonpregnant patients were documented by Kennedy and co-workers (1968).

TABLE 19-5. Absolute Contraindications to Regional Analgesia

- Refractory maternal hypotension
- Maternal coagulopathy
- Maternal use of once-daily dose of low-molecular-weight heparin within 12 hours
- Untreated maternal bacteremia
- Skin infection over site of needle placement
- Increased intracranial pressure caused by a mass lesion

Reprinted, with permission, from American College of Obstetricians and Gynecologists. Obstetric analgesia and anesthesia. ACOG Practice Bulletin 36. Washington, DC: ACOG; 2002.

Disorders of coagulation and defective hemostasis also preclude the use of spinal analgesia (see Chap. 47, p. 1022). Although there are no randomized studies to guide the management of anticoagulation at the time of delivery, consensus opinion suggests that women given subcutaneous unfractionated heparin or low-molecular-weight heparin should be instructed to stop therapy when labor begins (Krivak and Zorn, 2007). Subarachnoid puncture is also contraindicated if there is cellulitis at the site of needle entry. Neurological disorders are considered by many to be a contraindication, if for no other reason than that exacerbation of the neurological disease might be attributed without cause to the anesthetic agent. Other maternal conditions, such as significant aortic stenosis or pulmonary hypertension, are also relative contraindications to the use of spinal analgesia (see Chap. 44, p. 958).

Preeclampsia

As with significant hemorrhage, severe preeclampsia is another complication in which markedly decreased blood pressure can be predicted when spinal analgesia is used. Gambling and Writer (1999) concluded that with severe preeclampsia, epidural analgesia is preferable to spinal blockade and especially preferable to a general anesthetic. Dyer and associates (2007), however, also concluded that single-dose spinal analgesia for cesarean delivery is safe.

As subsequently discussed, hypotension is also a risk with epidural analgesia and severe preeclampsia. Wallace and colleagues (1995) randomly assigned 80 women with severe preeclampsia undergoing cesarean delivery to receive general anesthesia or either epidural or combined spinal-epidural analgesia. There were no differences in maternal or neonatal outcomes. However, 30 percent of women given epidural analgesia and 22 percent of those given spinal-epidural blockade developed hypotension—the average reduction in mean arterial pressure was between 15 and 25 percent. In another randomized study of 100 women with severe preeclampsia, Visalyaputra and co-workers (2005) reported similar maternal and neonatal

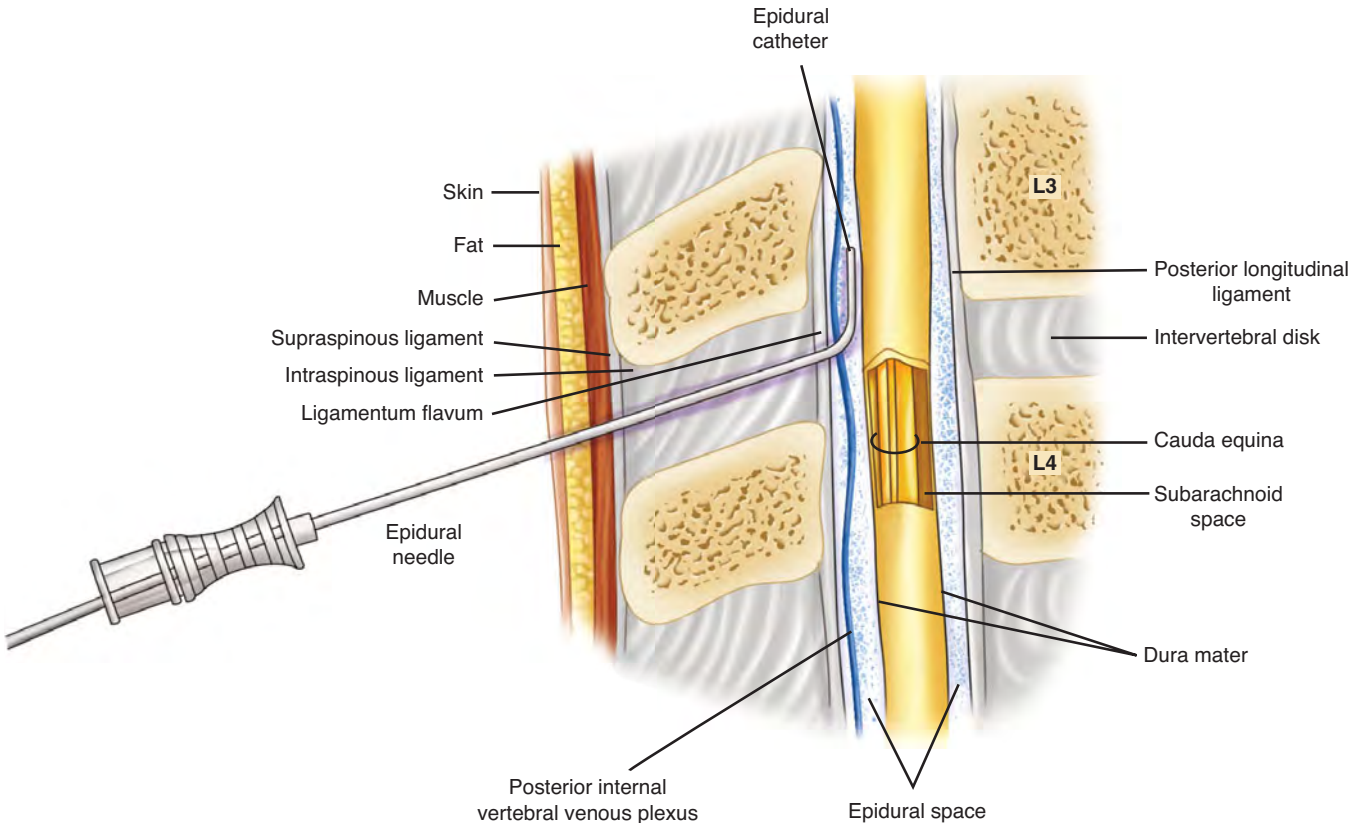

FIGURE 19-4 Introduction of a catheter into the epidural space through a Tuohy needle.

outcomes with spinal versus epidural analgesia given for cesarean delivery.

Epidural Analgesia

Relief of labor and childbirth pain, including cesarean delivery, can be accomplished by injection of a local anesthetic agent into the epidural or peridural space (Fig. 19-4). This potential space contains areolar tissue, fat, lymphatics, and the internal venous plexus. This plexus becomes engorged during pregnancy such that the volume of the epidural space is appreciably reduced. Entry for obstetrical analgesia is usually through a lumbar intervertebral space. Although only one injection may be given, usually an indwelling catheter is placed for repeat injections or continuous infusion using a volumetric pump.

Continuous Lumbar Epidural Block

Complete analgesia for the pain of labor and vaginal delivery necessitates a block from the T10 to the S5 dermatomes (Figs. 19-1 and 19-3). For cesarean delivery, a block extending from the T4 to the S1 dermatomes is desired. The spread of the anesthetic depends upon the location of the catheter tip; the dose, concentration, and volume of anesthetic agent used (see Table 19-3); and whether the mother is head-down, horizontal, or head-up (Setayesh and colleagues, 2001). Individual variations in anatomy or presence of synechiae may preclude a completely satisfactory block. Finally, the catheter tip may migrate from its original location during the course of labor.

Technique. One example of the sequential steps and techniques for performance of epidural analgesia is detailed in Table 19-6. Before injection of the local anesthetic agent's therapeutic dose, a test dose is given. The woman is observed for features of toxicity from intravascular injection and for signs of spinal blockade from subarachnoid injection. If these are absent, only then is a full dose given. Analgesia is maintained by intermittent boluses of similar volume, or small volumes of the drug are delivered continuously by infusion pump (Halpern and Carvalho, 2009). The addition of small doses of a short-acting narcotic—fentanyl or sufentanil—has been shown to improve analgesic efficacy while avoiding motor blockade (Chestnut and colleagues, 1988). **Appropriate resuscitation equipment and drugs must be available during administration of epidural analgesia.**

Complications

Epidural analgesia usually provides unparalleled relief from the pain of labor and delivery. That said, as shown in Table 19-4, there are certain problems inherent in its use. As with spinal blockade, it is imperative that close monitoring, including the level of analgesia, be performed by trained personnel.

Total Spinal Blockade. Dural puncture with inadvertent subarachnoid injection may cause total spinal blockade. Sprigge and Harper (2008) cited an incidence of 0.91 percent recognized accidental dural punctures at the time of epidural analgesia in more than 18,000 women. Personnel and facilities must

TABLE 19-6. Technique for Labor Epidural Analgesia

1. Informed consent is obtained, and the obstetrician consulted.
2. Monitoring includes the following:
   - Blood pressure every 1 to 2 minutes for 15 minutes after giving a bolus of local anesthetic.
   - Continuous maternal heart rate monitoring during analgesia induction.
   - Continuous fetal heart rate monitoring.
   - Continual verbal communication.
3. Hydration with 500 to 1000 mL of lactated Ringer solution.
4. The woman assumes a lateral decubitus or sitting position.
5. The epidural space is identified with a loss-of-resistance technique.
6. The epidural catheter is threaded 3 to 5 cm into the epidural space.
7. A test dose of 3 mL of 1.5% lidocaine with 1:200,000 epinephrine or 3 mL of 0.25% bupivacaine with 1:200,000 epinephrine is injected after careful aspiration to avert intravascular injection and after a uterine contraction. This minimizes the chance of confusing tachycardia that results from labor pain with that of tachycardia from intravenous injection of the test dose.
8. If the test dose is negative, one or two 5-mL doses of 0.25% bupivacaine are injected to achieve a sensory T10 level.
9. After 15 to 20 minutes, the block is assessed using loss of sensation to cold or pinprick. If no block is evident, the catheter is replaced. If the block is asymmetrical, the epidural catheter is withdrawn 0.5 to 1.0 cm and an additional 3 to 5 mL of 0.25% bupivacaine is injected. If the block remains inadequate, the catheter is replaced.
10. The woman is positioned in the lateral or semilateral position to avoid aortocaval compression.
11. Subsequently, maternal blood pressure is recorded every 5 to 15 minutes. The fetal heart rate is monitored continuously.
12. The level of analgesia and intensity of motor blockade are assessed at least hourly.

This table was published in Local anesthetic techniques, by B Glosten, in *Obstetric Anesthesia: Principles and Practice*, 2nd ed., DH Chestnut (ed), p. 363, Copyright Elsevier 1999.

be immediately available to manage this complication as described on page 452.

Ineffective Analgesia. Using currently popular continuous epidural infusion regimens such as 0.125-percent bupivacaine with 2-mg/mL fentanyl, 90 percent of women rate their pain relief as good to excellent (Sharma and colleagues, 1997). Alternatively, a few women find epidural analgesia to be inadequate for labor. In a study of almost 2000 parturients, Hess and associates (2001) found that approximately 12 percent complained of three or more episodes of pain or pressure. Risk factors for such breakthrough pain included nulliparity, heavier fetal weights, and epidural catheter placement at an earlier cervical dilatation. Dresner and colleagues (2006) reported that epidural analgesia was more likely to fail as body mass index increased. If the epidural analgesia is allowed to dissipate before another injection of anesthetic drug, subsequent pain relief may be delayed, incomplete, or both.

In some women, epidural analgesia is not sufficient for cesarean delivery. For example, in the MFMU Network study cited earlier, 4 percent of women initially given epidural analgesia required a general anesthetic for cesarean delivery (Bloom and colleagues, 2005). Also, at times, perineal analgesia for delivery is difficult to obtain, especially with the lumbar epidural technique. When this situation is encountered, pudendal block or systemic analgesia or rarely general anesthesia may be added.

Hypotension. Sympathetic blockade from epidurally injected analgesic agents may cause hypotension and decreased cardiac output. In normal pregnant women, hypotension induced by epidural analgesia usually can be prevented by rapid infusion of 500 to 1000 mL of crystalloid solution as described for spinal analgesia. Danilenko-Dixon and associates (1996) showed that maintaining a lateral position minimized hypotension compared with the supine position. Despite these precautions, hypotension is the most common side effect and is severe enough to require treatment in a third of women (Sharma and colleagues, 1997).

Central Nervous Stimulation. Convulsions are an uncommon but serious complication, the immediate management of which was described previously. Also cited was the case described by Smarkusky and co-workers (2006) of acute onset of intrapartum headache due to a postdural pneumocephalus.

Maternal Fever. Since the observation by Fusi and associates (1989) that the mean temperature increased in laboring women given epidural analgesia, a number of randomized and retrospective cohort studies have confirmed that some women develop intrapartum fever following this procedure. Many studies are limited by inability to control for other risk factors, such as length of labor, duration of ruptured membranes, and number of vaginal examinations (Yancey and co-workers, 2001a). With this in mind, the frequency of intrapartum fever associated with epidural analgesia was found by Lieberman and O'Donoghue (2002) to be 10 to 15 percent above the baseline rate.

The two general theories concerning the etiology of maternal hyperthermia are *maternal-fetal infection* or *dysregulation of body temperature.* Dashe and co-workers (1999) studied placental histopathology in laboring women given epidural analgesia and identified intrapartum fever only when there was placental inflammation. This suggests that fever is due to infection. The other

proposed mechanisms include alteration of the hypothalamic thermoregulatory set point, impairment of peripheral thermoreceptor input to the central nervous system with selective blockage of warm stimuli, or imbalance between heat production and heat loss (Yancey and co-workers, 2001a). To support this theory, Goetzl and colleagues (2007) reported that hyperthermia is seen in a minority of women and that it develops soon after epidural injection. Whatever the mechanism, women with persistent fever are usually treated with antimicrobials for presumed chorioamnionitis.

Back Pain. An association between epidural analgesia and back pain has been reported by some, but not all (Breen, 1994; Howell, 2001; MacArthur, 1997, and all their colleagues). In a prospective cohort study, Butler and Fuller (1998) reported that back pain after delivery was common with epidural analgesia, however, persistent pain was uncommon. Based on their systematic review, Lieberman and O'Donoghue (2002) concluded that available data do not support an association between epidural analgesia and development of de novo, long-term backache.

Miscellaneous Complications. A spinal or epidural hematoma rarely complicates placement of an epidural catheter (Grant, 2007). Epidural abscesses are equally rare (Darouiche, 2006). Uncommonly, the plastic epidural catheter is sheared off (Noblett and co-workers, 2007).

Effect on Labor

Most studies, including the combined five randomized trials from Parkland Hospital shown in Table 19-7, report that epidural analgesia prolongs labor and increases the use of oxytocin stimulation. Alexander and associates (2002) examined the effects of epidural analgesia on the Friedman (1955) labor curve described in Chapter 17 (p. 389). There were 459 nulliparas randomly assigned to patient-controlled epidural analgesia or patient-controlled intravenous meperidine. Compared with Friedman's original criteria, epidural analgesia prolonged the active phase of labor by 1 hour. As shown in Table 19-7, epidural analgesia also increases the need for operative vaginal instrumented delivery because of prolonged second-stage labor, but importantly, without adverse neonatal effects (Chestnut, 1999; Thorp and Breedlove, 1996). A more contemporaneous concern is perineal trauma associated with instrumented delivery. This relationship is discussed in detail in Chapter 17 (p. 401) and Chapter 23 (p. 519).

Fetal Heart Rate

Hill and colleagues (2003) examined the effects of epidural analgesia with 0.25-percent bupivacaine on fetal heart rate patterns. Compared with intravenous meperidine, no deleterious effects were identified. In fact, reduced beat-to-beat variability and fewer accelerations were more common in fetuses whose mothers received meperidine (see Chap. 18, p. 417). Based on their systematic review of eight studies, Reynolds and co-workers (2002) reported that epidural analgesia was associated with improved neonatal acid-base status compared with meperidine.

Cesarean Delivery

A more contentious issue in the past was whether epidural analgesia increased the risk for cesarean delivery. Evidence that it did was from the era when dense blocks of local anesthetic agents were used that impaired motor function and therefore likely contributed to increased rates of cesarean delivery. As techniques were refined, many investigators were of the opinion that epidural administration of *dilute* anesthetic solutions did not increase cesarean delivery rates (Chestnut, 1997; Thompson and colleagues, 1998). Several studies conducted at Parkland Hospital were designed to answer this and related questions. From 1995 to 2002, a total of 2703 nulliparous women at term and in spontaneous labor were enrolled in five trials to evaluate epidural analgesia techniques compared with methods for administration of intravenous meperidine. The results from these are summarized in Figure 19-5 and show that epidural analgesia does not significantly increase cesarean delivery rates.

Yancey and co-workers (1999) described the effects of an on-demand labor epidural analgesia service at Tripler Army Hospital in Hawaii. This followed a policy change in military medical centers. As a result, the incidence of labor epidural analgesia

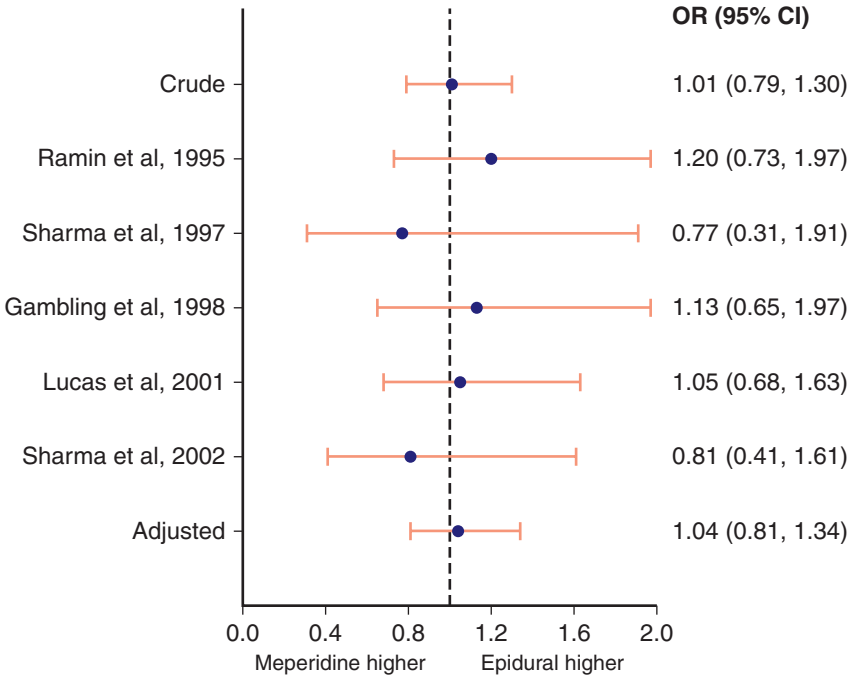

FIGURE 19-5 Results of five studies comparing the incidence of cesarean delivery in women given either epidural analgesia or intravenous meperidine. The individual odds ratios (ORs) with 95-percent confidence intervals (CIs) for each randomized study, as well as overall crude and adjusted ORs with 95-percent CIs, are shown. An OR of less than 1.0 favored epidural over meperidine analgesia. (From Sharma and associates, 2004, with permission.)

increased from 1 percent before the policy to 60 percent within 2 years. The primary cesarean delivery rate was 13.4 percent before and 13.2 percent after this dramatic change. In a follow-up study, Yancey and co-workers (2001b) reported that fetal malpresentations at vaginal delivery were not more common after epidural usage increased. The only significant difference that they found was an increased duration of second-stage labor of approximately 25 minutes (Zhang and co-workers, 2001).

Based on these randomized studies and a meta-analysis of 14 such trials, Sharma and Leveno (2003) and Leighton and Halpern (2002) concluded that epidural analgesia is not associated with an increased rate of cesarean deliveries.

Timing of Epidural Placement

In several retrospective studies, epidural placement in early labor was linked to an increased risk of cesarean delivery (Lieberman, 1996; Rogers, 1999; Seyb, 1999, and all their co-workers). These observations prompted at least five randomized trials, which showed that timing of epidural placement has no effect on the risk of cesarean birth, forceps delivery, or fetal malposition (Chestnut, 1994a, b; Luxman, 1998; Ohel, 2006; Wong, 2005, 2009, and all their associates). Thus, withholding epidural placement until some arbitrary cervical dilation has been reached is unsupportable and serves only to deny women maximal labor pain relief.

Safety

The relative safety of epidural analgesia is attested to by the extraordinary experiences reported by Crawford (1985) from the Birmingham Maternity Hospital in England. From 1968 through 1985, more than 26,000 women were given epidural analgesia for labor, and there were no maternal deaths. The nine potentially life-threatening complications followed either inadvertent intravenous or intrathecal injection of lidocaine, bupivacaine, or both. Similarly, according to the Confidential Enquiries into Maternal Deaths in the United Kingdom between 2003 and 2005, there were only a few anesthesia-related deaths associated with epidural use (Lewis, 2007).

There were no anesthesia-related maternal deaths among nearly 20,000 women who received epidural analgesia in the MFMU Network study cited earlier (Bloom and colleagues, 2005). And finally, Ruppen and associates (2006) reviewed data from 27 studies involving 1.4 million pregnant women who received epidural analgesia. They calculated risks of 1:145,000 for deep epidural infection, 1:168,000 for epidural hematoma, and 1:240,000 for persistent neurological injury.

Contraindications

As with spinal analgesia, contraindications to epidural analgesia include actual or anticipated serious maternal hemorrhage, infection at or near the sites for puncture, and suspicion of neurological disease (see Table 19-5).

Thrombocytopenia. Although low platelet counts are intuitively worrisome, the level at which epidural bleeding *might* develop is unknown according to the American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (2007). Epidural hematomas are extremely rare, and incidence of nerve damage from a hematoma is estimated to be 1 in 150,000 (Grant, 2007). The American College of Obstetricians and Gynecologists (2002) has concluded that women with a platelet count of 50,000 to 100,000/μL may be candidates for regional analgesia.

Anticoagulation. Women receiving anticoagulation therapy who are given regional analgesia are at increased risk for spinal cord hematoma and compression (see Chap. 47, p. 1022). The American College of Obstetricians and Gynecologists (2002) has concluded the following:

1. Women receiving unfractionated heparin therapy should be able to receive regional analgesia if they have a normal activated partial thromboplastin time (aPTT)
2. Women receiving prophylactic doses of unfractionated heparin or low-dose aspirin are not at increased risk and can be offered regional analgesia
3. For women receiving once-daily low-dose low-molecular-weight heparin, regional analgesia should not be placed until 12 hours after the last injection

4. Low-molecular-weight heparin should be withheld for at least 2 hours after the removal of an epidural catheter
5. The safety of regional analgesia in women receiving twice-daily low-molecular-weight heparin has not been studied sufficiently. It is not known whether delaying regional analgesia for 24 hours after the last injection is adequate.

Severe Preeclampsia-Eclampsia. Potential concerns with epidural analgesia in those with severe preeclampsia include hypotension as well as hypertension from pressor agents given to correct hypotension. Additionally, there is the potential for pulmonary edema following infusion of large volumes of crystalloid. These are outweighed by disadvantages of general anesthesia. Tracheal intubation may be difficult because of upper airway edema. Moreover, general anesthesia can lead to severe, sudden hypertension that can cause pulmonary or cerebral edema or intracranial hemorrhage.

With improved techniques for infusion of dilute local anesthetics into the epidural space, most obstetricians and obstetrical anesthesiologists have come to favor epidural blockade for labor and delivery in women with severe preeclampsia (Cheek and Samuels, 1991; Gambling and Writer, 1999; Gutsche, 1986). There seems to be no argument that epidural analgesia for women with severe preeclampsia-eclampsia can be safely used when specially trained anesthesiologists and obstetricians are responsible for the woman and her fetus (American College of Obstetricians and Gynecologists, 2002; Cunningham and Leveno, 1995). In a study from Parkland Hospital, Lucas and colleagues (2001) randomly assigned 738 women with hypertension to epidural analgesia or patient-controlled intravenous analgesia during labor. A standardized protocol for prehydration, incremental epidural administration, and ephedrine use was employed. They concluded that labor epidural analgesia was safe in women with hypertensive disorders. In a similar study from the University of Alabama at Birmingham, Head and colleagues (2002) randomly assigned 116 women with severe preeclampsia to receive either intrapartum epidural or patient-controlled intravenous opioid analgesia. Epidural analgesia provided superior pain relief without a significant increase in maternal or neonatal complications.

Intravenous Fluid Preload. Women with severe preeclampsia have remarkably diminished intravascular volume compared with normal pregnancy (Zeeman and colleagues, 2009). Conversely, total body water is increased because of the capillary leak caused by endothelial cell activation (see Chap. 34, p. 712). This imbalance is manifested as pathological peripheral edema, proteinuria, ascites, and total lung water. For all of these reasons, aggressive volume replacement increases the risk for pulmonary edema, especially in the first 72 hours postpartum (Clark and colleagues, 1985; Cotton and associates, 1986). In one study, Hogg and associates (1999) reported that 3.5 percent of women with severe preeclampsia developed pulmonary edema when preloaded without a protocol limitation to volume. Importantly, this risk can be reduced or obviated with judicious prehydration—usually with 500 to 1000 mL of crystalloid solution. Specifically, in the study by Lucas and colleagues (2001) cited earlier, there were no instances of pulmonary edema among the women in whom crystalloid preload was limited to 500 mL. Moreover, vasodilation produced by epidural blockade is less abrupt if the analgesia level is achieved slowly with dilute solutions of local anesthetic agents. This allows maintenance of blood pressure while simultaneously avoiding infusion of large volumes of crystalloid.

With vigorous intravenous crystalloid therapy, there is also concern about development of cerebral edema (see Chap. 34, p. 724). Moreover, Heller and co-workers (1983) demonstrated that most cases of *pharyngolaryngeal edema* were related to aggressive volume therapy.

Epidural Opiate Analgesia

Injection of opiates into the epidural space to relieve pain from labor has become popular. Their mechanism of action derives from interaction with specific receptors in the dorsal horn and dorsal roots. Opiates alone usually will not provide adequate analgesia, and they most often are given with a local anesthetic agent such as bupivacaine. The major advantages of using such a combination are the rapid onset of pain relief, a decrease in shivering, and less dense motor blockade (Meister and colleagues, 2000). Side effects are common and include pruritus and urinary retention. Immediate or delayed respiratory depression is worrisome (Ackerman and colleagues, 1992). Naloxone, given intravenously, will abolish these symptoms without affecting the analgesic action.

COMBINED SPINAL–EPIDURAL TECHNIQUES

The combination of spinal and epidural techniques has increased in popularity and may provide rapid and effective analgesia for labor as well as for cesarean delivery. An introducer needle is first placed in the epidural space. A small-gauge spinal needle is then introduced through the epidural needle into the subarachnoid space—this is called the *needle-through-needle technique*. A single bolus of an opioid, sometimes in combination with a local anesthetic, is injected into the subarachnoid space. The spinal needle is withdrawn, and an epidural catheter is then placed through the introducer needle. The use of a subarachnoid opioid bolus results in the rapid onset of profound pain relief with virtually no motor blockade. The epidural catheter permits repeated dosing of analgesia. However, in a randomized comparison, Abrão and associates (2009) reported that combined spinal-epidural analgesia was associated with a greater incidence of fetal heart rate abnormalities related to uterine hypertonus than was epidural analgesia alone.

LOCAL INFILTRATION FOR CESAREAN DELIVERY

A local block is occasionally useful to augment an inadequate or "patchy" regional block that was given in an emergency. On more rare occasions, local infiltration may be used to perform an emergency cesarean delivery to save the life of a fetus in the absence of any anesthesia support.

Technique

In one technique, the skin is infiltrated in the line of the proposed incision, and the subcutaneous, muscle, and rectus sheath layers are injected as the abdomen is opened. A dilute solution of lidocaine—30 mL of 2-percent with 1:200,000 epinephrine diluted with 60 mL of normal saline—is prepared, and a total of

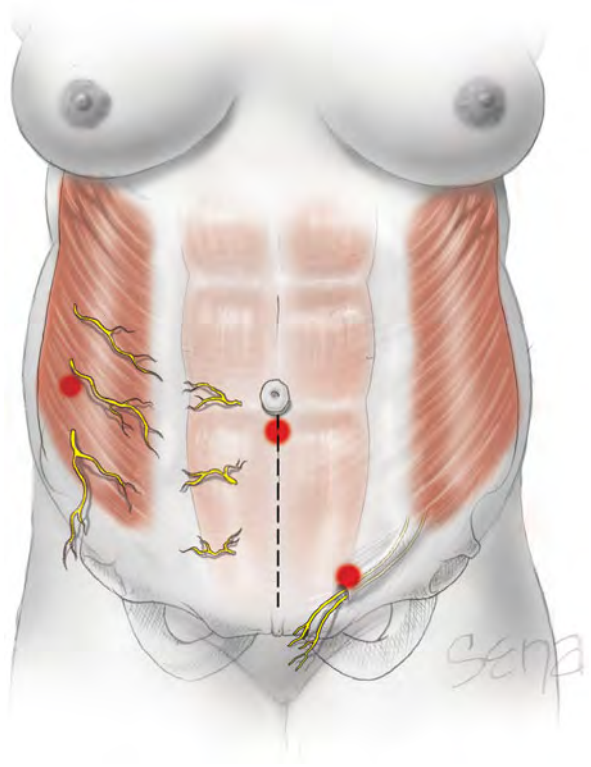

FIGURE 19-6 Local anesthetic block for cesarean delivery. The first injection site is halfway between the costal margin and iliac crest in the midaxillary line to block the 10th, 11th, and 12th intercostal nerves. A second injection at the external inguinal ring blocks branches of the genitofemoral and ilioinguinal nerves. These sites are infiltrated bilaterally. A final site is along the line of proposed skin incision.

100 to 120 mL is infiltrated. Injection of large volumes into the fatty layers, which are relatively devoid of nerve supply, is avoided to limit the total dose of local anesthetic needed.

A second technique involves a field block of the major branches supplying the abdominal wall, to include the 10th, 11th, and 12th intercostal nerves and the ilioinguinal and genitofemoral nerves (Busby, 1963). As shown in **Figure 19-6**, the former group of nerves is located at a point midway between the costal margin and iliac crest in the midaxillary line. The latter group is found at the level of the external inguinal ring. Only one skin puncture is made at each of the four sites (right and left sides). At the intercostal block site, the needle is directed medially and injection is carried down to the transversalis fascia, avoiding injection of the subcutaneous fat. Approximately 5 to 8 mL of 0.5-percent lidocaine is injected. The procedure is repeated at a 45-degree angle cephalad and caudad to this line. The other side is then injected. At the ilioinguinal and genitofemoral sites, the injection is started at a site 2 to 3 cm lateral from the pubic tubercle at a 45-degree angle. Finally, the skin overlying the planned incision is injected.

GENERAL ANESTHESIA

The increased safety of regional analgesia has increased the relative risk of general anesthesia. The case-fatality rate of general anesthesia for cesarean delivery is estimated to be approximately 32 per million live births compared with 1.9 per million for regional analgesia (Hawkins and associates, 1997b). In the Michigan Mortality Surveillance report by Mhyre and colleagues (2007), 4 of 8 anesthesia-related maternal deaths were associated with the use of general anesthesia.

One common cause of death cited for general anesthesia is failed intubation. This occurs in approximately 1 of every 250 general anesthetics administered to pregnant women—a tenfold higher rate than in nonpregnant patients (Barnardo and Jenkins, 2000). The American College of Obstetricians and Gynecologists (2002) has concluded that this relative increase in morbidity and mortality rates suggests that regional analgesia is the preferred method of pain control and should be used unless contraindicated (see Table 19-5). Indeed, in the MFMU Network study that has been cited, 93 percent of more than 37,000 cesarean deliveries were attempted with regional analgesia (Bloom and colleagues, 2005). Trained personnel and specialized equipment—including fiberoptic intubation—are mandatory for the safe use of general anesthesia.

Patient Preparation

Prior to anesthesia induction, several steps should be taken to help minimize the risk of complications for the mother and fetus. These include the use of antacids, lateral uterine displacement, and preoxygenation.

Antacids

The practice of administering antacids shortly before induction of anesthesia has probably done more to decrease mortality rates from general anesthesia than any other single practice (Gibbs and Banner, 1984). The American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (2007) recommends timely administration of a nonparticulate antacid, an H_2-receptor antagonist, or metoclopramide. For many years, we have recommended administration of 30 mL of Bicitra—sodium citrate with citric acid—within a few minutes of the anticipated time of anesthesia induction, by either general or major regional block. If more than 1 hour has passed between when a first dose was given and when anesthesia is induced, then a second dose is given.

Uterine Displacement

As discussed in Chapter 5 (p. 120), the uterus may compress the inferior vena cava and aorta when the mother is supine. With lateral uterine displacement, the duration of general anesthesia has less effect on neonatal condition than when the woman remains supine (Crawford and colleagues, 1972).

Preoxygenation

Because functional reserve lung capacity is reduced, pregnant women become hypoxemic more rapidly during periods of apnea than do nonpregnant patients. Obesity exacerbates this tendency (McClelland and associates, 2009). To minimize hypoxia between the time of muscle relaxant injection and intubation, it is important first to replace nitrogen in the lungs with oxygen. This is accomplished by administering 100-percent oxygen via face mask for 2 to 3 minutes prior to anesthesia induction. In an emergency, four vital capacity breaths of 100-percent oxygen via a tight breathing circuit will provide similar benefit (Norris and Dewan, 1985).

Induction of Anesthesia

Thiopental

This thiobarbiturate given intravenously is widely used and offers easy and rapid induction, prompt recovery, and minimal risk of vomiting. Thiopental and similar compounds are poor analgesic agents, and administration of sufficient drug given alone to maintain anesthesia may cause appreciable newborn depression.

Ketamine

This agent also may be used to render a patient unconscious. Doses of 1 mg/kg induce general anesthesia. Alternatively, given intravenously in low doses of 0.2 to 0.3 mg/kg, ketamine may be used to produce analgesia and sedation just prior to vaginal delivery. Ketamine may also prove useful in women with acute hemorrhage because, unlike thiopental, it is not associated with hypotension. Conversely, it usually causes a rise in blood pressure, and thus it generally should be avoided in women who are already hypertensive. Unpleasant delirium and hallucinations are commonly induced by this agent.

Intubation

Immediately after a patient is rendered unconscious, a muscle relaxant is given to aid intubation. *Succinylcholine,* a rapid-onset and short-acting agent, commonly is used. Cricoid pressure—the *Sellick maneuver*—is used by a trained assistant to occlude the esophagus from the onset of induction until intubation is completed. Before the operation begins, proper placement of the endotracheal tube must be confirmed.

Failed Intubation

Although uncommon, failed intubation is a major cause of anesthesia-related maternal mortality (Wallace and Sidawi, 1997). In their review of 67 maternal deaths associated with general anesthesia, Hawkins and colleagues (1997b) reported that 22 percent were secondary to induction or intubation problems. A history of previous difficulties with intubation as well as a careful assessment of anatomical features of the neck and of maxillofacial, pharyngeal, and laryngeal structures may help predict a difficult intubation. Even in cases in which the initial airway assessment was unremarkable, edema may develop intrapartum and present considerable difficulties (Farcon and associates, 1994). Morbid obesity is also a major risk factor for failed or difficult intubation. The American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (2007) stresses the importance of appropriate preoperative preparation to include the immediate availability of specialized equipment. These include a variety of different shaped laryngoscopes, laryngeal mask airways, a fiber-optic bronchoscope, and a transtracheal ventilation set, as well as liberal use of awake oral intubation techniques.

Management. An important principle is to start the operative procedure only after it has been ascertained that tracheal intubation has been successful and that adequate ventilation can be accomplished. Even with an abnormal fetal heart rate pattern, initiation of cesarean delivery will only serve to complicate matters if there is difficult or failed intubation. Frequently, the woman must be allowed to awaken and a different technique used, such as an awake intubation or regional analgesia.

Following failed intubation, the woman is ventilated by mask and cricoid pressure is applied to reduce the chance of aspiration (Cooper and colleagues, 1994). Surgery may proceed with mask ventilation, or the woman may be allowed to awaken. In those cases in which the woman has been paralyzed and in which ventilation cannot be reestablished by insertion of an oral airway, laryngeal mask airway, or use of a fiberoptic laryngoscope to intubate the trachea, a life-threatening emergency exists. To restore ventilation, percutaneous or even open cricothyrotomy is performed, and jet ventilation begun (Reisner and colleagues, 1999). Failed intubation drills have been recommended to optimize response to such an emergency (Lewis, 2007; Nair and Alderson, 2006).

Gas Anesthetics

Once the endotracheal tube is secured, a 50:50 mixture of nitrous oxide and oxygen is administered to provide analgesia. Usually, a volatile halogenated agent is added to provide amnesia and additional analgesia. The mechanisms of action of inhaled anesthetics have been reviewed by Campagna and colleagues (2003).

Volatile Anesthetics

The most commonly used volatile anesthetics in the United States include *isoflurane* and two of its derivatives, *desflurane* and *sevoflurane.* They are usually added in low concentrations to the nitrous oxide-oxygen mixture to provide amnesia. They are potent, nonexplosive agents that produce remarkable uterine relaxation when given in high concentrations. These are used when relaxation is a requisite such as for internal podalic version of the second twin (see Chap. 39, p. 883), breech decomposition (see Chap. 24, p. 535), and replacement of the acutely inverted uterus (see Chap. 35, p. 780).

Extubation

The tracheal tube may be safely removed only if the woman is conscious to a degree that enables her to follow commands and is capable of maintaining oxygen saturation with spontaneous respiration. Consideration should be given to emptying the stomach via a nasogastric tube prior to extubation. As induction has become safer, extubation may now be more perilous. Of 15 anesthesia-related deaths of pregnant women from 1985 to 2003 in Michigan, none occurred during induction, whereas five resulted from hypoventilation or airway obstruction during emergence, extubation, or recovery (Mhyre and colleagues, 2007).

Aspiration

Massive gastric acidic inhalation causing pulmonary insufficiency from aspiration pneumonitis was first described by the obstetrician Mendelson, and the syndrome bears his name (Marik, 2001). Such pneumonitis has in the past been the most common cause of anesthetic deaths in obstetrics and therefore deserves special attention. In a survey of maternal deaths between 1979 and 1990, the Centers for Disease Control and Prevention identified that inhalation of gastric contents was associated with 23 percent of the 129 anesthesia-related deaths (Hawkins and colleagues, 1997b). To mini-

mize the occurrence of this complication, antacids should be given routinely, intubation should be accompanied by cricoid pressure, and regional analgesia should be employed when possible.

Fasting

According to the American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (2007), there is insufficient data regarding fasting times for clear liquids and the risk of pulmonary aspiration during labor. Recommendations are that modest amounts of clear liquids such as water, clear tea, black coffee, carbonated beverages, and pulp-free fruit juices be allowed in uncomplicated laboring women. Obvious solid foods should be avoided. The Task Force also recommended a fasting period of 6 to 8 hours, depending on the type of food ingested, for uncomplicated parturients undergoing elective cesarean delivery or puerperal tubal ligation.

Pathophysiology

In 1952, Teabeaut demonstrated experimentally that if the pH of aspirated fluid was below 2.5, severe chemical pneumonitis developed. It was later demonstrated that the pH of gastric juice of nearly half of women tested intrapartum was below 2.5 (Taylor and Pryse-Davies, 1966). The right mainstem bronchus usually offers the simplest pathway for aspirated material to reach the lung parenchyma, and therefore the right lower lobe is most often involved. In severe cases, there is bilateral widespread involvement.

The woman who aspirates may develop evidence of respiratory distress immediately or as long as several hours after aspiration, depending in part on the material aspirated and the severity of the response. Aspiration of a large amount of solid material causes obvious signs of airway obstruction. Smaller particles without acidic liquid may lead to patchy atelectasis and later to bronchopneumonia.

When highly acidic liquid is inspired, decreased oxygen saturation along with tachypnea, bronchospasm, rhonchi, rales, atelectasis, cyanosis, tachycardia, and hypotension are likely to develop. At the sites of injury, there is pulmonary capillary leakage and exudation of protein-rich fluid containing numerous erythrocytes into the lung interstitium and alveoli. This causes decreased pulmonary compliance, shunting of blood, and severe hypoxemia. Radiographic changes may not appear immediately, and they may be variable, although the right lung most often is affected. Therefore, chest radiographs alone should not be used to exclude aspiration.

Treatment

The methods recommended for treatment of aspiration have changed appreciably in recent years, indicating that previous therapy was not very successful. Suspicion of aspiration of gastric contents demands close monitoring for evidence of pulmonary damage. Respiratory rate and oxygen saturation as measured by pulse oximetry are the most sensitive and earliest indicators of injury.

As much of the inhaled fluid as possible should be immediately wiped out of the mouth and removed from the pharynx and trachea by suction. Saline lavage may further disseminate the acid throughout the lung and is not recommended. If large particulate matter is inspired, bronchoscopy may be indicated to relieve airway obstruction. There is no convincing clinical or experimental evidence that corticosteroid therapy or prophylactic antimicrobial administration is beneficial (Marik, 2001). If clinical evidence of infection develops, however, then vigorous treatment is given. If acute respiratory distress syndrome develops, mechanical ventilation with positive end-expiratory pressure may prove lifesaving (see Chap. 42, p. 930).

SHOULDER DYSTOCIA 481
MATERNAL AND FETAL COMPLICATIONS WITH DYSTOCIA 485

In 2007, the cesarean delivery rate was 31.8 percent—the highest level ever reported for the United States (Hamilton and co-workers, 2009). According to the American College of Obstetricians and Gynecologists (2003), approximately 60 percent of primary cesarean deliveries in the United States are attributable to the diagnosis of dystocia. Roy (2003) has proposed that this high frequency results from environmental changes that are developing more rapidly than Darwinian natural selection. Humans are poorly adapted to the affluence of the modern diet, and one result is dystocia. Evidence in support of this comes from Barau and associates (2006), who analyzed prepregnancy body mass index (BMI) and the risk of cesarean delivery. They studied 16,592 singleton births and reported a linear association between BMI and cesarean delivery. This has been similarly shown by others (Leung, 2008; Nuthalapaty, 2004; Roman, 2008; Treacy, 2006; Wilkes, 2003, and all their colleagues). As further discussed in Chapter 43, Getahun and co-workers (2007) reported that obesity is associated with an increased cesarean delivery rate. Interestingly, these researchers found that a decrease in weight from obese to normal eliminates this risk.

OVERVIEW OF DYSTOCIA

Dystocia literally means *difficult labor* and is characterized by abnormally slow labor progress. It arises from four distinct abnormalities that may exist singly or in combination:

1. Abnormalities of the expulsive forces. Uterine contractions may be insufficiently strong or inappropriately coordinated to efface and dilate the cervix—uterine dysfunction. Also, there may be inadequate voluntary maternal muscle effort during second-stage labor.
2. Abnormalities of presentation, position, or development of the fetus.
3. Abnormalities of the maternal bony pelvis—that is, pelvic contraction.
4. Abnormalities of soft tissues of the reproductive tract that form an obstacle to fetal descent (see Chap. 40, p. 890).

More simply, these abnormalities can be mechanistically simplified into three categories that include abnormalities of: the *powers*—uterine contractility and maternal expulsive effort; the *passenger*—the fetus; and the *passage*—the pelvis. Common clinical findings in women with these labor abnormalities are summarized in **Table 20-1**.

Dystocia Definitions

Combinations of the abnormalities shown in Table 20-1 often interact to produce dysfunctional labor. Today, expressions such as *cephalopelvic disproportion* and *failure to progress* often are used to describe ineffective labors:

1. The expression *cephalopelvic disproportion* came into use prior to the 20th century to describe obstructed labor resulting from disparity between the size of the fetal head and maternal pelvis. But the term originated at a time when the main indication for cesarean delivery was overt pelvic

TABLE 20-1. Common Clinical Findings in Women with Ineffective Labor

Inadequate cervical dilation or fetal descent:
- Protracted labor—slow progress
- Arrested labor—no progress
- Inadequate expulsive effort—ineffective pushing

Fetopelvic disproportion:
- Excessive fetal size
- Inadequate pelvic capacity
- Malpresentation or position of the fetus

Ruptured membranes without labor

contracture due to rickets (Olah and Neilson, 1994). Such absolute disproportion is now rare, and most cases result from malposition of the fetal head within the pelvis (asynclitism) or from ineffective uterine contractions. True disproportion is a tenuous diagnosis because two thirds or more of women undergoing cesarean delivery for this reason subsequently deliver even larger newborns vaginally (see Chap. 26, p. 565).

2. *Failure to progress* in either spontaneous or stimulated labor has become an increasingly popular description of ineffectual labor. This term is used to include lack of progressive cervical dilatation or lack of fetal descent. Most precisely, however, the specific terms and their definitions should be used to describe abnormal labor (Table 20-2).

Overdiagnosis of Dystocia

As discussed, dystocia is the most common current indication for primary cesarean delivery. Gifford and colleagues (2000) reported that lack of progress in labor was the reason for 68 percent of unplanned cesarean deliveries for cephalic-presenting fetuses.

It is generally agreed that dystocia leading to cesarean delivery is overdiagnosed in the United States and elsewhere. The reasons for this, however, are controversial. Those implicated have included incorrect diagnosis, epidural analgesia, fear of litigation, and even clinician convenience (Lieberman and coworkers, 1996; Savage and Francome, 1994; Thorp and colleagues, 1993a).

It appears that variability of criteria for diagnosis is a major determinant of this increase. For example, Gifford and associates (2000) found that almost 25 percent of the cesarean deliveries performed annually in the United States for lack of progress were in women with cervical dilatation of only 0 to 3 cm (Fig. 20-1). This practice is contrary to recommendations of the American College of Obstetricians and Gynecologists (1995a) that the cervix be dilated to 4 cm or more before dystocia is diagnosed. Thus, the diagnosis often is made before active labor, and therefore before an adequate trial of labor. Another factor implicated is insufficient oxytocin stimulation of labor in women with slow labor (Rouse and Owen, 1999b). King (1993) found that cesarean deliveries for dystocia in private patients in the United Kingdom were related to office hours and surgery schedules whereas the timing of procedures for fetal distress were evenly distributed throughout the day.

TABLE 20-2. Abnormal Labor Patterns, Diagnostic Criteria, and Methods of Treatment

	Diagnostic Criteria			
Labor Pattern	**Nulliparas**	**Multiparas**	**Preferred Treatment**	**Exceptional Treatment**
Prolongation Disorder				
Prolonged latent phase	> 20 hr	> 14 hr	Bed rest	Oxytocin or cesarean delivery for urgent problems
Protraction Disorders				
Protracted active-phase dilatation	< 1.2 cm/hr	< 1.5 cm/hr	Expectant and support	Cesarean delivery for CPD
Protracted descent	< 1 cm/hr	< 2 cm/hr		
Arrest Disorders				
Prolonged deceleration phase	> 3 hr	> 1 hr	Evaluate for CPD: CPD: cesarean delivery No CPD: oxytocin	Rest if exhausted Cesarean delivery
Secondary arrest of dilatation	> 2 hr	> 2 hr		
Arrest of descent	> 1 hr	> 1 hr		
Failure of descent	No descent in deceleration phase or second stage			

CPD = cephalopelvic disproportion.
Modified from Cohen and Friedman (1983).

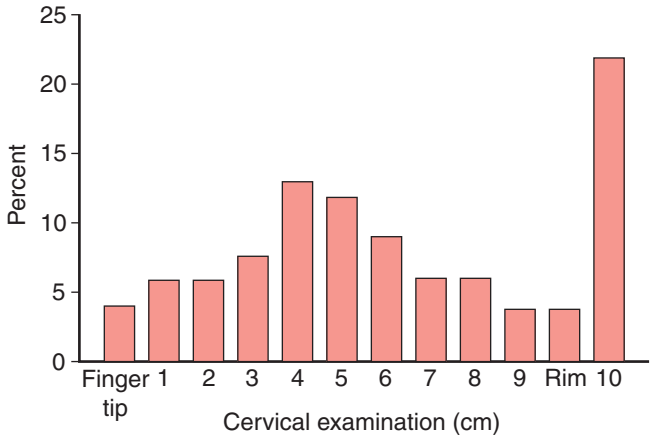

FIGURE 20-1 Distribution of cervical dilatation at the time of cesarean delivery for dystocia. (Adapted from Gifford and colleagues, 2000, with permission.)

Mechanisms of Dystocia

Dystocia described by Williams (1903) in the first edition of this text is still true today. Figure 20-2 is from that edition, and it demonstrates the mechanical process of labor and the potential obstacles. The cervix and lower uterus are shown at the end of pregnancy and at the end of labor. At the end of pregnancy, the fetal head, to traverse the birth canal, must encounter a relatively thicker lower uterine segment and undilated cervix. The uterine fundus muscle is less developed and presumably less powerful. Uterine contractions, cervical resistance, and the forward pressure exerted by the leading fetal part are the factors influencing the progress of first-stage labor (see Chap. 6, p. 141).

After complete cervical dilatation (see Fig. 20-2), however, the mechanical relationship between the fetal head size and position and the pelvic capacity, namely *fetopelvic proportion*, becomes clearer as the fetus descends. Accordingly, abnormalities in fetopelvic proportions become more apparent once the second stage is reached.

Uterine muscle malfunction can result from uterine overdistension or obstructed labor or both. Thus, ineffective labor is generally accepted as a possible warning sign of fetopelvic disproportion.

Artificial separation of labor abnormalities into pure *uterine dysfunction* and *fetopelvic disproportion* simplifies classification, but is an incomplete characterization because these two abnormalities are so closely interlinked. Indeed, according to the American College of Obstetricians and Gynecologists (1995a), the bony pelvis rarely limits vaginal delivery.

In the absence of objective means of precisely distinguishing these two causes of labor failure, clinicians must rely on a *trial of labor* to determine if labor can be successful in effecting vaginal delivery. In our opinion, defining the adequacy of a trial of labor is a priority in moderating the primary cesarean delivery rate for dystocia.

ABNORMALITIES OF THE EXPULSIVE FORCES

Cervical dilatation and propulsion and expulsion of the fetus are brought about by contractions of the uterus, reinforced during the second stage by voluntary or involuntary muscular action of the abdominal wall—"pushing." The diagnosis of uterine dysfunction in the latent phase is difficult and sometimes can be made only in retrospect (see Chap. 17, p. 389). Women who are not yet in active labor commonly are erroneously treated for uterine dysfunction.

During the past 50 to 60 years, there have been at least three significant advances in the treatment of uterine dysfunction:

1. Realization that undue prolongation of labor may contribute to maternal and perinatal morbidity and mortality rates.
2. Use of dilute intravenous infusion of oxytocin in the treatment of certain types of uterine dysfunction.
3. More frequent use of cesarean delivery rather than difficult midforceps delivery when oxytocin fails or its use is inappropriate.

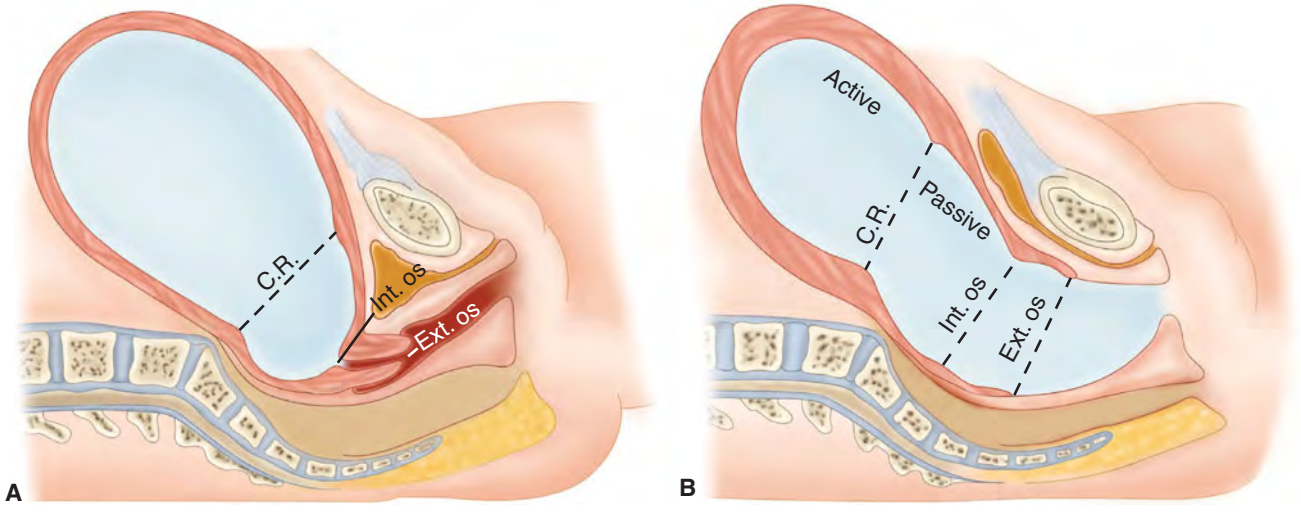

FIGURE 20-2 Diagrams of the birth canal **(A)** at the end of pregnancy and **(B)** during the second stage of labor, showing formation of the birth canal. (C.R. = contraction ring; Int. = internal; Ext = external.) (Adapted from from Williams, 1903.)

Types of Uterine Dysfunction

Reynolds and co-workers (1948) emphasized that uterine contractions of normal labor are characterized by a gradient of myometrial activity. These forces are greatest and last longest at the fundus—considered fundal dominance—and they diminish toward the cervix. Caldeyro-Barcia and colleagues (1950) from Montevideo, Uruguay, inserted small balloons into the myometrium at various levels (see Chap. 18, p. 437). They reported that in addition to a gradient of activity, there was a time differential in the onset of the contractions in the fundus, midzone, and lower uterine segments. Larks (1960) described the stimulus as starting in one cornu and then several milliseconds later in the other. The excitation waves then join and sweep over the fundus and down the uterus. The Montevideo group also ascertained that the lower limit of contraction pressure required to dilate the cervix is 15 mm Hg. This figure is in agreement with the findings of Hendricks and co-workers (1959), who reported that normal spontaneous contractions often exert pressures of approximately 60 mm Hg.

From these observations, it is possible to define two types of uterine dysfunction. In the more common *hypotonic uterine dysfunction,* there is no basal hypertonus and uterine contractions have a normal gradient pattern (synchronous), but pressure during a contraction is insufficient to dilate the cervix. In the second type, *hypertonic uterine dysfunction* or *incoordinate uterine dysfunction,* either basal tone is elevated appreciably or the pressure gradient is distorted. Gradient distortion may result from contraction of the uterine midsegment with more force than the fundus or from complete asynchronism of the impulses originating in each cornu or a combination of these two.

Active-Phase Disorders

Labor abnormalities are clinically divided into either slower-than-normal progress—*protraction disorder*—or complete cessation of progress—*arrest disorder*. A woman must be in the active phase of labor with cervical dilatation to at least 3 to 4 cm to be diagnosed with either of these. Handa and Laros (1993) diagnosed active-phase arrest, defined as no dilatation for 2 hours or more, in 5 percent of term nulliparas. This incidence has not changed since the 1950s (Friedman, 1978). Inadequate uterine contractions, defined as less than 180 Montevideo units, calculated as shown in **Figure 20-3**, were diagnosed in 80 percent of women with active-phase arrest.

Protraction disorders are less well described, and the time necessary before diagnosing slow progress is undefined. The World Health Organization (1994) has proposed a labor management *partograph* in which protraction is defined as less than 1 cm/hr cervical dilatation for a minimum of 4 hours. Criteria for the diagnosis of protraction and arrest disorders have been recommended by the American College of Obstetricians and Gynecologists (1995a). These criteria were adapted from those of Cohen and Friedman (1983), shown in Table 20-2.

Hauth and co-workers (1986, 1991) reported that when labor is effectively induced or augmented with oxytocin, 90 percent of women achieve 200 to 225 Montevideo units, and 40 percent achieve at least 300 Montevideo units. These results suggest that there are certain minimums of uterine activity that should be achieved before performing cesarean delivery for dystocia. Accordingly, the American College of Obstetricians and Gynecologists (1989) has suggested that before the diagnosis of arrest during first-stage labor is made, both of these criteria should be met:

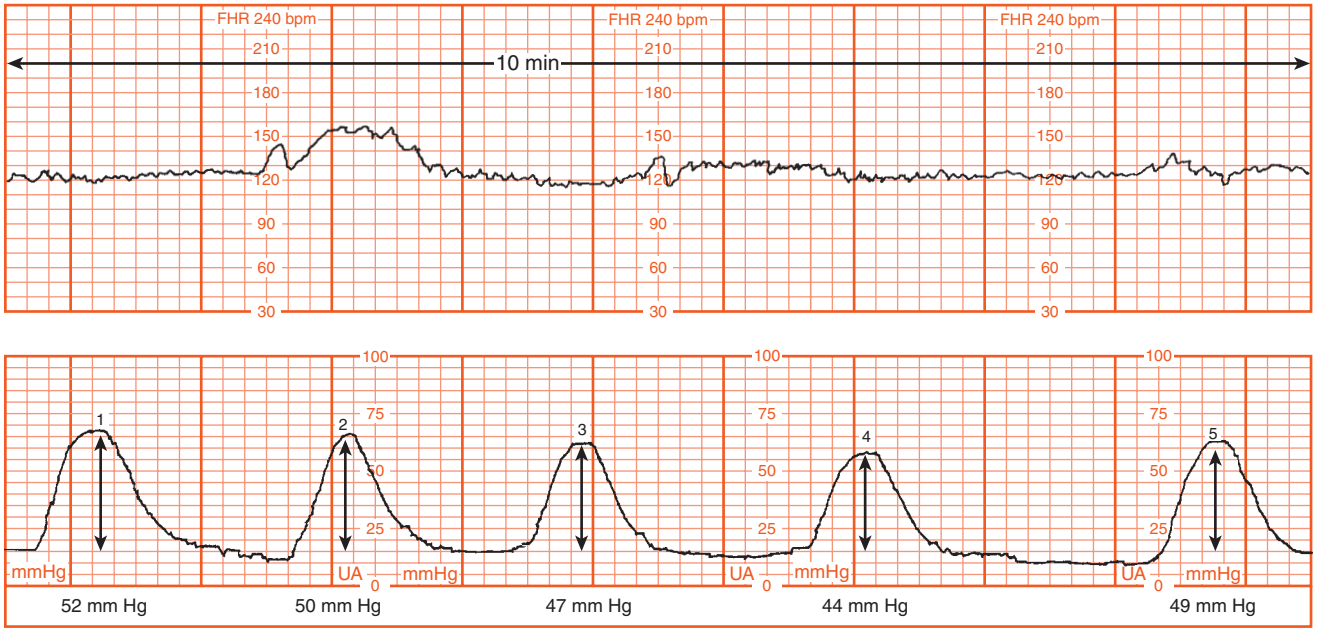

FIGURE 20-3 Montevideo units are calculated by subtracting the baseline uterine pressure from the peak contraction pressure for each contraction in a 10-minute window and adding the pressures generated by each contraction. In the example shown, there were five contractions, producing pressure changes of 52, 50, 47, 44, and 49 mm Hg, respectively. The sum of these five contractions is 242 Montevideo units.

1. The latent phase has been completed, and the cervix is dilated 4 cm or more.
2. A uterine contraction pattern of 200 Montevideo units or more in a 10-minute period has been present for 2 hours without cervical change.

Rouse and Owen (1999b) have challenged the "2-hour rule" on the grounds that a longer time, that is, at least 4 hours, is necessary before concluding that the active phase of labor has failed. We agree.

Second-Stage Disorders

As discussed in Chapter 17 (see p. 389 and Fig. 17-20), fetal descent largely follows complete dilatation. Moreover, the second stage incorporates many of the cardinal movements necessary for the fetus to negotiate the birth canal. Accordingly, disproportion of the fetus and pelvis frequently becomes apparent during second-stage labor.

Until recently, there have been unquestioned second-stage rules that limited its duration. These rules were established in American obstetrics by the beginning of the 20th century. They stemmed from concerns about maternal and fetal health, likely regarding infection and led to difficult forceps operations. The second stage in nulliparas was limited to 2 hours and extended to 3 hours when regional analgesia was used. For multiparas, 1 hour was the limit, extended to 2 hours with regional analgesia. At Parkland Hospital during 1999, only 6 percent of second-stage labors in nulliparas at term exceeded 2 hours.

Cohen (1977) investigated the fetal effects of second-stage labor length at Beth Israel Hospital. He included 4403 term nulliparas in whom electronic fetal heart rate monitoring was performed. The neonatal mortality rate was not increased in women whose second-stage labor exceeded 2 hours. Epidural analgesia was used commonly, and this likely accounted for the large number of pregnancies with a prolonged second stage. These data influenced decisions to permit an additional hour for the second stage when regional analgesia was used.

Menticoglou and colleagues (1995a, b) challenged the prevailing dictums on the duration of the second stage. These arose because of grave neonatal injuries associated with forceps rotations to shorten second-stage labor. As a result, they allowed a longer second stage to decrease the vaginal operative delivery rate. Between 1988 and 1992, second-stage labor exceeded 2 hours in a fourth of 6041 nulliparas at term. Labor epidural analgesia was used in 55 percent. The length of the second stage, even in those lasting up to 6 hours or more, was not related to neonatal outcome. These results were attributed to careful use of electronic monitoring and scalp pH measurements. These investigators concluded that there is no compelling reason to intervene with a possibly difficult forceps or vacuum extraction because a certain number of hours have elapsed. They observed, however, that after 3 hours in the second stage, delivery by cesarean or other operative method increased progressively. By 5 hours, the prospects for spontaneous delivery in the subsequent hour are only 10 to 15 percent.

Myles and Santolaya (2003) analyzed both the maternal and neonatal consequences of prolonged second-stage labor in 7818 women in Chicago between 1996 and 1999. Maternal outcomes in relation to the duration of second-stage labor are shown in Table 20-3. Neonatal mortality and morbidity rates were not related to the length of the second stage.

Maternal Pushing Efforts. With full cervical dilatation, most women cannot resist the urge to "bear down" or "push" each time the uterus contracts (see Chap. 17, p. 394). The combined force created by contractions of the uterus and abdominal musculature propels the fetus downward. Bloom and colleagues (2006) studied effects of actively coaching expulsive efforts. They reported that although the second stage was slightly shorter in the coached women, there were no other maternal or neonatal advantages.

At times, force created by abdominal musculature is compromised sufficiently to slow or even prevent spontaneous vaginal delivery. Heavy sedation or regional analgesia may reduce the reflex urge to push and may impair the ability to contract abdominal muscles sufficiently. In other instances, the inherent urge to push is overridden by the intense pain created by bearing down. Two approaches to second-stage pushing in women with epidural analgesia have yielded contradictory results. The first advocates pushing forcefully with contractions after complete dilation, regardless of the urge to push. With the second, analgesia infusion is stopped and

TABLE 20-3. Clinical Outcomes in Relation to the Duration of Second-Stage Labor

	Duration of Second Stage		
Clinical Outcome	< 2 hr n = 6259 (%)	2–4 hr n = 384 (%)	> 4 hr n = 148 (%)
Cesarean delivery	1.2	9.2	34.5
Instrumented delivery	3.4	16.0	35.1
Perineal trauma	3.6	13.4	26.7
Postpartum hemorrhage	2.3	5.0	9.1
Chorioamnionitis	2.3	8.9	14.2

Adapted from Myles and Santolaya (2003).

pushing begun only after the woman regains the sensory urge to bear down. Fraser and co-workers (2000) found that delayed pushing reduced difficult operative deliveries, whereas Manyonda and associates (1990) reported the opposite. Hansen and colleagues (2002) randomly assigned 252 women with epidural analgesia to one of the two approaches. There were no adverse maternal or neonatal outcomes linked to delayed pushing despite significantly prolonging second-stage labor. Plunkett and co-workers (2003), in a similar study, confirmed these findings.

Fetal Station at Onset of Active Labor

Descent of the leading edge of the presenting part to the level of the ischial spines (0 station) is defined as engagement. Friedman and Sachtleben (1965, 1976) reported a significant association between higher station at the onset of labor and subsequent dystocia. Handa and Laros (1993) found that fetal station at the time of arrested labor was also a risk factor for dystocia. Roshanfekr and associates (1999) analyzed fetal station in 803 nulliparous women at term in active labor. At admission, approximately 30 percent with the fetal head at or below 0 station had a 5-percent cesarean delivery rate. This is compared with a 14-percent rate for those with higher stations. The prognosis for dystocia, however, was not related to incrementally higher fetal head stations above the pelvic midplane (0 station). Importantly, 86 percent of nulliparous women without fetal head engagement at diagnosis of active labor delivered vaginally. These observations apply especially for parous women because the head typically descends later in labor.

Reported Causes of Uterine Dysfunction

Various labor factors have been implicated as causes of uterine dysfunction.

Epidural Analgesia

It is important to emphasize that epidural analgesia can slow labor (Sharma and Leveno, 2000). As shown in **Table 20-4**, epidural analgesia has been associated with lengthening of both first- and second-stage labor and with slowing of the rate of fetal descent. This is documented further in Chapter 19 (p. 456).

Chorioamnionitis

Because of the association of prolonged labor with maternal intrapartum infection, some clinicians have suggested that infection itself contributes to abnormal uterine activity. Satin and co-workers (1992) studied the effects of chorioamnionitis on oxytocin stimulation in 266 pregnancies. Infection diagnosed late in labor was found to be a marker of cesarean delivery for dystocia, whereas this was not observed in women diagnosed as having chorioamnionitis early in labor. Specifically, 40 percent of women developing chorioamnionitis after requiring oxytocin for dysfunctional labor later required cesarean delivery for dystocia. It is likely that uterine infection in this clinical setting is a consequence of dysfunctional, prolonged labor rather than a cause of dystocia.

Maternal Position During Labor

Advocacy for recumbency or ambulation during labor has vacillated. Proponents of walking report it to shorten labor, decrease rates of oxytocin augmentation, decrease the need for analgesia, and lower the frequency of operative vaginal delivery (Flynn and co-workers, 1978; Read and colleagues, 1981).

According to Miller (1983), the uterus contracts more frequently but with less intensity with the mother lying on her back rather than on her side. Conversely, contraction frequency and intensity have been reported to increase with sitting or standing. Lupe and Gross (1986) concluded, however, that there is no conclusive evidence that upright maternal posture or ambulation improves labor. They reported that women preferred to lie on their side or sit in bed. Few chose to walk, fewer to squat, and none wanted the knee-chest position. They tended to assume fetal positions in later labor. Most women enthusiastic about ambulation returned to bed when active labor began (Carlson and associates, 1986; Williams and co-workers, 1980).

Bloom and colleagues (1998) conducted a randomized trial to study the effects of walking during first-stage labor. In 1067 women with uncomplicated term pregnancies delivered at Parkland Hospital, these investigators reported that ambulation did not affect labor duration. Ambulation did not reduce the need for analgesia nor was it harmful to the fetus-neonate. Because of these observations, we give women without complications the option of electing either recumbency or supervised ambulation during labor. This policy is in agreement with the American

TABLE 20-4. Effect of Epidural Analgesia on the Progress of Labor in 199 Nulliparous Women Delivered Spontaneously at Parkland Hospital

Labor Characteristics[a]	Epidural Analgesia	Meperidine Analgesia	*p* value
Cervical dilatation at analgesia	4.1 cm	4.2 cm	NS
Active phase	7.9 hr	6.3 hr	.005
Second stage	60 min	48 min	.03
Fetal descent	4.2 cm/hr	7.9 cm/hr	.003

College of Obstetricians and Gynecologists (2003), which has concluded that ambulation in labor is not harmful, and mobility may result in greater comfort.

Birthing Position in Second-Stage Labor

Considerable interest has been shown in alternative second-stage labor birth positions and their effect on labor. Gupta and Hofmeyr (2004) in their Cochrane database review compared upright positions with supine or lithotomy positions. Upright positions included sitting in a "birthing chair," kneeling, squatting, or resting with the back at a 30-degree elevation. With these positions, they found a 4-minute shorter interval to delivery, less pain, and lower incidences of nonreassuring fetal heart rate patterns and of operative vaginal delivery. They did report increased rates of blood loss exceeding 500 mL. Berghella and colleagues (2008) hypothesized that parity, less intense aortocaval compression, improved fetal alignment, and larger pelvic outlet diameters might explain these findings. In an earlier study, Russell (1969) described a 20- to 30-percent increase in the area of the pelvic outlet with squatting compared with that in the supine position. Finally, Babayer and associates (1998) cautioned that prolonged sitting or squatting during the second stage may cause peroneal neuropathy.

Water Immersion

A birthing tub or bath has been advocated as a means of relaxation that may contribute to more efficient labor. Cluett and colleagues (2004) randomly assigned 99 laboring women at term in first-stage labor identified to have dystocia to immersion in a birthing pool or to oxytocin augmentation. Water immersion lowered the rate of epidural analgesia use but did not alter the rate of operative delivery. More infants of women in the immersion group were admitted to the neonatal intensive care unit (NICU). These findings were similar to their Cochrane database review except that NICU admissions were not increased in their review (Cluett and Burns, 2009).

Robertson and associates (1998) reported that immersion was not associated with chorioamnionitis or endometritis. Moreover, Kwee and co-workers (2000) studied the effects of immersion in 20 women and reported that blood pressure decreased, whereas fetal heart rate was unaffected. Neonatal complications unique to underwater birth that have been described include drowning, hyponatremia, waterborne infection, cord rupture, and polycythemia (Austin and colleagues, 1997; Pinette and associates, 2004).

RUPTURED MEMBRANES WITHOUT LABOR

Membrane rupture at term without spontaneous uterine contractions complicates approximately 8 percent of pregnancies. Until recently, management generally included labor stimulation if contractions did not begin after 6 to 12 hours. This intervention evolved approximately 40 years ago because of maternal and fetal complications due to chorioamnionitis (Calkins, 1952). Such routine intervention was the accepted practice until challenged by Kappy and co-workers (1979), who reported excessive cesarean delivery in term pregnancies with ruptured membranes managed with labor stimulation compared with those expectantly managed.

Hannah (1996) and Peleg (1999) and their associates enrolled a total of 5042 pregnancies with ruptured membranes in a randomized investigation. They measured the effects of induction versus expectant management and also compared induction using intravenous oxytocin with that using prostaglandin E_2 gel. There were approximately 1200 pregnancies in each of the four study arms. They concluded that labor induction with intravenous oxytocin was the preferred management. This determination was based on significantly fewer intrapartum and postpartum infections in women whose labor was induced. There were no significant differences in cesarean delivery rates. Subsequent analysis by Hannah and colleagues (2000) indicated increased adverse outcomes when expectant management at home was compared with in-hospital observation. Mozurkewich and associates (2009) reported lower rates of chorioamnionitis, metritis, and NICU admissions for women with term ruptured membranes whose labors were induced compared with those managed expectantly. At Parkland Hospital, labor is induced soon after admission when ruptured membranes are confirmed at term.

PRECIPITOUS LABOR AND DELIVERY

Not only can labor be too slow, but it also can be abnormally rapid. *Precipitous labor* is extremely rapid labor and delivery. It may result from an abnormally low resistance of the soft parts of the birth canal, from abnormally strong uterine and abdominal contractions, or *rarely* from the absence of painful sensations and thus a lack of awareness of vigorous labor.

Definition and Incidence

According to Hughes (1972), precipitous labor terminates in expulsion of the fetus in less than 3 hours. Using this definition, 89,047 live births—2 percent—were complicated by precipitous labor in the United States during 2006 (Martin and coworkers, 2009). Despite this incidence, there is little published information concerning adverse effects.

Maternal Effects

Precipitous labor and delivery seldom are accompanied by serious maternal complications if the cervix is effaced appreciably and compliant, if the vagina has been stretched previously, and if the perineum is relaxed. Conversely, vigorous uterine contractions combined with a long, firm cervix and a noncompliant birth canal may lead to uterine rupture or extensive lacerations of the cervix, vagina, vulva, or perineum. It is in these latter circumstances that the rare condition of *amnionic fluid embolism* most likely develops (see Chap. 35, p. 788). **The uterus that contracts with unusual vigor before delivery is likely to be hypotonic after delivery, with hemorrhage from the placental implantation site as the consequence.** Postpartum hemorrhage from uterine atony is discussed in Chapter 35 (p. 774).

Mahon and colleagues (1994) described 99 pregnancies delivered within 3 hours of labor onset. *Short labors* were defined

as a rate of cervical dilatation of 5 cm/hr or faster for nulliparas and 10 cm/hr for multiparas. Such short labors were more common in multiparas who typically had contractions at intervals less than 2 minutes and were associated with placental abruption, meconium, postpartum hemorrhage, cocaine abuse, and low Apgar scores.

Fetal and Neonatal Effects

Adverse perinatal outcomes from precipitous labor may be increased considerably for several reasons. The tumultuous uterine contractions, often with negligible intervals of relaxation, prevent appropriate uterine blood flow and fetal oxygenation. Resistance of the birth canal may rarely cause intracranial trauma. Acker and colleagues (1988) reported that Erb or Duchenne brachial palsy was associated with such labors in a third of cases (see Chap. 29, p. 636). Finally, during an unattended birth, the newborn may fall to the floor and be injured, or it may need resuscitation that is not immediately available.

Treatment

Unusually forceful spontaneous uterine contractions are not likely to be modified to a significant degree by analgesia. The use of tocolytic agents such as magnesium sulfate is unproven in these circumstances. Use of general anesthesia with agents that impair uterine contractibility, such as isoflurane, is often excessively heroic. Certainly, any oxytocin agents being administered should be stopped immediately.

FETOPELVIC DISPROPORTION

Fetopelvic disproportion arises from diminished pelvic capacity, excessive fetal size, or more usually, a combination of both.

Pelvic Capacity

Any contraction of the pelvic diameters that diminishes its capacity can create dystocia during labor. There may be contractions of the pelvic inlet, the midpelvis, or the pelvic outlet, or a generally contracted pelvis may be caused by combinations of these. Normal pelvic dimension are additionally discussed in Chapter 2 (p. 31).

Contracted Inlet

The pelvic inlet usually is considered to be contracted if its shortest anteroposterior diameter is less than 10 cm or if the greatest transverse diameter is less than 12 cm. The anteroposterior diameter of the inlet is commonly approximated by manually measuring the diagonal conjugate, which is approximately 1.5 cm greater (see Chap. 2, p. 31). Therefore, inlet contraction usually is defined as a diagonal conjugate of less than 11.5 cm.

Using clinical and at times, imaging pelvimetry, it is important to identify the shortest anteroposterior diameter through which the fetal head must pass. Occasionally, the body of the first sacral vertebra is displaced forward so that the shortest distance may actually be between this abnormal sacral promontory and the symphysis pubis.

Prior to labor, the fetal biparietal diameter has been shown to *average* from 9.5 to as much as 9.8 cm. Therefore, it might prove difficult or even impossible for some fetuses to pass through an inlet that has an anteroposterior diameter of less than 10 cm. Mengert (1948) and Kaltreider (1952), employing x-ray pelvimetry, demonstrated that the incidence of difficult deliveries is increased to a similar degree when either the anteroposterior diameter of the inlet is less than 10 cm or the transverse diameter is less than 12 cm. As expected, when both diameters are contracted, dystocia is much greater than when only one is contracted.

A small woman is likely to have a small pelvis, but she is also likely to have a small neonate. Thoms (1937) studied 362 nulliparas and found the mean birthweight of their offspring was significantly lower—280 g—in women with a small pelvis than in those with a medium or large pelvis. In veterinary obstetrics, in most species, maternal size rather than paternal size is the important determinant of fetal size.

Normally, cervical dilatation is aided by hydrostatic action of the unruptured membranes or after their rupture, by direct application of the presenting part against the cervix (see Fig. 6-8, p. 145). In contracted pelves, however, because the head is arrested in the pelvic inlet, the entire force exerted by the uterus acts directly on the portion of membranes that contact the dilating cervix. Consequently, early spontaneous rupture of the membranes is more likely.

After membrane rupture, absent pressure by the head against the cervix and lower uterine segment predisposes to less effective contractions. Hence, further dilatation may proceed very slowly or not at all. Cibils and Hendricks (1965) reported that the mechanical adaptation of the fetal passenger to the bony passage plays an important part in determining the efficiency of contractions. The better the adaptation, the more efficient are the contractions. Thus, cervical response to labor provides a prognostic view of labor outcome in women with inlet contraction.

A contracted inlet plays an important part in the production of abnormal presentations. In normal nulliparas, the presenting part at term commonly descends into the pelvic cavity before the onset of labor. When the inlet is contracted considerably, however, descent usually does not take place until after labor onset, if at all. Cephalic presentations still predominate, but the head floats freely over the pelvic inlet or rests more laterally in one of the iliac fossae. Accordingly, very slight influences may cause the fetus to assume other presentations. *In women with contracted pelves, face and shoulder presentations are encountered three times more frequently, and the cord prolapses four to six times more often.*

Contracted Midpelvis

This finding is more common than inlet contraction. It frequently causes transverse arrest of the fetal head, which potentially can lead to a difficult midforceps operation or to cesarean delivery.

The obstetrical plane of the midpelvis extends from the inferior margin of the symphysis pubis through the ischial spines and touches the sacrum near the junction of the fourth and fifth vertebrae (see Chap. 2, p. 32). A transverse line theoretically connecting the ischial spines divides the midpelvis into anterior and posterior portions. The former is bounded anteriorly by

the lower border of the symphysis pubis and laterally by the ischiopubic rami. The posterior portion is bounded dorsally by the sacrum and laterally by the sacrospinous ligaments, forming the lower limits of the sacrosciatic notch.

Average midpelvis measurements are as follows: *transverse,* or interischial spinous, 10.5 cm; *anteroposterior,* from the lower border of the symphysis pubis to the junction of S4-S5, 11.5 cm; and *posterior sagittal*, from the midpoint of the interspinous line to the same point on the sacrum, 5 cm. The definition of midpelvic contractions has not been established with the same precision possible for inlet contractions. Even so, the midpelvis is likely contracted when the sum of the interspinous and posterior sagittal diameters of the midpelvis—normal, 10.5 plus 5 cm, or 15.5 cm—falls to 13.5 cm or less. This concept was emphasized by Chen and Huang (1982) in evaluating possible midpelvic contraction. There is reason to suspect midpelvic contraction whenever the interspinous diameter is less than 10 cm. When it measures less than 8 cm, the midpelvis is contracted.

Although there is no precise manual method of measuring midpelvic dimensions, a suggestion of contraction sometimes can be inferred if the spines are prominent, the pelvic sidewalls converge, or the sacrosciatic notch is narrow. Moreover, Eller and Mengert (1948) noted that the relationship between the intertuberous and interspinous diameters of the ischium is sufficiently constant that narrowing of the interspinous diameter can be anticipated when the intertuberous diameter is narrow. A normal intertuberous diameter, however, does not always exclude a narrow interspinous diameter.

Contracted Outlet

This finding usually is defined as an interischial tuberous diameter of 8 cm or less. The pelvic outlet may be roughly likened to two triangles, with the interischial tuberous diameter constituting the base of both. The sides of the anterior triangle are the pubic rami, and its apex is the inferoposterior surface of the symphysis pubis. The posterior triangle has no bony sides but is limited at its apex by the tip of the last sacral vertebra—not the tip of the coccyx. Diminution of the intertuberous diameter with consequent narrowing of the anterior triangle must inevitably force the fetal head posteriorly. Floberg and associates (1987) reported that outlet contractions were found in almost 1 percent of more than 1400 unselected nulliparas with term pregnancies. A contracted outlet may cause dystocia not so much by itself as through the often-associated midpelvic contraction. *Outlet contraction without concomitant midplane contraction is rare.*

Although the disproportion between the fetal head and the pelvic outlet is not sufficiently great to give rise to severe dystocia, it may play an important part in the production of perineal tears. With increasing narrowing of the pubic arch, the occiput cannot emerge directly beneath the symphysis pubis but is forced increasingly farther down upon the ischiopubic rami. The perineum, consequently, becomes increasingly distended and thus exposed to greater danger of laceration.

Pelvic Fractures

Speer and Peltier (1972) reviewed experiences with pelvic fractures and pregnancy. Trauma from automobile collisions was the most common cause of pelvic fractures. With bilateral fractures of the pubic rami, compromise of the birth canal capacity by callus formation or malunion was common. A history of pelvic fracture warrants careful review of previous radiographs and possibly computed tomographic pelvimetry later in pregnancy.

Estimation of Pelvic Capacity

The techniques for clinical evaluation using digital examination of the bony pelvis during labor are described in detail in Chapter 2 (p. 31). Briefly, the examiner attempts to judge the anteroposterior diameter of the inlet—the diagonal conjugate, the interspinous diameter of the midpelvis, and the intertuberous distances of the pelvic outlet. A narrow pelvic arch of less than 90 degrees can signify a narrow pelvis. An unengaged fetal head can indicate either excessive fetal head size or reduced pelvic inlet capacity.

X-Ray Pelvimetry. Even when widely used, the prognosis for successful vaginal delivery in any given pregnancy cannot be established using x-ray pelvimetry alone (Mengert, 1948). Thus, x-ray pelvimetry is considered to be of limited value in the management of labor with a cephalic presentation (American College of Obstetricians and Gynecologists, 1995b).

Computed Tomographic (CT) Scanning. Advantages of CT pelvimetry, such as that shown in **Figure 20-4**, compared with those of conventional x-ray pelvimetry include reduced radiation exposure, greater accuracy, and easier performance. With either method, costs are comparable and x-ray exposure is small (see Chap. 41, p. 918). With conventional x-ray pelvimetry, the mean gonadal exposure is estimated by the Committee on Radiological Hazards to Patients to be 885 mrad (Osborn, 1963). Depending on the machine and technique employed, fetal doses with computed tomography may range from 250 to 1500 mrad (Moore and Shearer, 1989).

Magnetic Resonance (MR) Imaging. The advantages of MR pelvimetry include lack of ionizing radiation, accurate measurements, complete fetal imaging, and the potential for evaluating soft tissue dystocia (McCarthy, 1986; Stark and coworkers, 1985). Zaretsky and colleagues (2005) used MR imaging to measure pelvic and fetal head volume in an effort to identify those women at greatest risk of undergoing cesarean delivery for dystocia. Although significant associations were found with some of the measures and cesarean delivery for dystocia, they could not with accuracy predict which woman would require cesarean delivery. Others have reported similar findings (Sporri and co-workers, 1997).

Fetal Dimensions in Fetopelvic Disproportion

Fetal size alone is seldom a suitable explanation for failed labor. Even with the evolution of current technology, a fetal size threshold to predict fetopelvic disproportion is still elusive. Most cases of disproportion arise in fetuses whose weight is well within the range of the general obstetrical population. As shown

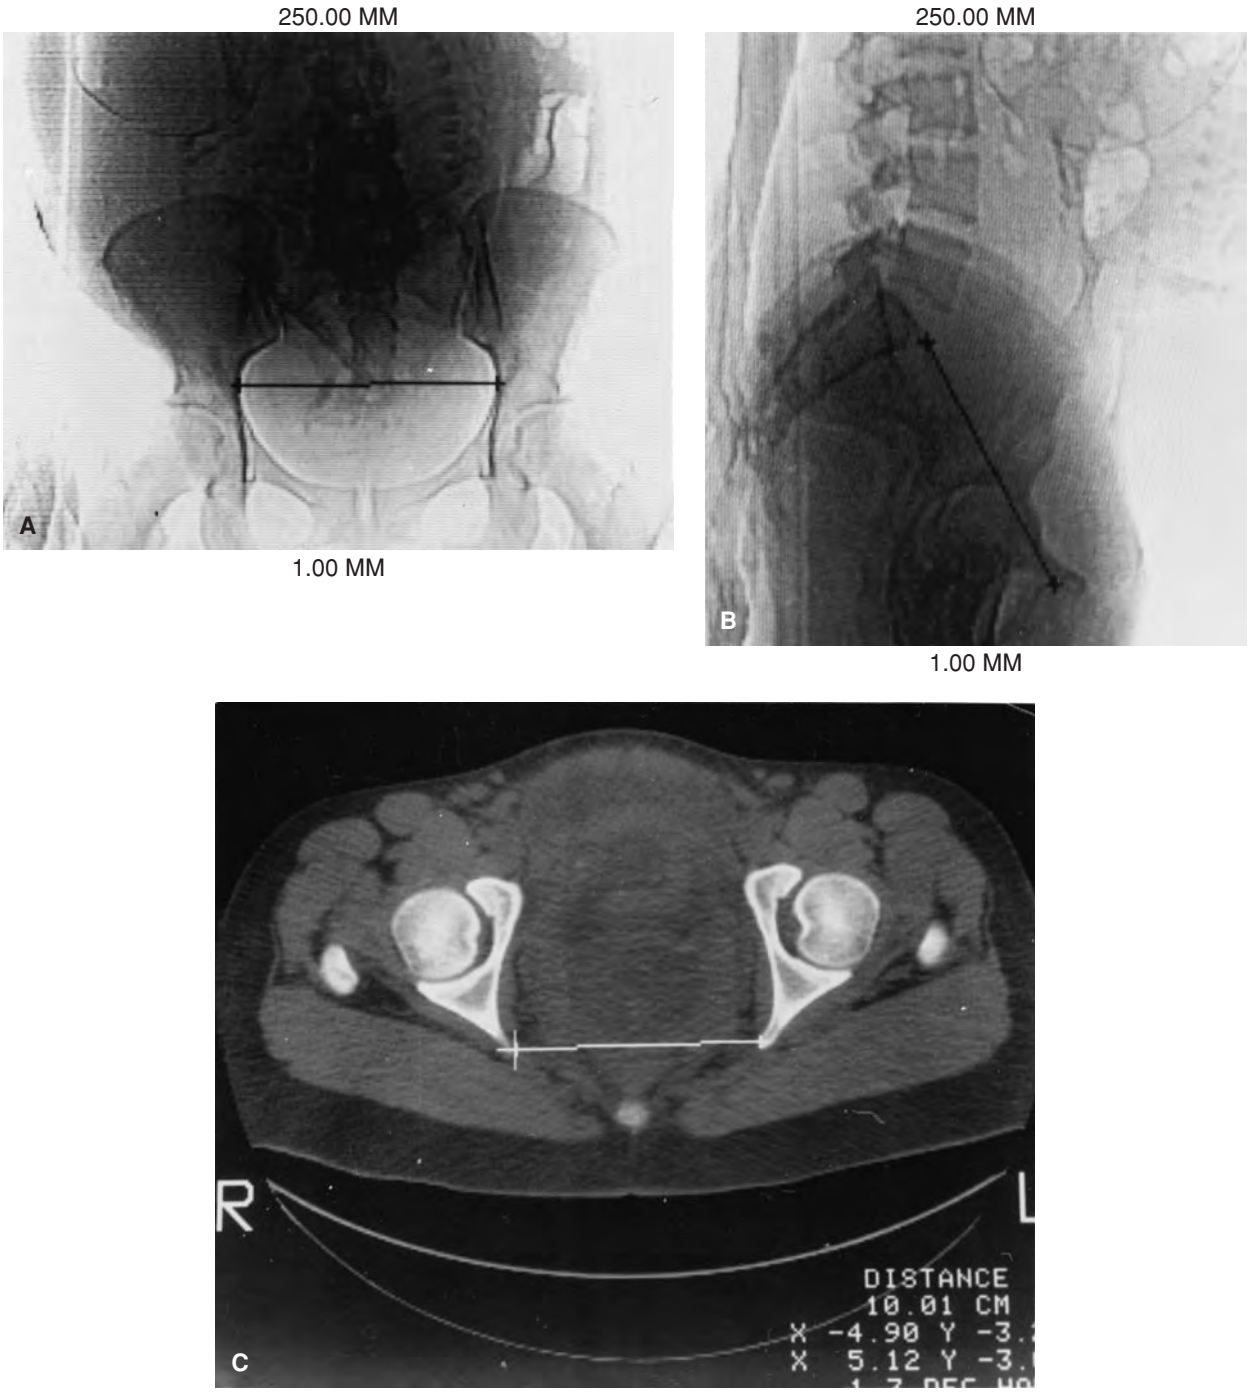

FIGURE 20-4 A. Anteroposterior view of a digital radiograph. Illustrated is the measurement of the transverse diameter of the pelvic inlet using an electronic cursor. The fetal body is clearly outlined. **B.** Lateral view of a digital radiograph. Illustrated are measurements of the anteroposterior diameters of the inlet using the electronic cursor. **C.** An axial computed tomographic section through the midpelvis. The level of the fovea of the femoral heads was ascertained from the anteroposterior digital radiograph because it corresponds to the level of the ischial spines. The interspinous diameter is measured using the electronic cursor. The total fetal radiation dose using the three exposures shown in parts **(A-C)** is approximately 250 mrad.

in Figure 20-5, two thirds of neonates who required cesarean delivery after failed forceps delivery weighed less than 3700 g. Thus, other factors, such as malposition of the head, obstruct fetal passage through the birth canal. These include asynclitism, occiput posterior position, and face and brow presentations.

Estimation of Fetal Head Size

Efforts to clinically and radiographically predict fetopelvic disproportion based on fetal head size have proved disappointing. Müller (1880) and Hillis (1930) described a clinical maneuver to predict disproportion. The fetal brow and the suboccipital

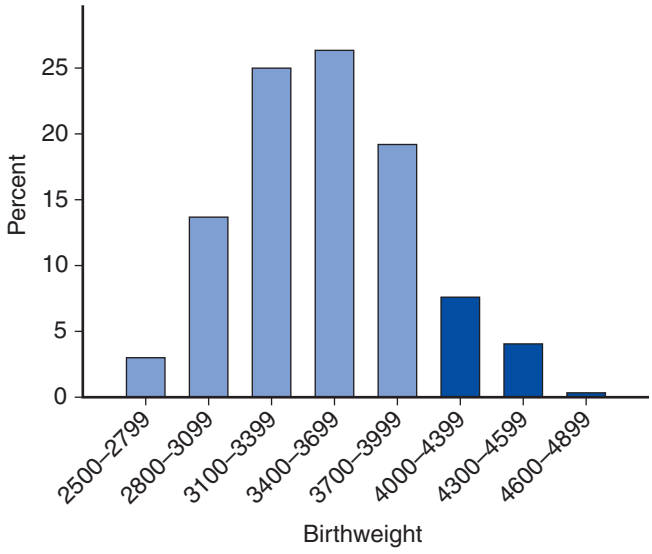

FIGURE 20-5 Birthweight distribution of 362 newborns delivered by cesarean at Parkland Hospital (1989–1999) after a failed attempt to effect vaginal delivery with forceps. Only 12 percent (n = 44) of the newborns weighed > 4000 g (*dark bars*).

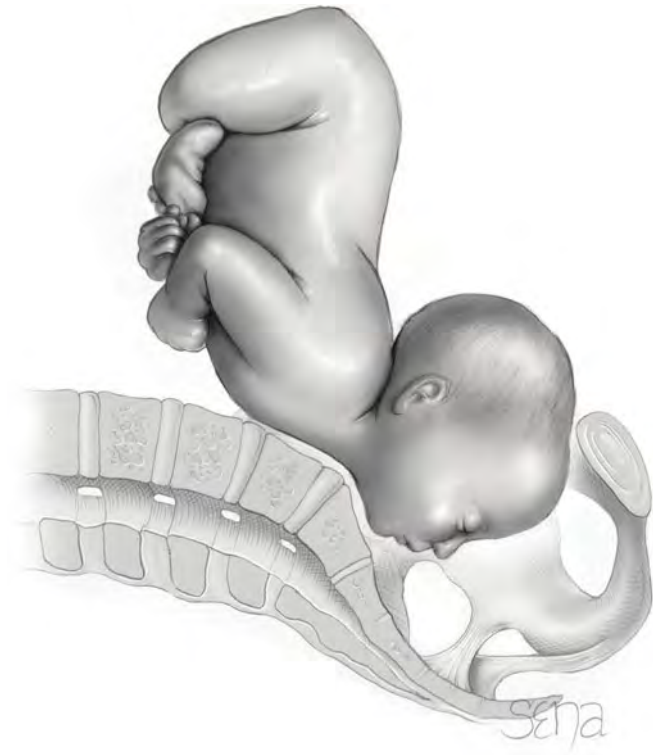

FIGURE 20-6 Face presentation. The occiput is the longer end of the head lever. The chin is directly posterior. Vaginal delivery is impossible unless the chin rotates anteriorly.

region are grasped through the abdominal wall with the fingers, and firm pressure is directed downward in the axis of the inlet. If no disproportion exists, the head readily enters the pelvis, and vaginal delivery can be predicted. Thorp and colleagues (1993b) performed a prospective evaluation of the *Mueller-Hillis maneuver* and concluded that there was no relationship between dystocia and failed descent during the maneuver.

Measurements of fetal head diameters using plain radiographic techniques are not used because of parallax distortions. The biparietal diameter and head circumference can be measured sonographically, and there have been attempts to use this information in the management of dystocia. Thurnau and co-workers (1991) used the *fetal-pelvic index* to identify labor complications. Unfortunately, the sensitivity of such measurements to predict cephalopelvic disproportion is poor (Ferguson and associates, 1998). We are of the view that there is no currently satisfactory method for accurate prediction of fetopelvic disproportion based on head size.

Face Presentation

With this presentation, the head is hyperextended so that the occiput is in contact with the fetal back, and the chin (mentum) is presenting (**Fig. 20-6**). The fetal face may present with the chin (mentum) anteriorly or posteriorly, relative to the maternal symphysis pubis (see Chap. 17, p. 379). Although many may persist, many mentum posterior presentations convert spontaneously to anterior even in late labor (Duff, 1981). If not, the fetal brow (bregma) is pressed against the maternal symphysis pubis. This position precludes flexion of the fetal head necessary to negotiate the birth canal.

Cruikshank and White (1973) reported an incidence of 1 in 600, or 0.17 percent. As shown in Table 17-1 (p. 375), among more than 70,000 singleton newborns delivered at Parkland, approximately 1 in 2000 had a face presentation at delivery.

Etiology. Causes of face presentations are numerous and include conditions that favor extension or prevent head flexion. Preterm infants, with their smaller head dimensions, can engage prior to conversion to vertex position (Shaffer and associates, 2006b). In exceptional instances, marked enlargement of the neck or coils of cord around the neck may cause extension. Bashiri and colleagues (2008) reported that fetal malformations and hydramnios were risk factors for face or brow presentations. Anencephalic fetuses naturally present by the face.

Extended positions develop more frequently when the pelvis is contracted or the fetus is very large. In a series of 141 face presentations studied by Hellman and co-workers (1950), the incidence of inlet contraction was 40 percent. This high incidence of pelvic contraction should be kept in mind when considering management.

High parity is a predisposing factor to face presentation (Fuchs and colleagues, 1985). In these cases, a pendulous abdomen permits the back of the fetus to sag forward or laterally, often in the same direction in which the occiput points. This promotes extension of the cervical and thoracic spine.

Diagnosis. Face presentation is diagnosed by vaginal examination and palpation of facial features. As discussed in Chapter 24 (p. 528), it is possible to mistake a breech for a face presentation because the anus may be mistaken for the mouth and the ischial tuberosities for the malar prominences. The radiographic demonstration of the hyperextended head with the facial bones at or below the pelvic inlet is characteristic.

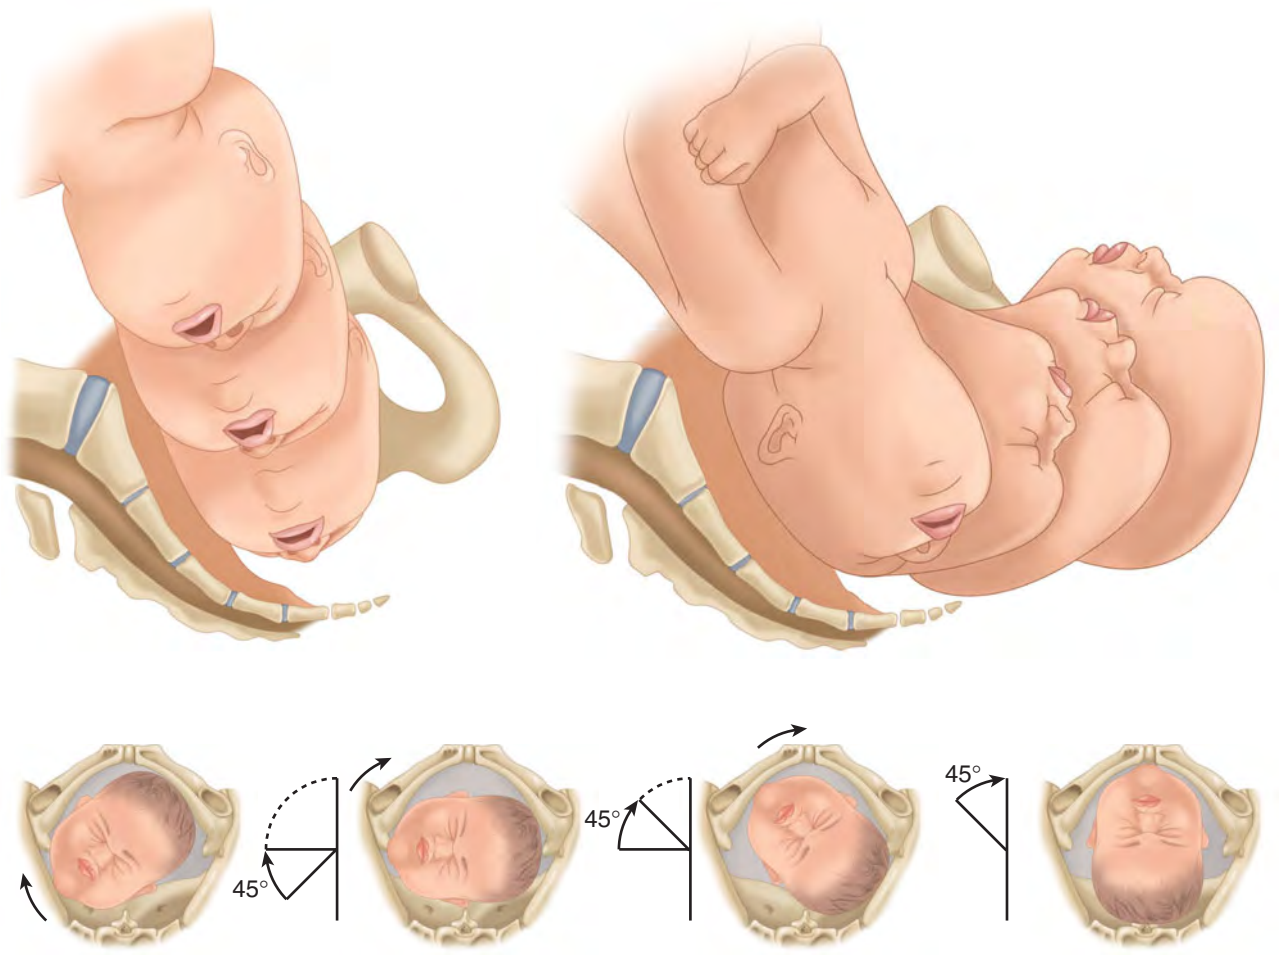

FIGURE 20-7 Mechanism of labor for right mentoposterior position with subsequent rotation of the mentum anteriorly and delivery.

Mechanism of Labor. Face presentations rarely are observed above the pelvic inlet. Instead, the brow generally presents early and is usually converted to present the face after further extension of the head during descent. The mechanism of labor in these cases consists of the cardinal movements of descent, internal rotation, and flexion, and the accessory movements of extension and external rotation (Fig. 20-7). Descent is brought about by the same factors as in cephalic presentations. Extension results from the relation of the fetal body to the deflected head, which is converted into a two-armed lever, the longer arm of which extends from the occipital condyles to the occiput. When resistance is encountered, the occiput must be pushed toward the back of the fetus while the chin descends.

The objective of internal rotation of the face is to bring the chin under the symphysis pubis. Only in this way can the neck traverse the posterior surface of the symphysis pubis. If the chin rotates directly posteriorly, the relatively short neck cannot span the anterior surface of the sacrum, which measures about 12 cm in length. Moreover, the fetal brow (bregma) is pressed against the maternal symphysis pubis. This position precludes flexion necessary to negotiate the birth canal. Hence, birth of the head from a mentum posterior position is impossible unless the shoulders enter the pelvis at the same time, an event that is impossible except when the fetus is extremely small or macerated. Internal rotation results from the same factors as in vertex presentations.

After anterior rotation and descent, the chin and mouth appear at the vulva, the undersurface of the chin presses against the symphysis, and the head is delivered by flexion (see Fig. 20-8). The nose, eyes, brow (bregma), and occiput then appear in succession over the anterior margin of the perineum. After birth of the head, the occiput sags backward toward the anus. Next, the chin rotates externally to the side toward which it was originally directed, and the shoulders are born as in cephalic presentations.

Edema may sometimes significantly distort the face. At the same time, the skull undergoes considerable molding, manifested by an increase in length of the occipitomental diameter of the head.

Management. In the absence of a contracted pelvis, and with effective labor, successful vaginal delivery usually will follow. Fetal heart rate monitoring is probably better done with external devices to avoid damage to the face and eyes. Because face presentations among term-size fetuses are more common when there is some degree of pelvic inlet contraction, cesarean delivery

FIGURE 20-8 Brow posterior presentation.

frequently is indicated. Attempts to convert a face presentation manually into a vertex presentation, manual or forceps rotation of a persistently posterior chin to a mentum anterior position, and internal podalic version and extraction are dangerous and not attempted.

Brow Presentation

This rare presentation is diagnosed when that portion of the fetal head between the orbital ridge and the anterior fontanel presents at the pelvic inlet. As shown in **Figure 20-8**, the fetal head thus occupies a position midway between full flexion (occiput) and extension (face). Except when the fetal head is small or the pelvis is unusually large, engagement of the fetal head and subsequent delivery cannot take place as long as the brow presentation persists.

Etiology and Diagnosis. The causes of persistent brow presentation are the same as those for face presentation. A brow presentation is commonly unstable and often converts to a face or an occiput presentation (Cruikshank and White, 1973). The presentation may be recognized by abdominal palpation when both the occiput and chin can be palpated easily, but vaginal examination is usually necessary. The frontal sutures, large anterior fontanel, orbital ridges, eyes, and root of the nose are felt on vaginal examination, but neither the mouth nor the chin is palpable.

Mechanism of Labor. With a very small fetus and a large pelvis, labor is generally easy, but with a larger fetus, it is usually difficult. This is because engagement is impossible until there is marked molding that shortens the occipitomental diameter or more commonly, until there is either flexion to an occiput presentation or extension to a face presentation. The considerable molding essential for vaginal delivery of a persistent brow characteristically deforms the head. The caput succedaneum is over the forehead, and it may be so extensive that identification of the brow by palpation is impossible. In these instances, the forehead is prominent and squared, and the occipitomental diameter is diminished.

In transient brow presentations, the prognosis depends on the ultimate presentation. If the brow persists, prognosis is poor for vaginal delivery unless the fetus is small or the birth canal is large. Principles of management are the same as those for a face presentation.

Transverse Lie

In this position, the long axis of the fetus is approximately perpendicular to that of the mother. When the long axis forms an acute angle, an *oblique lie* results. The latter is usually only transitory, because either a longitudinal or transverse lie commonly results when labor supervenes. For this reason, the oblique lie is called an *unstable lie* in Great Britain.

In a transverse lie, the shoulder is usually positioned over the pelvic inlet. The head occupies one iliac fossa, and the breech the other. This creates a *shoulder presentation* in which the side of the mother on which the acromion rests determines the designation of the lie as right or left acromial. And because in either position the back may be directed anteriorly or posteriorly, superiorly or inferiorly, it is customary to distinguish varieties as dorsoanterior and dorsoposterior (**Fig. 20-9**).

Transverse lie was found once in 322 singleton deliveries (0.3 percent) at both the Mayo Clinic and the University of Iowa Hospital (Cruikshank and White, 1973; Johnson, 1964). This is remarkably similar to the incidence at Parkland Hospital of approximately 1 in 335 singleton fetuses.

Etiology. Some of the more common causes of transverse lie include: (1) abdominal wall relaxation from high parity, (2) preterm fetus, (3) placenta previa, (4) abnormal uterine anatomy, (5) hydramnios, and (6) contracted pelvis.

Women with four or more deliveries have a 10-fold incidence of transverse lie compared with nulliparas. A relaxed and pendulous abdomen allows the uterus to fall forward, deflecting the long axis of the fetus away from the axis of the birth canal and into an oblique or transverse position. Placenta previa and pelvic contraction act similarly. A transverse or oblique lie occasionally develops in labor from an initial longitudinal position.

Diagnosis. A transverse lie is usually recognized easily, often by inspection alone. The abdomen is unusually wide, whereas the uterine fundus extends to only slightly above the umbilicus. No fetal pole is detected in the fundus, and the ballottable head is found in one iliac fossa and the breech in the other. The position of the back is readily identifiable. When the back is anterior (see Fig. 20-9), a hard resistance plane extends across the front of the abdomen. When it is posterior, irregular nodulations representing fetal small parts are felt through the abdominal wall.

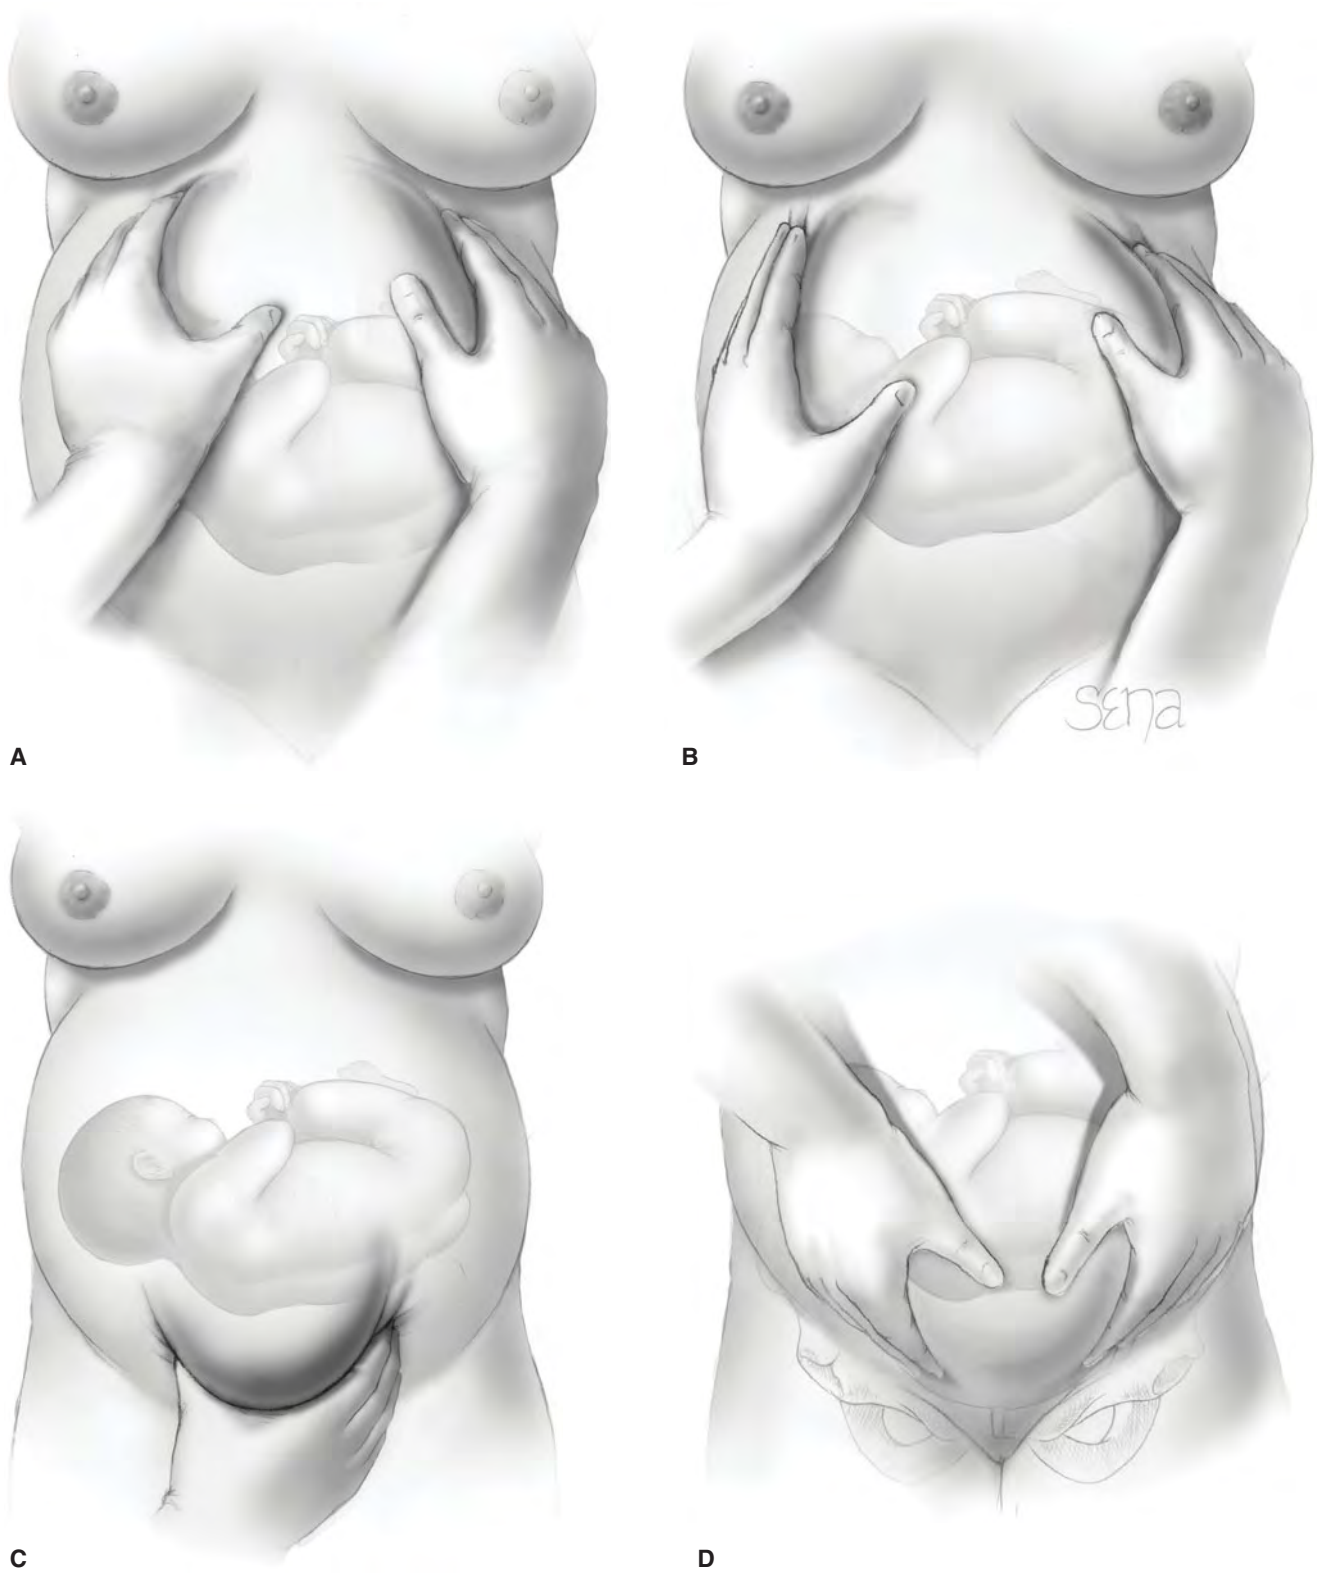

FIGURE 20-9 Leopold maneuver performed on women with a fetal transverse lie, right acromidorsoanterior position. **A.** First maneuver. **B.** Second maneuver. **C.** Third maneuver. **D.** Fourth maneuver.

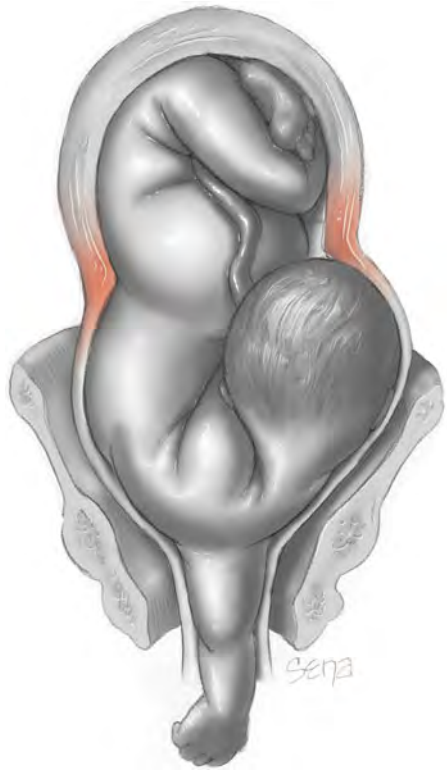

FIGURE 20-10 Neglected shoulder presentation. A thick muscular band forming a pathological retraction ring has developed just above the thin lower uterine segment. The force generated during a uterine contraction is directed centripetally at and above the level of the pathological retraction ring. This serves to stretch further and possibly to rupture the thin lower segment below the retraction ring.

On vaginal examination, in the early stages of labor, if the side of the thorax can be reached, it may be recognized by the "gridiron" feel of the ribs. With further dilatation, the scapula and the clavicle are distinguished on opposite sides of the thorax. The position of the axilla indicates the side of the mother toward which the shoulder is directed.

Mechanism of Labor. Spontaneous delivery of a fully developed newborn is impossible with a persistent transverse lie. After rupture of the membranes, if labor continues, the fetal shoulder is forced into the pelvis, and the corresponding arm frequently prolapses (**Fig. 20-10**). After some descent, the shoulder is arrested by the margins of the pelvic inlet, with the head in one iliac fossa and the breech in the other. As labor continues, the shoulder is impacted firmly in the upper part of the pelvis. The uterus then contracts vigorously in an unsuccessful attempt to overcome the obstacle. With time, a retraction ring rises increasingly higher and becomes more marked. With this *neglected transverse lie,* the uterus will eventually rupture. Even without this complication, morbidity is increased because of the frequent association with placenta previa, the increased likelihood of cord prolapse, and the necessity for major operative efforts.

If the fetus is small—usually less than 800 g—and the pelvis is large, spontaneous delivery is possible despite persistence of the abnormal lie. The fetus is compressed with the head forced against its abdomen. A portion of the thoracic wall below the shoulder thus becomes the most dependent part, appearing at the vulva. The head and thorax then pass through the pelvic cavity at the same time. The fetus, which is doubled upon itself and thus sometimes referred to as *conduplicato corpore*, is expelled.

Management. Active labor in a woman with a transverse lie is usually an indication for cesarean delivery. Before labor or early in labor, with the membranes intact, attempts at external version are worthwhile in the absence of other complications. If the fetal head can be maneuvered by abdominal manipulation into the pelvis, it should be held there during the next several contractions in an attempt to fix the head in the pelvis.

With cesarean delivery, because neither the feet nor the head of the fetus occupies the lower uterine segment, a low transverse incision into the uterus may lead to difficult fetal extraction. This is especially true of dorsoanterior presentations. Therefore, a vertical incision is typically indicated (see Chap. 25, p. 555).

Compound Presentation

In a compound presentation, an extremity prolapses alongside the presenting part, and both present simultaneously in the pelvis (**Fig. 20-11**).

Incidence and Etiology. Goplerud and Eastman (1953) identified a hand or arm prolapsed alongside the head once in every 700 deliveries. Much less common was prolapse of one or both lower extremities alongside a cephalic presentation or a hand

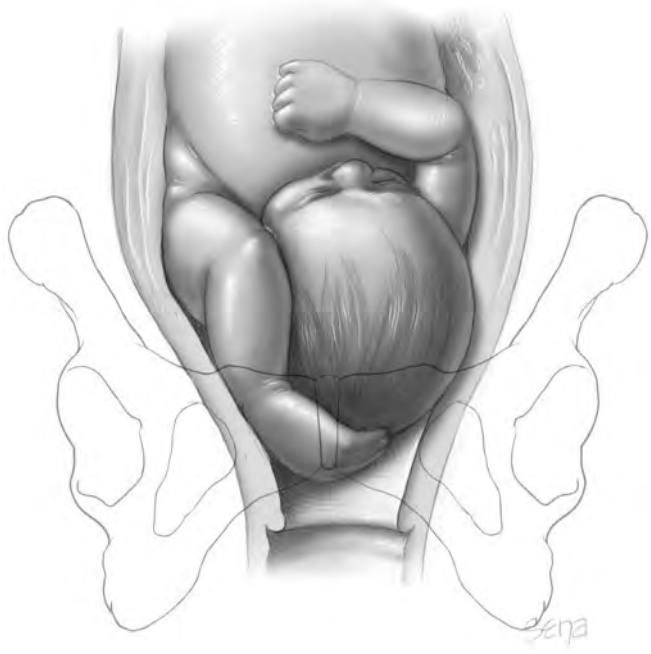

FIGURE 20-11 Compound presentation. The left hand is lying in front of the vertex. With further labor, the hand and arm may retract from the birth canal, and the head may then descend normally.

alongside a breech. At Parkland Hospital, compound presentations were identified in only 68 of more than 70,000 singleton fetuses—an incidence of approximately 1 in 1000. Causes of compound presentations are conditions that prevent complete occlusion of the pelvic inlet by the fetal head, including preterm labor (Goplerud and Eastman, 1953).

Management and Prognosis. In most cases, the prolapsed part should be left alone, because most often it will not interfere with labor. If the arm is prolapsed alongside the head, the condition should be observed closely to ascertain whether the arm retracts out of the way with descent of the presenting part. If it fails to retract and if it appears to prevent descent of the head, the prolapsed arm should be pushed gently upward and the head simultaneously downward by fundal pressure. Tebes and co-workers (1999) described a tragic outcome in a newborn delivered spontaneously with the hand alongside the head. The infant developed ischemic necrosis of the presenting forearm, which required amputation. In general, rates of perinatal mortality and morbidity are increased as a result of concomitant preterm delivery, prolapsed cord, and traumatic obstetrical procedures.

Persistent Occiput Posterior Position

Most occiput posterior positions undergo spontaneous anterior rotation followed by uncomplicated delivery. Although the precise reasons for failure of spontaneous rotation are not known, transverse narrowing of the midpelvis is undoubtedly a contributing factor. Gardberg and associates (1998) used sonography to record the position of the fetal head in 408 term pregnancies at entry into labor (Fig. 20-12). Early in labor, approximately 15 percent of fetuses were occiput posterior, and 5 percent were in this position at delivery. Importantly, two thirds of occiput posterior deliveries occurred with fetuses who were occiput anterior at the beginning of labor. Thus, most occiput posterior presentations at delivery are the result of malrotation of occiput anterior position during labor, and almost 90 percent of occiput posterior presentations at the outset of labor spontaneously rotate anteriorly.

Labor and delivery need not differ remarkably from that with the occiput anterior. Progress may be determined by assessing cervical dilatation and descent of the head. In most instances, delivery usually can be accomplished without great difficulty once the head reaches the perineum. The possibilities for vaginal delivery are: (1) spontaneous delivery, (2) forceps delivery with the occiput posterior, (3) manual rotation to the occiput anterior followed by spontaneous or forceps delivery, and (4) forceps rotation to occiput anterior and delivery.

Spontaneous Delivery. If the pelvic outlet is roomy and the vaginal outlet and perineum are somewhat relaxed from previous deliveries, rapid spontaneous delivery often will take place. If the vaginal outlet is resistant to stretch and the perineum is firm, late first-stage or second-stage labor or both may be appreciably prolonged. During each expulsive effort, the head is driven against the perineum to a much greater degree than when anterior. Therefore, forceps delivery often is indicated. A generous episiotomy usually is needed.

Forceps Delivery as an Occiput Posterior. The need for more traction can be minimized if perineal resistance is lowered by creating a larger episiotomy. The use of forceps and a large episiotomy warrant more complete analgesia than may be achieved with pudendal block and local perineal infiltration. The forceps are applied bilaterally along the occipitomental diameter, as described in Chapter 23 (p. 516).

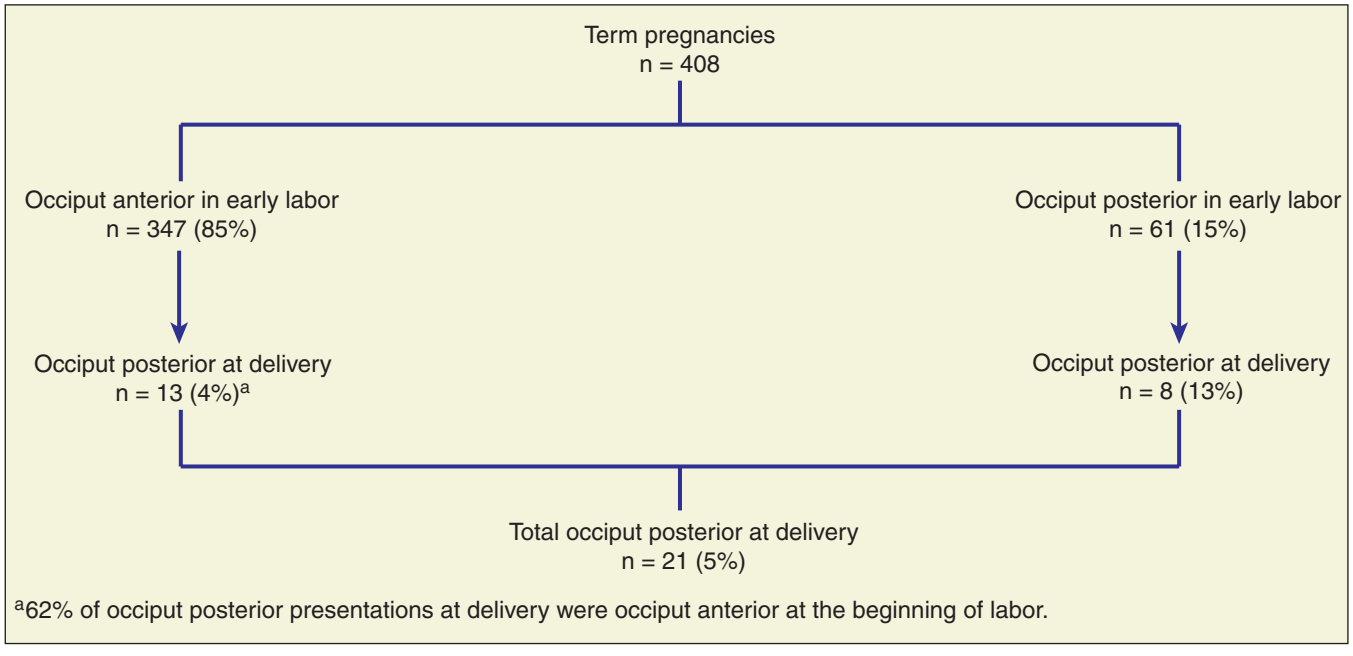

FIGURE 20-12 Occiput posterior presentation in early labor compared with presentation at delivery. Sonography was used to determine position of the fetal head in early labor. (From Gardberg and associates, 1998.)

Infrequently, protrusion of fetal scalp through the introitus is the consequence of marked elongation of the fetal head from molding combined with formation of a large caput succedaneum. In some cases, the head may not even be engaged—that is, the biparietal diameter may not have passed through the pelvic inlet. In these, labor is characteristically long and descent of the head is slow. Careful palpation above the symphysis may disclose the fetal head to be above the pelvic inlet. Prompt cesarean delivery is appropriate.

Manual Rotation. The requirements for forceps rotation must be met before performing a manual rotation. When the hand is introduced to locate the posterior ear and thus confirm the posterior position, the occiput often spontaneously rotates toward the anterior position. If not, the head may be grasped with the fingers over one ear and the thumb over the other and rotation of the occiput to the anterior position attempted (see Chap. 23, p. 516). Shaffer and associates (2006a) performed manual rotation in 742 women with fetuses in occiput posterior or occiput transverse positions. Of those successfully rotated, only 2 percent required cesarean delivery.

Forceps Rotation. If the head is engaged, the cervix fully dilated, and the pelvis adequate, forceps rotation may be attempted. These circumstances most likely prevail when expulsive efforts of the mother during the second stage are ineffective. Rotation with forceps is described in Chapter 23 p. 517).

Menticoglou and co-workers (1995b) reviewed the obstetrical features of 15 newborns with birth-related high-cervical spinal cord injuries in 13 Canadian hospitals between 1982 and 1994. All of these neonates underwent cephalic delivery with forceps rotation of 90 degrees or more from occipitoposterior or occipitotransverse positions. Investigators could not determine whether these serious, albeit rare, fetal injuries resulted from mismanagement or from an intrinsic risk of properly performed forceps rotation. They estimated that this complication developed in less than 1 per 1000 forceps rotations.

Outcome. There are notable differences when persistent occiput posterior position is compared with the occiput anterior. Cheng and colleagues (2006) compared outcomes of 2591 women with persistent occiput position to those of 28,801 women with occiput anterior presentations. Virtually every possible delivery complication was found more frequently with a persistent occiput posterior. Only 46 percent of these women delivered spontaneously, and they accounted for 9 percent of cesarean deliveries performed. In addition, occiput posterior position at delivery was associated with increased adverse short-term neonatal outcomes. Similar results were reported by Ponkey (2003) and Fitzpatrick (2001) and their associates.

At Parkland Hospital, spontaneous delivery is preferred. Either manual rotation to the anterior position followed by forceps delivery or forceps delivery from the occiput posterior position is used for the others. If neither can be completed with relative ease, cesarean delivery is performed.

Persistent Occiput Transverse Position

In the absence of a pelvic architecture abnormality or asynclitism, the occiput transverse position is usually transitory. Thus, unless contractions are hypotonic, spontaneous anterior rotation usually is completed rapidly.

Delivery. If rotation ceases because of poor expulsive forces and pelvic contractures are absent, vaginal delivery usually can be accomplished readily in a number of ways. The easiest is that the occiput may be manually rotated anteriorly or posteriorly. If successful, Le Ray and co-workers (2007) reported a 4-percent cesarean delivery rate compared with nearly 60-percent in women who failed manual rotation. Alternatively, some clinicians apply Kielland forceps to the occiput transverse position as described in Chapter 23 (p. 517). These forceps are used to rotate the occiput to the anterior position. The head is delivered either with the same forceps or with Simpson or Tucker–McLane forceps. If spontaneous rotation fails because of hypotonic uterine contractions *without cephalopelvic disproportion,* oxytocin may be infused and closely monitored.

The genesis of the occiput transverse position is not always so simple or the treatment so benign. With the platypelloid (anteroposteriorly flattened) and the android (heart-shaped) pelves, there may not be adequate room for rotation of the occiput to either the anterior or the posterior position (see Fig. 2-24, p. 33). With the android pelvis, the head may not even be engaged, yet the scalp may be visible through the vaginal introitus as the consequence of considerable molding and caput formation. Consequently, if forceps delivery is attempted, undue force should be avoided.

Dystocia from Hydrocephalus

Macrocephaly from excessive accumulation of cerebrospinal fluid may prohibit vaginal delivery. Normal fetal head circumference at term ranges between 32 and 38 cm. With hydrocephalus, the circumference often exceeds 50 cm and may reach 80 cm. Fluid volume is usually between 500 and 1500 mL but as much as 5 L may accumulate. For a number of reasons, discussed in Chapter 13 (p. 287), it is uncommon with births at term. Associated defects are frequent, especially neural-tube defects. Breech presentation is found in at least a third of fetuses and may present problems in undiagnosed cases (**Fig. 20-13**).

Management. If the biparietal diameter (BPD) is < 10 cm or if the head circumference is < 36 cm, vaginal delivery may be permitted (Anteby and Yagel, 2003). In many cases, however, the macrocephalic head must be reduced in size to deliver it. Even with cesarean delivery, it may be desirable to remove cerebrospinal fluid just before incising the uterus to circumvent extensions of a low transverse or vertical incision or to avoid deliberately creating a long vertical uterine incision. Removal of fluid by *cephalocentesis* was a mainstay in the historical intrapartum management of hydrocephalus, but it has come under considerable scrutiny in recent years. Chervenak and colleagues (1985) described results of cephalocentesis in 11 fetuses for whom the procedure was used to permit vaginal or cesarean delivery. Ten of these fetuses died either in utero or within 3 hours of delivery. Seven had intracranial bleeding at autopsy. Chervenak

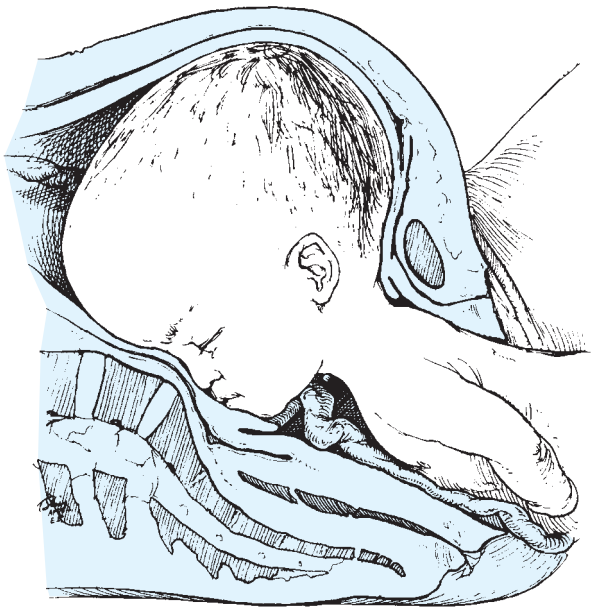

FIGURE 20-13 Severe dystocia from hydrocephalus and breech presentation. Note the distension of the lower uterine segment.

and McCullough (1986) and Chasen and associates (2001) advocate that cephalocentesis use be limited to fetuses with severe associated abnormalities. They recommended that all others be delivered abdominally. Such management requires precise knowledge of the extent of fetal malformations, which is not always possible.

Fetal Abdominal Distension

Enlargement of the fetal abdomen sufficient to cause dystocia is usually the result of a *greatly distended bladder, ascites,* or *enlargement of the kidneys or liver.* Occasionally, the edematous fetal abdomen may attain such proportions that spontaneous delivery is impossible (**Fig. 20-14**). These abnormalities are frequently diagnosed sonographically before delivery, and the decision must be made whether or not to perform cesarean delivery (Clark and co-workers, 1985). In general, fetal prognosis is poor, regardless of the delivery method.

SHOULDER DYSTOCIA

The incidence of shoulder dystocia varies greatly depending on the criteria used for diagnosis. For example, Gross and co-workers (1987) reported that 0.9 percent of almost 11,000 vaginal deliveries were coded for shoulder dystocia at the Toronto General Hospital. True shoulder dystocia, however, diagnosed as such when maneuvers were required to deliver the shoulders in addition to downward traction and episiotomy, was identified in only 0.2 percent. Current reports cite an incidence of shoulder dystocia that varies between 0.6 percent and 1.4 percent (American College of Obstetricians and Gynecologists, 2002; Gottlieb and Galan, 2007).

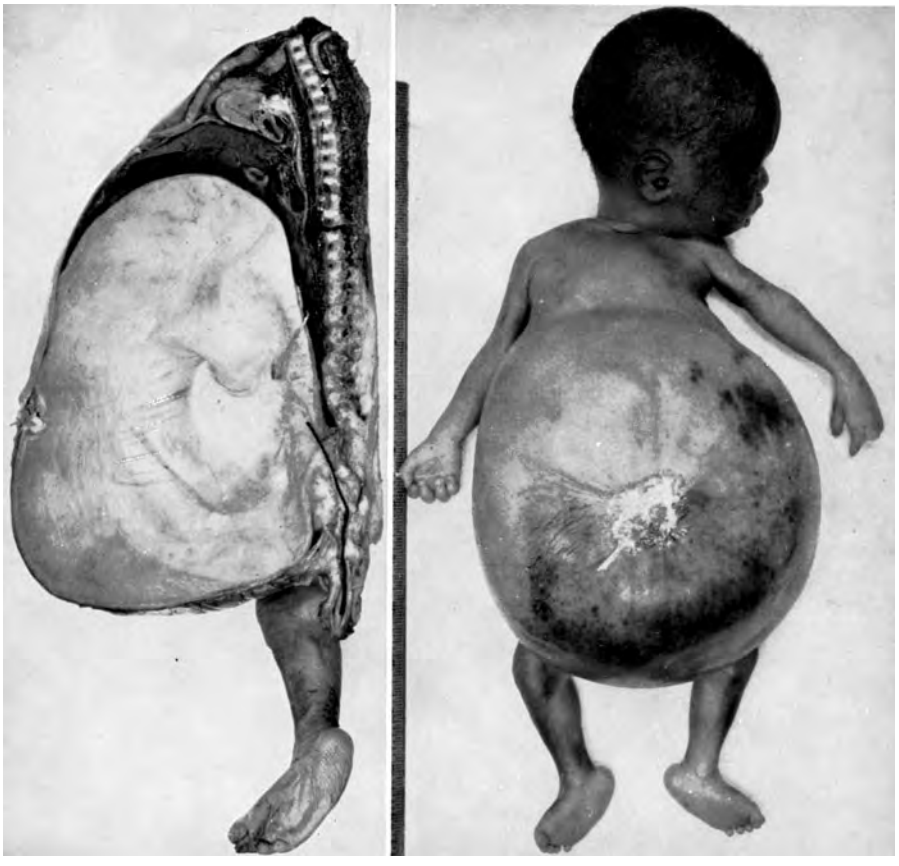

FIGURE 20-14 Fetal abdominal dystocia at 28 weeks caused by an immensely distended bladder. Delivery was made possible by expression of fluid through a bladder perforation at the level of the fetal umbilicus. Section shows the interior of the bladder and compression of organs of abdominal and thoracic cavities. A black thread has been laid in the urethra. (This figure was published in *American Journal of Obstetrics & Gynecology*, Vol. 29, JE Savage, Dystocia due to dilation of the fetal urinary bladder, p. 267, Copyright Elsevier 1935.)

There is evidence that the incidence of shoulder dystocia has increased in recent decades, likely due to increasing birthweight (Hopwood, 1982; MacKenzie and colleagues, 2007). The increased incidence may be due to more attention to its appropriate documentation (Nocon and co-workers, 1993). As discussed in Chapter 38 (p. 853), gross fetal birthweight—*macrosomia*—is important, but distribution of excessive tissue with *large-for-gestational age* infants is also important in its etiology.

The use of maneuvers to define shoulder dystocia has been appropriately questioned (Beall and associates, 1998; Spong and colleagues, 1995). In deliveries in which shoulder dystocia is anticipated, one or more maneuvers may be used prophylactically, and the diagnosis not recorded. In other cases, one or two maneuvers may be used with rapid resolution of dystocia and with an excellent

outcome, and the diagnosis also is not recorded. Spong and colleagues (1995) attempted to more objectively define shoulder dystocia by witnessing 250 unselected deliveries and timing the intervals from delivery of the head, to delivery of the shoulders, and to completion of the birth. The incidence of 11 percent, defined by the use of obstetrical maneuvers, was much higher than previously reported. Only half were recorded as such by the clinicians. The mean head-to-body delivery time in normal births was 24 seconds compared with 79 seconds in those with shoulder dystocia. These investigators proposed that a head-to-body delivery time exceeding 60 seconds be used to define shoulder dystocia.

Maternal Consequences

Postpartum hemorrhage, usually from uterine atony, but also from vaginal and cervical lacerations, is the major maternal risk from shoulder dystocia (Benedetti and Gabbe, 1978; Parks and Ziel, 1978).

Fetal Consequences

Shoulder dystocia may be associated with significant fetal morbidity and even mortality. Gherman and co-workers (1998) reviewed 285 cases of shoulder dystocia and found that 25 percent were associated with fetal injuries. Transient Erb or Duchenne brachial plexopathy accounted for two thirds of injuries. In this same cohort of 285 infants, 38 percent had a clavicular fracture, and 17 percent sustained a humeral fracture. There was one neonatal death, and four newborns had persistent brachial plexopathy injuries. Mehta and associates (2007) found a similar number of injuries in a study of 205 shoulder dystocia cases in which 36 or 17.5 percent had injury—again, most involved the brachial plexus.

Brachial Plexopathy

Nerve injury to the brachial plexus may be localized to the upper or lower part of the plexus (see Chap. 29, p. 636). It usually results from stretch on the plexus during passage of the fetus through the birth canal and subsequent delivery. Downward traction on the brachial plexus during delivery of the anterior shoulder is thought to present a particular risk for such stretch.

Importantly, this is likely not the only factor that can result in brachial plexus injury. Using computer modeling, Gonik and colleagues (2003) demonstrated that stretching of the brachial plexus is greater from endogenous forces, which include maternal pushing and uterine contractions, than from iatrogenic applied force. Moreover, Jennett and associates (2001, 2002) have presented evidence that brachial plexus injuries may precede delivery itself and may occur even prior to labor. Consistent with this evidence, Alexander and co-workers (2008) reported four cases of brachial plexus in women undergoing cesarean delivery without labor.

Erb palsy and Klumpke paralysis may result from injury to the brachial plexus. These are fully described in Chapter 29 (p. 636). Chauhan and colleagues (2005) reported the incidence and outcome of brachial plexus injury during a 22-year period from 1980 to 2002. There were 89 injuries identified in 89,978 deliveries. Of the 85 delivering vaginally, only half were associated with shoulder dystocia. Importantly, 88 percent of the injuries resolved by 1 year of life.

Clavicular Fracture

These fractures are relatively common and have been diagnosed in 0.4 percent of newborns delivered vaginally at Parkland Hospital (Roberts and co-workers, 1995). Although at times associated with shoulder dystocia, the clavicle often fractures without any suspect clinical events. Investigators have concluded that isolated clavicular fractures are unavoidable, unpredictable, and have no clinical consequences (Lam and colleagues, 2002).

Prediction and Prevention of Shoulder Dystocia

There has been considerable evolution in obstetrical thinking about the preventability of shoulder dystocia. Although there are clearly several risk factors associated with shoulder dystocia, identification of individual instances before the fact has proven to be impossible.

Risk Factors

Various maternal, intrapartum, and fetal characteristics have been implicated in the development of shoulder dystocia. Several, including obesity, multiparity, and diabetes, all exert their effects because of associated increased birthweight. For example, Keller and co-workers (1991) identified shoulder dystocia in 7 percent of pregnancies complicated by gestational diabetes. Similarly, the association of postterm pregnancy with shoulder dystocia is likely because many fetuses continue to grow after 42 weeks (see Chap. 37, p. 837). Table 20-5 shows the incidence of shoulder dystocia related to birthweight groupings at Parkland

TABLE 20-5. Incidence of Shoulder Dystocia According to Birthweight Grouping in Singleton Neonates Delivered Vaginally in 1994 at Parkland Hospital

Birthweight Group	Births No.	Shoulder Dystocia No. (%)
≤ 3000 g	2953	0
3001–3500 g	4309	14 (0.3)
3501–4000 g	2839	28 (1.0)
4001–4500 g	704	38 (5.4)
> 4500 g	91	17 (19.0)
All weights	10,896	97 (0.9)

Hospital during 1994. Clearly, shoulder dystocia rates increase with greater birthweight, but almost half of the newborns with shoulder dystocia weighed less than 4000 g.

Despite this, some advocate identification of macrosomia with sonography and liberal use of cesarean delivery to avoid shoulder dystocia (O'Leary, 1992). Others have disputed the concept that cesarean delivery is indicated for large fetuses, even those estimated to weigh 4500 g. Rouse and Owen (1999a) concluded that a prophylactic cesarean delivery policy for macrosomic newborns would require more than 1000 cesarean deliveries and millions of dollars to avert a single permanent brachial plexus injury. The American College of Obstetricians and Gynecologists (2002) has concluded that performing cesarean deliveries for all women suspected of carrying a macrosomic fetus is not appropriate, except possibly for an estimated fetal weight > 5000 g in nondiabetic women and > 4500 g in those with diabetes.

Intrapartum complications associated with development of shoulder dystocia include midforceps delivery and prolonged first- and second-stage labor (Baskett and Allen, 1995; Nocon and associates, 1993). Conversely, McFarland and co-workers (1995) found that abnormalities of first- and second-stage labor were not useful predictors. Beall and colleagues (2003) randomly assigned 128 women with a fetus estimated to weigh > 3800 g to delivery with or without prophylactic McRoberts maneuvers. They found that such use of this maneuver was not beneficial.

Prior Shoulder Dystocia. Most have reported an increased risk of recurrent shoulder dystocia with a range from 13 to 25 percent (Ginsberg and Moisidis, 2001; Moore and associates, 2008; Usta and co-workers, 2008). In contrast, Baskett and Allen (1995) found the recurrence risk to be only 1 to 2 percent. Gurewitsch and colleagues (2007) have suggested that shoulder dystocia prevention in the general population is neither feasible nor cost-effective, but that intervention in women with a prior history of shoulder dystocia may minimize recurrence and the associated morbidities. The American College of Obstetricians and Gynecologists (2002) recommends that estimated fetal weight, gestational age, maternal glucose intolerance, and severity of prior neonatal injury should be evaluated and risks and benefits of cesarean delivery discussed with any woman with a history of shoulder dystocia.

Summary

The American College of Obstetricians and Gynecologists (2002) reviewed studies and concluded that:

1. Most cases of shoulder dystocia cannot be accurately predicted or prevented.
2. Elective induction of labor or elective cesarean delivery for all women suspected of having a macrosomic fetus is not appropriate.
3. Planned cesarean delivery may be considered for the nondiabetic woman with a fetus whose estimated fetal weight is > 5000 g or for the diabetic woman whose fetus is estimated to weigh > 4500 g.

Management

Because shoulder dystocia cannot be accurately predicted, clinicians should be well versed in its management principles. Following delivery of the head, the umbilical cord is compressed within the vagina, and fetal oxygenation declines. Thus, reduction in the time from delivery of the head to delivery of the body is of great importance for survival. An initial gentle attempt at traction, assisted by maternal expulsive efforts, is recommended. Some clinicians have advocated performing a large episiotomy, and adequate analgesia is certainly ideal. Moreover, a variety of techniques can be used to free the anterior shoulder from its impacted position behind the symphysis pubis:

Moderate *suprapubic pressure* can be applied by an assistant while downward traction is applied to the fetal head.

The *McRoberts maneuver* was described by Gonik and associates (1983) and named for William A. McRoberts, Jr., who popularized its use at the University of Texas at Houston. The maneuver consists of removing the legs from the stirrups and sharply flexing them up onto the abdomen (**Fig. 20-15**). Gherman and colleagues (2000) analyzed the McRoberts maneuver using x-ray pelvimetry. They found that the procedure caused straightening of the sacrum relative to the lumbar vertebrae, rotation of the symphysis pubis toward the maternal head, and a decrease in the angle of pelvic inclination. Although this does not increase pelvic dimensions, pelvic rotation cephalad tends to free the impacted anterior shoulder. Gonik and co-workers (1989) tested the McRoberts position objectively with laboratory models and found that the maneuver reduced the forces needed to free the fetal shoulder.

Woods (1943) reported that by progressively rotating the posterior shoulder 180 degrees in a corkscrew fashion, the impacted anterior shoulder could be released. This is frequently referred to as the *Woods corkscrew maneuver* (**Fig. 20-16**).

Delivery of the posterior shoulder consists of carefully sweeping the posterior arm of the fetus across the chest, followed by delivery of the arm. The shoulder girdle is then rotated into one of the oblique diameters of the pelvis with subsequent delivery of the anterior shoulder (**Fig. 20-17**).

Rubin (1964) recommended two maneuvers. First, the fetal shoulders are rocked from side to side by applying force to the maternal abdomen. If this is not successful, the pelvic hand reaches the most easily accessible fetal shoulder, which is then pushed toward the anterior surface of the chest. This maneuver most often results in abduction of both shoulders, which in turn produces a smaller shoulder-to-shoulder diameter. This permits displacement of the anterior shoulder from behind the symphysis pubis (**Fig. 20-18**).

Deliberate *fracture of the clavicle* by pressing the anterior clavicle against the pubic ramus can be performed to free the shoulder impaction. In practice, however, it is difficult to deliberately fracture the clavicle of a large neonate. If successful, the fracture will heal rapidly and is usually trivial compared with brachial nerve injury, asphyxia, or death.

Hibbard (1982) recommended that pressure be applied to the fetal jaw and neck in the direction of the maternal rectum, with strong fundal pressure applied by an assistant as the anterior shoulder is freed. Strong fundal pressure, however, applied at the wrong time may result in even further impaction of the anterior shoulder. Gross and associates (1987) reported that fundal pressure in the absence of other maneuvers "resulted in a 77-percent complication rate and was strongly associated with (fetal) orthopedic and neurologic damage."

FIGURE 20-15 The McRoberts maneuver. The maneuver consists of removing the legs from the stirrups and sharply flexing the thighs up onto the abdomen. The assistant is also providing suprapubic pressure simultaneously (*arrow*).

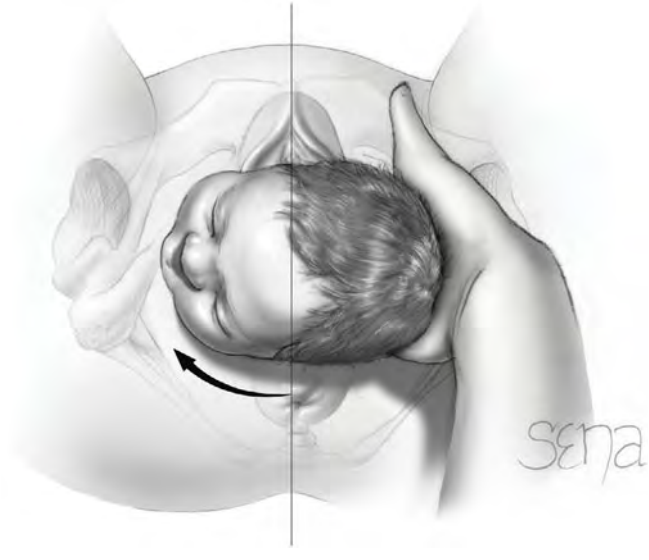

FIGURE 20-16 Woods maneuver. The hand is placed behind the posterior shoulder of the fetus. The shoulder is then rotated progressively 180 degrees in a corkscrew manner so that the impacted anterior shoulder is released.

Sandberg (1985) reported the *Zavanelli maneuver* for cephalic replacement into the pelvis followed by cesarean delivery. The first part of the maneuver consists of returning the head to the occiput anterior or posterior position. The operator flexes the head and slowly pushes it back into the vagina, following which cesarean delivery is performed. Terbutaline, 0.25 mg, is given subcutaneously to produce uterine relaxation.

Sandberg (1999) has subsequently reviewed 103 reported cases in which the Zavanelli maneuver was used. This maneuver was successful in 91 percent of cephalic cases and in all cases of breech head entrapments. Despite successful replacement, fetal injuries were still common in the desperate circumstances under which the Zavanelli maneuver was used. They reported six stillbirths, eight neonatal deaths, and 10 neonates who suffered brain damage. Uterine rupture also was reported. Ross and Beall (2006) report a case of dislocation of the cervical spine and associated stillbirth in an attempt to deliver a macrosomic infant from an impacted shoulder with this maneuver.

Cleidotomy consists of cutting the clavicle with scissors or other sharp instruments and is usually used for a dead fetus (Schramm, 1983). *Symphysiotomy* also has been applied successfully, as

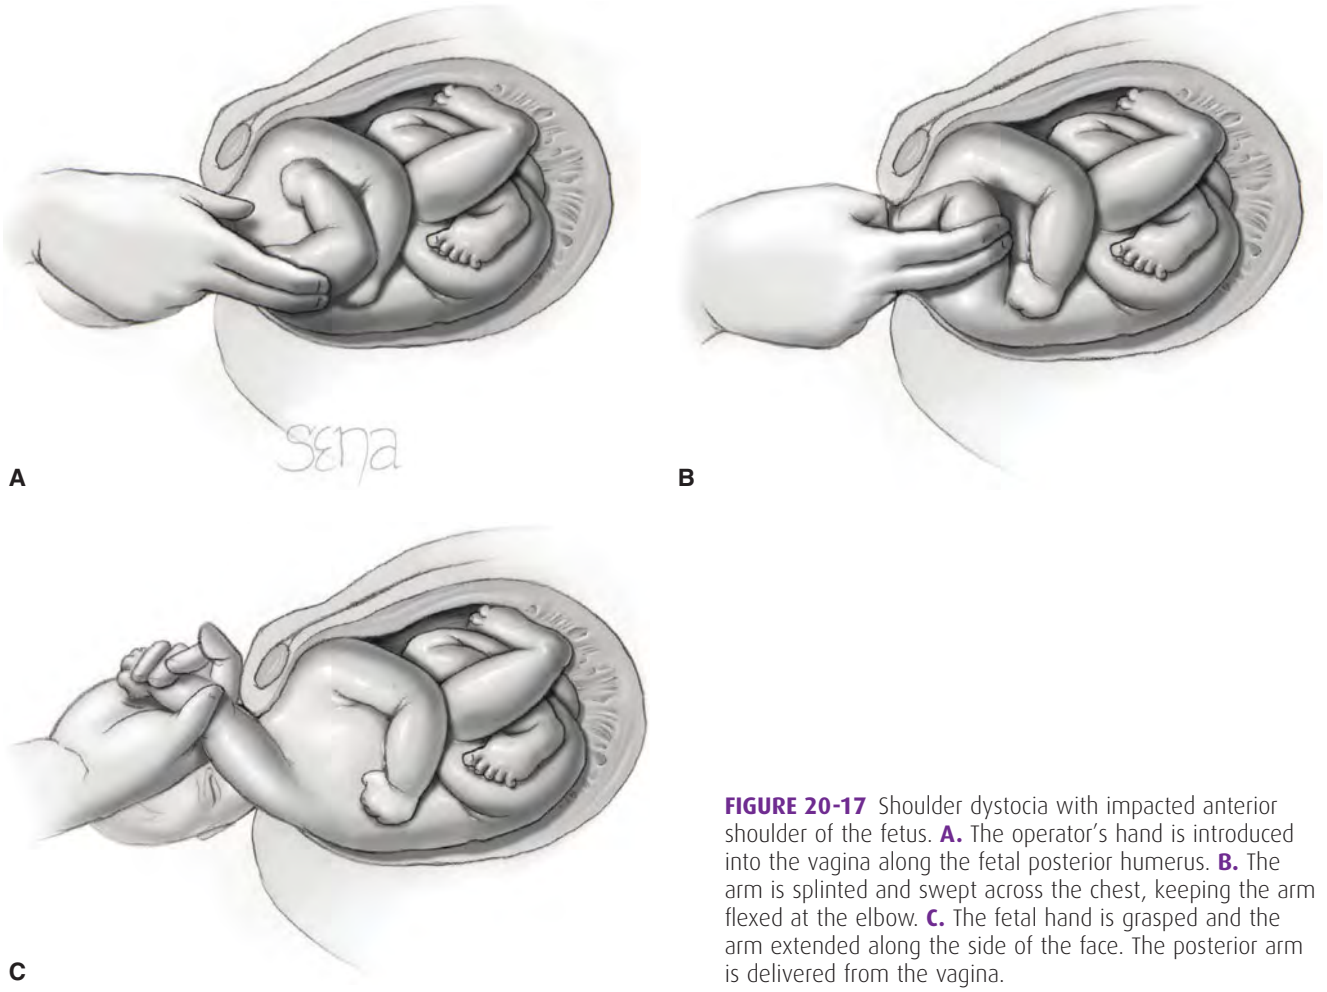

FIGURE 20-17 Shoulder dystocia with impacted anterior shoulder of the fetus. **A.** The operator's hand is introduced into the vagina along the fetal posterior humerus. **B.** The arm is splinted and swept across the chest, keeping the arm flexed at the elbow. **C.** The fetal hand is grasped and the arm extended along the side of the face. The posterior arm is delivered from the vagina.

described by Hartfield (1986). Goodwin and colleagues (1997) reported three cases in which symphysiotomy was performed after the Zavanelli maneuver had failed. All three neonates died, and maternal morbidity was significant due to urinary tract injury.

Hernandez and Wendel (1990) suggested use of a *shoulder dystocia drill* to better organize emergency management of an impacted shoulder:

1. Call for help—mobilize assistants, an anesthesiologist, and a pediatrician. Initially, a gentle attempt at traction is made. Drain the bladder if it is distended.
2. A generous episiotomy—consider mediolateral or episioproctotomy—may afford room posteriorly.
3. Suprapubic pressure is used initially by most practitioners because it has the advantage of simplicity. Only one assistant is needed to provide suprapubic pressure while normal downward traction is applied to the fetal head.
4. The McRoberts maneuver requires two assistants. Each assistant grasps a leg and sharply flexes the maternal thigh against the abdomen.

These maneuvers will resolve most cases of shoulder dystocia. If they fail, however, the following steps may be attempted:

1. The Woods screw maneuver.
2. Delivery of the posterior arm is attempted, but with a fully extended arm, this is usually difficult to accomplish.

Other techniques generally should be reserved for cases in which all other maneuvers have failed. These include intentional fracture of the anterior clavicle or humerus and the Zavanelli maneuver. Crofts (2006, 2007), Goffman (2008), Draycott (2008) and their colleagues have shown benefit from shoulder dystocia training using simulation-based education. The American College of Obstetricians and Gynecologists (2002) has concluded that there is no evidence that any one maneuver is superior to another in releasing an impacted shoulder or reducing the chance of injury. Performance of the McRoberts maneuver, however, was deemed a reasonable initial approach.

MATERNAL AND FETAL COMPLICATIONS WITH DYSTOCIA

Dystocia, especially if labor is prolonged, is associated with an increased incidence of several common obstetrical and neonatal complications. Although maternal and fetal effects resulting from dystocia are divided arbitrarily in the following discussion, dystocia may result in serious consequences to either or both simultaneously. Many are discussed in detail in other chapters.

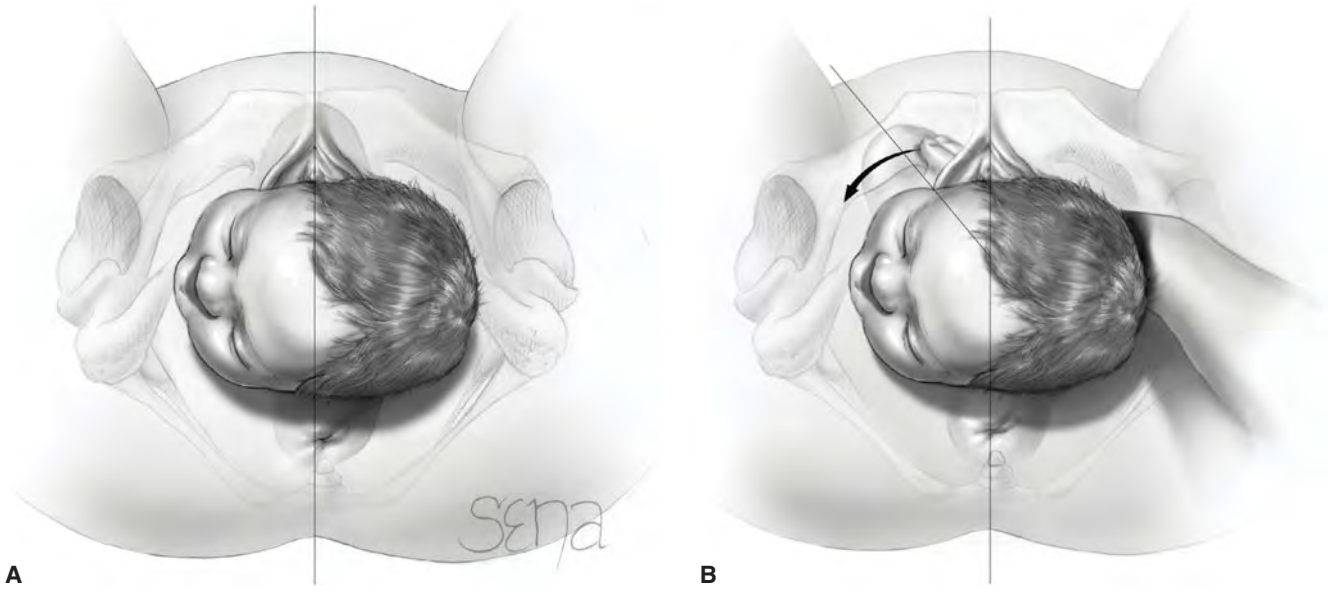

FIGURE 20-18 The second Rubin maneuver. **A.** The shoulder-to-shoulder diameter is aligned vertically. **B.** The more easily accessible fetal shoulder (the anterior is shown here) is pushed toward the anterior chest wall of the fetus (*arrow*). Most often, this results in abduction of both shoulders, reducing the shoulder-to-shoulder diameter and freeing the impacted anterior shoulder.

Maternal Complications

Intrapartum chorioamnionitis and postpartum pelvic infection are more common with desultory and prolonged labors (see Chap. 31, p. 661). Postpartum hemorrhage from atony is increased with prolonged and augmented labors and is discussed in Chapter 35 (p. 774). Hemorrhage from cesarean delivery is contributory, and there is a higher incidence of uterine tears with hysterotomy if the fetal head is impacted in the pelvis.

Uterine Rupture

Abnormal thinning of the lower uterine segment creates a serious danger during prolonged labor, particularly in women of high parity and in those with a prior cesarean delivery (see Chap. 35, p. 784). When disproportion is so pronounced that there is no engagement or descent, the lower uterine segment becomes increasingly stretched, and rupture may follow. In such cases, there is usually an exaggeration of the normal *contraction ring* shown in Figure 20-2 and also described in Chapter 6 (p. 143 and Fig. 6-3).

Pathological Retraction Ring. Localized rings or constrictions of the uterus develop in association with prolonged obstructed labors that are seldom encountered today. The *pathological retraction ring of Bandl* is associated with marked stretching and thinning of the lower uterine segment. The ring may be seen clearly as a uterine indentation and signifies impending rupture of the lower uterine segment.

Following birth of a first twin, a pathological ring may still develop occasionally as hourglass constrictions of the uterus. The ring can sometimes be relaxed and delivery effected with appropriate general anesthesia, but occasionally prompt cesarean delivery offers a better prognosis for the second twin (see Chap. 39, p. 882).

Fistula Formation

With dystocia, the presenting part is firmly wedged into the pelvic inlet and does not advance for a considerable time. Tissues of the birth canal lying between the leading part and the pelvic wall may be subjected to excessive pressure. Because of impaired circulation, necrosis may result and become evident several days after delivery as vesicovaginal, vesicocervical, or rectovaginal fistulas. Most often, pressure necrosis follows a very prolonged second stage. They are rarely seen today except in undeveloped countries.

Pelvic Floor Injury

Injury to the pelvic floor muscles, nerve supply, or interconnecting fascia is a common consequence of vaginal delivery, particularly if the delivery is difficult (Branham, 2007; Kearney, 2006; Weidner, 2006, and all their associates). During childbirth, the pelvic floor is exposed to direct compression from the fetal head and to downward pressure from maternal expulsive efforts. These forces stretch and distend the pelvic floor, resulting in functional and anatomical alterations in the muscles, nerves, and connective tissues (see Fig. 2-26, p. 34). There is accumulating concern that such effects on the pelvic floor during childbirth lead to urinary and anal incontinence and to pelvic organ prolapse (Delancey, 2008; Dietz, 2005; Nichols, 2005, and all their colleagues). As discussed in Chapter 17 (p. 400), the anal sphincter is torn in 3 to 6 percent of deliveries, and approximately half of these women report subsequent fecal or gas incontinence (Zetterstrom and co-workers, 1999).

At Parkland Hospital, Casey and colleagues (2005) found that the incidence of pelvic floor dysfunction symptoms were increased with forceps delivery, birthweight > 4000 g, and episiotomy. In an earlier poll of English female obstetricians, 30 percent expressed preference for an elective cesarean delivery rather than vaginal delivery and cited avoidance of pelvic floor injury as the explanation for their choice (Wagner, 2000). Many of these long-term sequelae have contributed to the current trend of *cesarean delivery for maternal request* discussed in Chapter 25 (p. 548).

Childbirth has also been increasingly recognized as one of many factors leading to pelvic floor prolapse (American College of Obstetricians and Gynecologists, 2007; Schaffer and Hughes, 2008). And according to Nygaard (2006), de novo postpartum incontinence, although uncommon, is likely caused by childbirth and should be the focus of preventative measures. Clearly, there is uncertainty regarding the long-term impact of childbirth-associated pelvic floor injury, and several groups are studying this.

Postpartum Lower Extremity Nerve Injury

Wong and colleagues (2003) reviewed neurological injury involving the lower extremities in association with labor and delivery. The most common mechanism is external compression of the peroneal nerve, usually caused by inappropriate leg positioning in stirrups, especially during a prolonged second-stage labor. These and other injuries are discussed in Chapter 30 (p. 656). Fortunately, symptoms resolve within 6 months of delivery in most women.

Perinatal Complications

Similar to the mother, the incidence of peripartum fetal sepsis is increased with longer labors. Mechanical injuries are more common because there are more operative as well as traumatic injuries. C*aput succedaneum* may be impressive and *molding*, is shown in Figure 17-19 (p. 387), and is commonly seen with dystocia (Buchmann and Libhaber, 2008). It must be distinguished from a *cephalohematoma*. These other injuries are discussed in Chapter 29 (p. 633).

CHAPTER 21

Disorders of Amnionic Fluid Volume

NORMAL AMNIONIC FLUID VOLUME 490
HYDRAMNIOS 491
OLIGOHYDRAMNIOS 495

Amnionic fluid serves several roles during pregnancy. It creates a physical space for the fetal skeleton to shape normally, promotes normal fetal lung development, and helps to avert compression of the umbilical cord. The most common intrinsic abnormalities that are encountered clinically are either too much or too little amnionic fluid.

NORMAL AMNIONIC FLUID VOLUME

Normally, amnionic fluid volume reaches 1 L by 36 weeks and decreases thereafter to less than 200 mL at 42 weeks (**Table 21-1**). Diminished fluid is termed *oligohydramnios*. Somewhat arbitrarily, more than 2 L of amnionic fluid is considered excessive and is termed *hydramnios* or *polyhydramnios*. In rare instances, the uterus may contain an enormous quantity of fluid, with reports of as much as 15 L. In most instances, chronic hydramnios develops, which is the gradual increase of excessive fluid. In acute hydramnios, the uterus may become markedly distended within a few days.

Measurement of Amnionic Fluid

Over the past decades, a number of sonographic methods have been used to measure the amount of amnionic fluid. Phelan and colleagues (1987) described quantification using the *amnionic fluid index—AFI*. This is calculated by adding the vertical depths of the largest pocket in each of four equal uterine quadrants. According to their calculations, significant hydramnios is defined by an index greater than 24 cm. Magann and colleagues (2000) performed a cross-sectional study of longitudinal changes in the amnionic fluid index in normal pregnancies (**Fig. 21-1**). Their curve and the ones of Hinh and Ladinsky (2005) and Machado and colleagues (2007) show a peak AFI at approximately 32 weeks followed by a steady decline until 42 weeks. Normal values for multifetal pregnancy have been provided by Porter and associates (1996) and Hill and co-workers (2000) and are discussed further in Chapter 39 (p. 879).

The group from the University of Mississippi has performed several investigations to assess the sonographic accuracy of AFI evaluation. Magann and associates (1992) compared AFI values with measurements obtained by dye dilution. They used this technique to measure amnionic fluid in 40 women undergoing amniocentesis in late pregnancy. They found that the AFI was reasonably reliable in determining normal or increased amnionic fluid but was inaccurate in diagnosing oligohydramnios. In comparison with other tools of amnionic fluid measurement, this group showed poor correlation among the AFI, the two-diameter fluid pocket, and the single deepest-pocket methods (Chauhan, 1997; Johnson, 2007; Magann, 2003a, b, 2004, and all their associates). In addition, Morris and colleagues (2003) studied 1584 women at term and found that the AFI was superior to the single deepest pocket. Magann and colleagues (2001) evaluated the addition of color Doppler imaging and concluded that its concurrent use with AFI measurements leads to overdiagnosis of oligohydramnios. Peedicayil and colleagues (1994) emphasized that borderline values should be repeated before interventions are undertaken.

Several factors may modulate the AFI. For example, Yancey and Richards (1994) reported that high altitude—6000 ft—was associated with an increased index. Most, but not all, have reported that maternal hydration increased the index (Bush, 1996; Deka, 2001; Kerr, 1996; Kilpatrick, 1993; Magann, 2003c, and all their associates). This effect dissipates by 24 hours and has not been proven to improve outcome (Malhotra and Deka, 2004).

TABLE 21-1. Typical Amniotic Fluid Volume

Weeks' Gestation	Fetus (g)	Placenta (g)	Amniotic Fluid (mL)	Percent Fluid
16	100	100	200	50
28	1000	200	1000	45
36	2500	400	900	24
40	3300	500	800	17

From Queenan (1991), with permission.

Conversely, fluid restriction or dehydration may lower the AFI. In postterm pregnancy, Oz and colleagues (2002) investigated the etiology of oligohydramnios. They found a reduction in renal artery end-diastolic velocity, suggesting that increased arterial impedance is an important etiological factor. Ross and colleagues (1996) administered 1-deamino-[8-D-arginine] vasopressin (DDAVP) to women with oligohydramnios. This resulted in maternal serum hypoosmolality—285 to 265 mOsm/kg—that was associated with an increase in the AFI from 4 to 8 cm within 8 hours.

HYDRAMNIOS

Incidence

Excessive amniotic fluid is identified in approximately 1 percent of pregnancies. The diagnosis usually is suspected clinically and confirmed by sonographic examination. An extreme example is shown in **Figure 21-2**. Most investigators define hydramnios as an AFI of greater than 24 to 25 cm—corresponding to greater than the 95th or 97.5th percentiles. Using an index of 25 cm or greater, Biggio and colleagues (1999) reported a 1-percent incidence in more than 36,000 women examined at the University of Alabama. These observations confirmed the findings of Hill and associates (1987). These findings, summarized in **Figure 21-3**, included 80 percent with mild hydramnios—defined as pockets measuring 8 to 11 cm in vertical dimension. Moderate hydramnios—defined as a pocket containing only small parts and measuring 12 to 15 cm deep—was found in 15 percent. Only 5 percent had severe hydramnios, defined by a free-floating fetus found in pockets of fluid of 16 cm or greater. Golan and co-workers (1993) reported remarkably similar findings in nearly 14,000 women.

Causes of Hydramnios

The degree of hydramnios, as well as its prognosis, is often related to the cause. Many reports are biased because they consist of observations from women referred for targeted sonographic evaluation. Others are population based but still may not reflect an accurate incidence unless universal sonographic screening is performed. In either case, obvious pathological hydramnios frequently is associated with fetal malformations, especially of the central nervous system or gastrointestinal tract. For example, hydramnios accompanies approximately half of cases of anencephaly and esophageal atresia. In the study by Hill and associates (1987), the cause of mild hydramnios was identified in only 15 percent of cases. Conversely, with moderate or severe hydramnios, the etiology was identified in more than 90 percent, and fetal anomalies were present in half of these cases. The opposite is not true, however, and in the Spanish Collaborative Study of Congenital Malformations with more than 27,000 anomalous fetuses, only 3.7 percent had hydramnios, whereas another 3 percent had oligohydramnios (Martinez-Frias and colleagues, 1999).

Damato and colleagues (1993) reported findings from 105 women referred for evaluation of excessive fluid, of whom

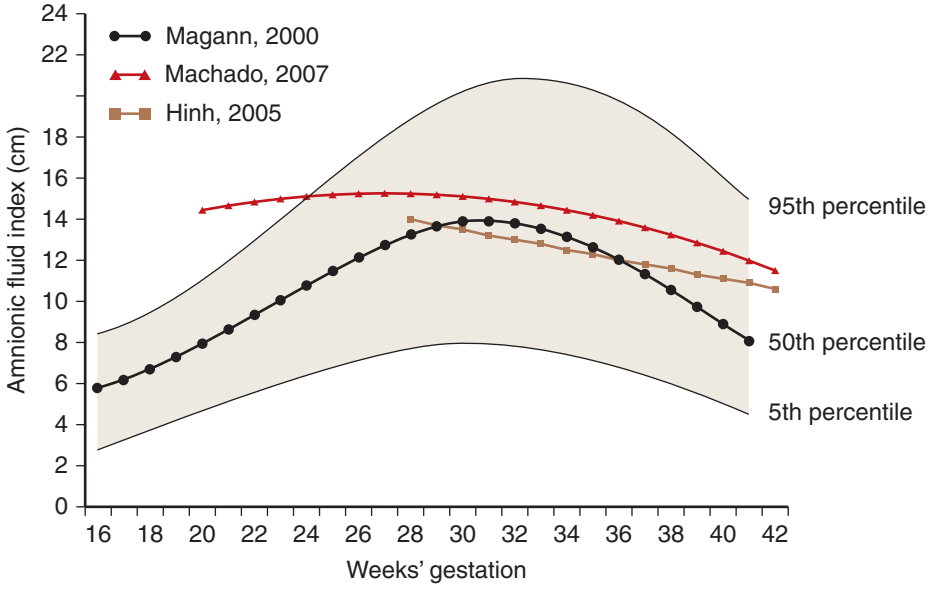

FIGURE 21-1 Normal percentiles for amniotic fluid index (AFI) during uncomplicated pregnancy. Black curves represent the 5th, 50th, and 95th percentile values from Magann and co-workers (2000). Red and tan curves represent 50th percentile values from Machado and colleagues (2007) and from Hinh and Ladinsky (2005), respectively.

FIGURE 21-2 Advanced degree of hydramnios—5500 mL of amnionic fluid was measured at delivery.

almost 65 percent had an abnormal outcome. There were 47 singletons with one or more abnormalities that included gastrointestinal anomalies (15), nonimmune hydrops (12), chromosomal abnormalities (7), and central nervous system (12), thoracic (9), skeletal (8), and cardiac malformations (4). Among 19 twin pregnancies, 12 involved twin-twin transfusion syndrome, and only two of the 19 were normal.

Other less common causes of hydramnios include fetal pseudohypoaldosteronism, fetal Bartter or hyperprostaglandin E syndrome, fetal nephrogenic diabetes insipidus, placental chorioangioma, fetal sacrococcygeal teratoma, and maternal substance abuse (Narchi and colleagues, 2000; Panting-Kemp and associates, 2002).

Idiopathic hydramnios is excess amnionic fluid not associated with congenital anomalies, malformations, maternal diabetes, isoimmunization, infection, tumors or multifetal gestation. It occurs in approximately half of all hydramnios cases. However, even when sonography and radiography show an apparently normal fetus, the prognosis is still guarded, because fetal malformations and chromosomal abnormalities are common. For example, Brady and colleagues (1992) identified 125 cases of unexplained or idiopathic hydramnios in 5000 population-based pregnancies. Of these, two fetuses had trisomy 18 and two had trisomy 21.

Pathogenesis

Early in pregnancy, the amnionic cavity is filled with fluid very similar in composition to extracellular fluid. During the first

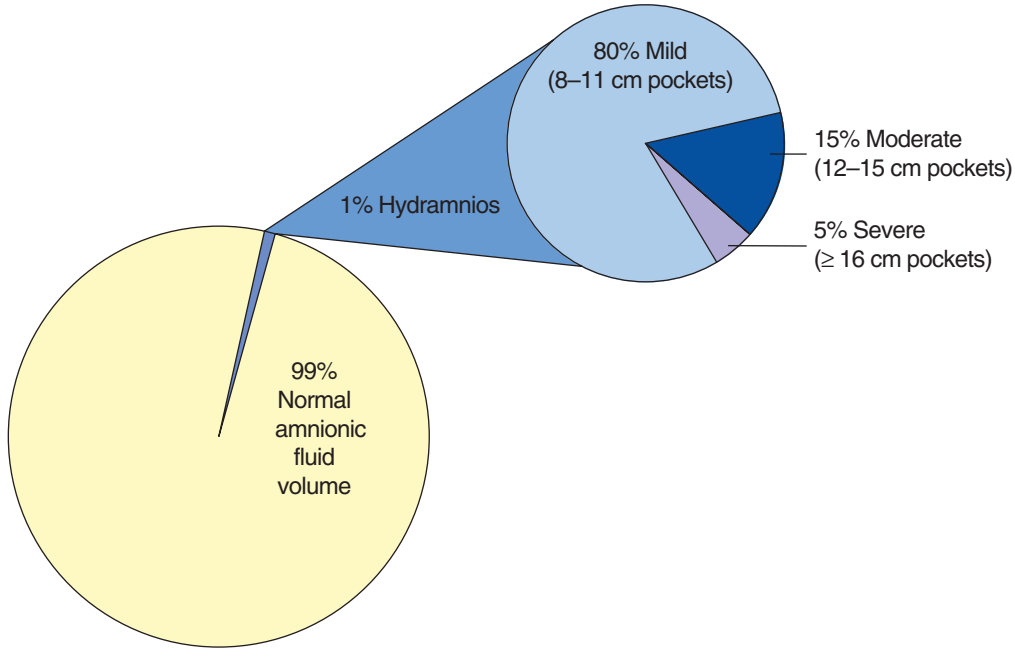

FIGURE 21-3 Amnionic fluid indexes in 36,796 pregnancies studied sonographically at 20 weeks or greater. (Data from Biggio and associates, 1999.)

half of pregnancy, transfer of water and other small molecules takes place not only across the amnion but also through fetal skin. During the second trimester, the fetus begins to urinate, swallow, and inspire amnionic fluid (Abramovich and colleagues, 1979; Duenhoelter and Pritchard, 1976). These processes have a modulating role in the control of fluid volume. Although the major source of amnionic fluid in hydramnios has most often been assumed to be the amnionic epithelium, no histological changes in amnion or chemical changes in amnionic fluid have been found.

The role of aquaporins—cell membrane water-channel proteins—has received attention recently. Some of these transmembrane proteins are expressed in fetal membranes and possibly ensure amnionic fluid homeostasis (Liu and associates, 2008; Wang and colleagues, 2007). Water-channel aquaporin 1 (AQP1) expression was found to be increased in membranes—especially reflected amnion—of pregnancies complicated by idiopathic hydramnios (Mann and associates, 2006). Additionally, aquaporin-1 knockout mice produce a greater volume of dilute amnionic fluid than do normal controls (Mann and coworkers, 2005).

Because the fetus normally swallows amnionic fluid, it has been assumed that this mechanism is one of the ways by which the volume is controlled. The theory gains validity by the nearly constant presence of hydramnios when fetal swallowing is inhibited, as in cases of esophageal atresia. But swallowing is not the only mechanism for preventing hydramnios. Specifically, Pritchard (1966) and Abramovich (1970) found in some instances of gross hydramnios that appreciable volumes of fluid were swallowed.

In cases of anencephaly and spina bifida, increased transudation of fluid from the exposed meninges into the amnionic cavity may result in hydramnios. Another possible explanation in anencephaly, which is not associated with abnormal swallowing, is excessive urination caused either by stimulation of cerebrospinal centers deprived of their protective coverings or by lack of antidiuretic effect because of impaired arginine vasopressin secretion.

In hydramnios associated with twin-twin transfusion syndrome (TTTS) in monozygotic twin pregnancy, the hypothesis has been advanced that one fetus usurps the greater part of the circulation common to both twins and develops cardiac hypertrophy, which in turn results in increased urine output (see Chap. 39, p. 874). Naeye and Blanc (1972) identified dilated renal tubules, an enlarged bladder, and increased urinary output in the recipient twin in the early neonatal period. This suggests that increased fetal urine production is responsible for hydramnios. Conversely, donor members of twin-twin transfusion syndrome pairs had dystrophic renal tubules and oligohydramnios. Several investigators have implicated the renin-angiotensin system in the fluid volume discordancy seen with TTTS (Galea and coworkers, 2008; Mahieu-Caputo and associates, 2000, 2005).

The hydramnios that commonly develops with maternal diabetes during the third trimester remains unexplained. One theory is that maternal hyperglycemia causes fetal hyperglycemia, resulting in osmotic diuresis. Bar-Hava and associates (1994) reported that increases in third-trimester amnionic fluid volume in women with gestational diabetes correlated with hyperglycemia the day prior to fluid measurement. Nordin and colleagues (2006) reported an association between the level of hypoglycemia and the diagnosis of hydramnios. Women requiring insulin had a fivefold increased risk of hydramnios compared with pregnant women with normal glucose control.

Clinical Manifestations

Major maternal symptoms accompanying hydramnios arise primarily from pressure exerted within the overdistended uterus and upon adjacent organs. When distension is excessive, the mother may suffer from severe dyspnea, and in extreme cases, she may be able to breathe only when upright (see Fig. 21-2). Edema, the consequence of major venous system compression by the enlarged uterus, is common. Swelling tends to be especially severe in the lower extremities, the vulva, and the abdominal wall. Rarely, oliguria may result from ureteral obstruction by the enlarged uterus (see Chap. 48, p. 1046). Hydramnios associated with fetal hydrops may cause the *mirror syndrome*, whereby the maternal condition mimics the fetus in that she develops edema and proteinuria, and frequently, preeclampsia (Carbillon and colleagues, 1997). This was originally described by Ballantyne in 1892, and it is discussed further in Chapter 29 (p. 627).

With chronic hydramnios, the accumulation of fluid takes place gradually, and a woman may tolerate excessive abdominal distension with relatively little discomfort. In acute hydramnios, however, distension may lead to disturbances sufficiently serious to be threatening. Acute hydramnios tends to develop earlier in pregnancy than does the chronic form—often as early as 16 to 20 weeks—and it may rapidly expand the uterus. As a rule, acute hydramnios leads to labor before 28 weeks, or the symptoms become so severe that intervention is mandatory.

Diagnosis

The primary clinical finding with hydramnios is uterine enlargement in association with difficulty in palpating fetal small parts and in hearing fetal heart tones. In severe cases, the uterine wall may be so tense that it is impossible to palpate any fetal parts (see Fig. 21-2). The differentiation among hydramnios, ascites, or a large ovarian cyst usually can be made by sonographic evaluation.

Pregnancy Outcome

The most frequent maternal complications associated with hydramnios are placental abruption, uterine dysfunction, and postpartum hemorrhage. The placenta may prematurely separate extensively after a rapid decrease in uterine surface area following uterine decompression due to amnionic fluid escape (see Chap. 35, p. 761). Uterine dysfunction and postpartum hemorrhage result from uterine atony consequent to overdistension. Abnormal fetal presentations and operative intervention are also common.

In general, the more severe the degree of hydramnios, the higher the perinatal mortality rate. The population-based study from the University of Alabama at Birmingham included more than 40,000 women (Biggio and co-workers, 1999). These investigators compared 370 women identified as having hydramnios with more than 36,000 women with normal fluid

TABLE 21-2. Outcomes in Women Identified to Have Hydramnios after 20 Weeks Compared with 36,426 Control Women with a Normal Amnionic Fluid Index

	Amnionic Fluid Index (AFI)			Hydramnios (n = 370)		
Factor	Hydramnios (n = 370)	Normal AFI (n = 36,426)	*p*	Diabetic (n = 71)	Nondiabetic (n = 299)	*p*
Perinatal outcomes						
Anomalies	8.4%	0.3%	<.001	0	10.4%	.005
Growth restriction	3.8%	6.7%	0.3	0	4.7%	NS

Mortality	49/1000	14/1000	<.001	0/1000	60/1000	.03
Maternal outcomes						
Cesarean delivery	47%	16.4%	<.001	70%	42%	<.001
Diabetes	19.5%	3.2%	<.001			

NS = not significant.
Data from Biggio and colleagues (1999).

volume studied at 20 weeks' gestation or later. As shown in Table 21-2, hydramnios was found to portend a significantly increased risk for adverse outcomes. Most of these were in nondiabetic women with hydramnios. Magann and colleagues (2007) found that idiopathic hydramnios is associated with fetal macrosomia, a higher risk of adverse pregnancy outcomes, and a two- to fivefold increase in perinatal mortality rates. A 12-month follow-up of infants from 24 pregnancies complicated by unexplained hydramnios found that 80 percent had normal outcomes. Of abnormal outcomes, there were two perinatal deaths, and three neonates with either West syndrome, polyuric syndrome, or pulmonary stenosis, respectively (Touboul and colleagues, 2007). Conversely, Panting-Kemp and co-workers (1999) found that idiopathic hydramnios was not associated with increased adverse outcomes except for cesarean delivery.

Furman and co-workers (2000) described substantively increased adverse perinatal outcomes if fetal-growth restriction accompanies hydramnios. Perinatal mortality rates are increased further by preterm delivery, and fetal death complicates up to 40 percent of pregnancies with hydramnios and an anomalous fetus. Other associated conditions adding to poor outcomes are erythroblastosis, maternal diabetes, and umbilical cord prolapse.

Midtrimester Hydramnios

The prognosis of midtrimester hydramnios depends on the severity. As with other cases, mild hydramnios has a reasonably good outcome. Glantz and co-workers (1994) studied 47 consecutive singleton pregnancies with a single deepest pocket of 6 to 10 cm that was identified at 14 to 27 weeks. Excessive fluid resolved spontaneously in three fourths of these pregnancies, and perinatal outcomes were similar to matched controls without hydramnios. In the group in which hydramnios persisted, two of 10 had fetal aneuploidy.

Management

Minor degrees of hydramnios rarely require treatment. Even moderate degrees with some discomfort usually can be managed without intervention until labor ensues or until the membranes rupture spontaneously. If dyspnea or abdominal pain is present or if ambulation is difficult, hospitalization becomes necessary. Bed rest, diuretics, and water and salt restriction are ineffective. More recently, indomethacin therapy has been used for symptomatic hydramnios.

Amniocentesis

The principal purpose of amniocentesis is to relieve maternal distress, and to that end, it is transiently successful. Amnionic fluid also can be tested to predict fetal lung maturity as described in Chapter 29 (p. 606). Elliott and associates (1994) reported results from 200 therapeutic amniocenteses in 94 women with hydramnios. Common causes included twin-twin transfusion syndrome—38 percent, idiopathic—26 percent, fetal or chromosomal anomalies—17 percent, and diabetes—12 percent. They removed a mean of 1650 mL of fluid at each procedure and gained an average duration-to-delivery of 7 weeks. Only three procedures were complicated—one woman had ruptured membranes, one developed chorioamnionitis, and another suffered placental abruption after 10 L of fluid were removed. Leung and co-workers (2004) cited a 3-percent incidence of complications in 134 rapid aminodrainage procedures.

Technique. To remove amnionic fluid, a clinician inserts a commercially available plastic catheter that tightly covers an 18-gauge needle through the locally anesthetized abdominal wall into the amnionic sac. The needle is withdrawn, and an intravenous infusion set is connected to the catheter hub. The opposite end of the tubing is dropped into a graduated cylinder placed at floor level. The flow of amnionic fluid is controlled

with the tubing screw clamp so that approximately 500 mL/hr is withdrawn. After 1500 to 2000 mL have been collected, the uterus usually has decreased in size sufficiently that the catheter may be withdrawn from the amnionic sac. At the same time, maternal relief is dramatic, and the danger of placental separation from decompression is slight. Using strict aseptic technique, this procedure can be repeated as necessary to provide patient comfort. Elliott and colleagues (1994) used wall suction and removed 1000 mL over 20 minutes (50 mL/min). However, we prefer more gradual removal.

Amniotomy

The disadvantage inherent with amniotomy during labor in women with excessive fluid is the possibility of cord prolapse and especially of placental abruption. Slow removal of fluid by amniocentesis helps to obviate these dangers.

Indomethacin Therapy

In their review of several studies, Kramer and colleagues (1994) concluded that indomethacin impairs fetal lung liquid production or enhances absorption, decreases fetal urine production, and increases fluid movement across fetal membranes. Maternal doses employed by most investigators range from 1.5 to 3 mg/kg per day. Cabrol and associates (1987) used indomethacin therapy for 2 to 11 weeks in eight women with idiopathic hydramnios from 24 to 35 weeks. Hydramnios, defined by at least one 8-cm fluid pocket, improved in all cases. There were no serious adverse effects, and the outcomes were good. Mamopoulos and colleagues (1990) treated 15 women—11 were diabetic—who had hydramnios at 25 to 32 weeks. Amnionic fluid volume decreased in all women after indomethacin was begun. The fluid in the maximum pocket decreased from a mean of 10.7 cm at 27 weeks to 5.9 cm after therapy. The outcome was good in all 15 newborns. Kriplani and colleagues (2001) successfully treated a patient with indomethacin who had hydramnios from a placental chorioangioma.

A major concern for the use of indomethacin is the potential for closure of the fetal ductus arteriosus (see Chap. 14, p. 319). Moise and colleagues (1988) reported that seven of 14 fetuses whose mothers received indomethacin had ductal constriction detected by Doppler study. Persistent constriction was not demonstrated in the reports described earlier in this section nor has it been described in studies in which indomethacin was given for tocolysis (Kramer and colleagues, 1994).

OLIGOHYDRAMNIOS

In rare instances, the volume of amnionic fluid may fall far below the normal limits and occasionally be reduced to only a few milliliters. In general, oligohydramnios developing early in pregnancy is less common and frequently has a poor prognosis. By contrast, in pregnancies that continue beyond term, diminished fluid volume may be found often. Marks and Divon (1992) found oligohydramnios—defined as an AFI of 5 cm or less—in 12 percent of 511 pregnancies of 41 weeks or greater. In 121 women studied longitudinally, there was a mean decrease of 25 percent per week in the AFI beyond 41 weeks. Gagnon and colleagues (2002) found that chronic severe placental insufficiency caused a reduction in amnionic fluid volume not attributable to reduced fetal urine production. The risk of cord compression, and in turn fetal distress, is increased with diminished fluid in all labors, but especially in postterm pregnancy (Grubb and Paul, 1992; Leveno and colleagues, 1984).

Early-Onset Oligohydramnios

A number of varied conditions have been associated with diminished amnionic fluid, and some are listed in Table 21-3. Oligohydramnios almost always is evident when there is either obstruction of the fetal urinary tract or renal agenesis. Therefore, anuria almost certainly has an etiological role in such cases. A chronic leak from a defect in the fetal membranes may reduce the volume of fluid appreciably, but most often labor soon ensues. Exposure to angiotensin-converting enzyme inhibitors has been associated with oligohydramnios (see Chap. 14, p. 319).

From 15 to 25 percent of cases of oligohydramnios are associated with the fetal anomalies shown in Table 21-4. Diminished fluid decreases the accuracy of sonographic imaging. For example, Pryde and co-workers (2000) were able to visualize fetal structures in only half of women referred for midtrimester oligohydramnios. After amnioinfusion, they were able to visualize 77 percent of routinely imaged structures. Identification of associated anomalies increased from 12 to 31 percent of fetuses.

Prognosis

Fetal outcome is generally poor with early-onset oligohydramnios. Shenker and colleagues (1991) described 80 pregnancies in which only half of the fetuses survived. Mercer and Brown (1986) described 34 midtrimester pregnancies complicated by

TABLE 21-4. Congenital Anomalies Associated with Oligohydramnios

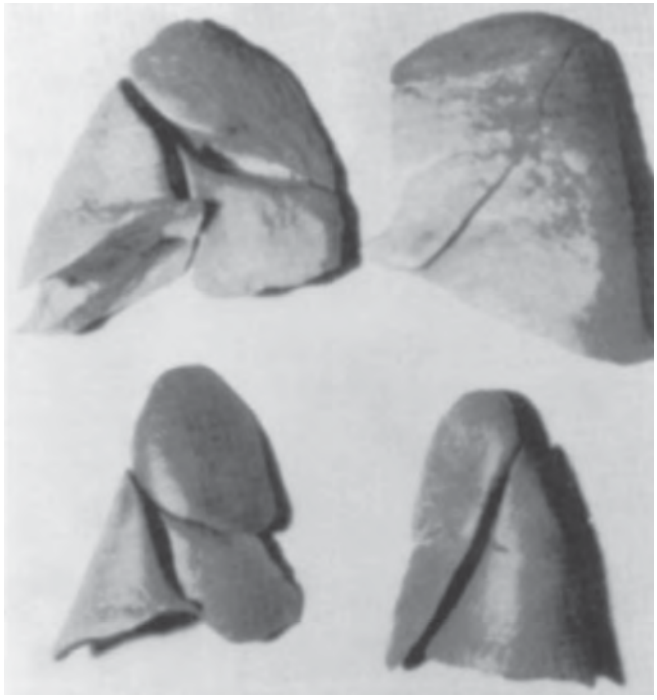

FIGURE 21-4 Normal-sized lungs (*top*) are shown in comparison with hypoplastic lungs (*bottom*) of fetuses at the same gestational age. (Reproduced from *BJOG,* Vol. 101, Issue X, MJ Newbould, M Lendon, and AJ Barson, Oligohydramnios sequence: The spectrum of renal malformations, 598, 1994, with the permission of the Royal College of Obstetricians and Gynaecologists.)

oligohydramnios defined by the absence of amnionic fluid pockets greater than 1 cm. Nine fetuses—a fourth— had anomalies, and 10 of the 25 who were phenotypically normal either aborted spontaneously or were stillborn because of severe maternal hypertension, restricted fetal growth, or placental abruption. Of the 14 liveborn infants, 8 were preterm and 7 died. The six infants who were delivered at term did well. Garmel and coworkers (1997) observed that appropriately grown fetuses associated with oligohydramnios prior to 37 weeks had a threefold increase in preterm birth but not of later growth restriction or fetal death.

Newbould and colleagues (1994) described autopsy findings in 89 infants with the Potter sequence or Potter syndrome (see Chap. 16, p. 360). Only 3 percent had a normal renal tract; 34 percent had bilateral renal agenesis; 34 percent had bilateral cystic dysplasia; 9 percent had unilateral agenesis with dysplasia; and 10 percent had minor urinary abnormalities.

Otherwise normal infants may suffer the consequences of early-onset severely diminished amnionic fluid. Adhesions between the amnion may entrap fetal parts and cause serious deformities, including amputation. Moreover, because the fetus is subjected to pressure from all sides, musculoskeletal deformities such as clubfoot are observed frequently.

Pulmonary Hypoplasia

The presence of oligohydramnios markedly increases the fetal risk for pulmonary hyperplasia such as shown in **Figure 21-4**. Its incidence at birth approximates 1 per 1000 infants, but when amnionic fluid is scant, pulmonary hypoplasia is common (Moessinger and colleagues, 1989). Winn and associates (2000) performed a prospective cohort study in 163 cases of oligohydramnios that followed prematurely ruptured membranes at 15 to 28 weeks. Almost 13 percent of fetuses developed pulmonary hypoplasia. When rupture occurred at earlier gestational ages, hypoplasia was more common. Kilbride and co-workers (1996) studied 115 women with prematurely ruptured membranes before 29 weeks. There ultimately were seven stillbirths and 40 neonatal deaths and a calculated perinatal mortality rate of 409 per 1000. The risk of lethal pulmonary hypoplasia was 20 percent. Adverse outcomes were more likely with earlier rupture as well as duration exceeding 14 days.

According to Fox and Badalian (1994) and Lauria and colleagues (1995), there are three possibilities that account for pulmonary hypoplasia. First, thoracic compression may prevent chest wall excursion and lung expansion. Second, lack of fetal breathing movements decreases lung inflow. The third and the most widely accepted model involves a failure to retain intrapulmonary amnionic fluid or an increased outflow with impaired lung growth and development. Albuquerque and colleagues (2002) found a relationship between oligohydramnios and spinal flexion in the human fetus that also may contribute to fetal pulmonary hypoplasia.

Oligohydramnios in Late Pregnancy

Using an amnionic fluid index of less that 5 cm, Casey and co-workers (2000) cited an incidence of oligohydramnios of

TABLE 21-5. Pregnancy Outcomes (in percent) in 147 Women with Oligohydramnios at 34 Weeks

Factor	Oligohydramnios[a] (n = 147)	Normal AFI (n = 6276)	*p*
Labor induction	42	18	<.001

Data from Casey and co-workers (2000).

2.3 percent in more than 6400 pregnancies undergoing sonography after 34 weeks at Parkland Hospital. They confirmed previous observations that this finding is associated with an increased risk of adverse perinatal outcomes (**Table 21-5**).

Management of oligohydramnios in late pregnancy depends on the clinical situation. Initially, an evaluation for fetal anomalies and growth is critical. In a pregnancy complicated by oligohydramnios and fetal-growth restriction, close fetal surveillance is important because of associated morbidity. In many cases, evidence for fetal or maternal compromise will override potential complications from preterm delivery. However, oligohydramnios detected before 36 weeks in the presence of normal fetal anatomy and growth may be managed expectantly in conjunction with increased fetal surveillance (see Chap. 15, p. 334).

The outcomes of pregnancies with intrapartum oligohydramnios are conflicting. Chauhan and associates (1999) performed meta-analysis of 18 studies comprising more than 10,500 pregnancies in which the intrapartum AFI was less than 5 cm. Compared with controls whose index was greater than 5 cm, women with oligohydramnios had a significantly increased 2.2-fold risk for cesarean delivery for fetal distress and a 5.2-fold increased risk for a 5-minute Apgar score of less than 7. Cord compression during labor is common with oligohydramnios. Baron and colleagues (1995) reported a 50-percent increase in variable decelerations during labor and a sevenfold increased cesarean delivery rate in these women. Divon and associates (1995) studied 638 women with a postterm pregnancy in labor and observed that only those whose amnionic fluid index was 5 cm or less had fetal heart rate decelerations and meconium. Interestingly, Chauhan and colleagues (1995) showed that diminished amnionic fluid index increased the cesarean delivery rate only in women whose labor attendants were made aware of the findings!

Conversely, using the RADIUS trial database, Zhang and colleagues (2004) reported that oligohydramnios of this degree was not associated with adverse perinatal outcomes. Similarly, Magann and co-workers (1999) did not find that associated oligohydramnios increased risks for intrapartum complications. Casey and co-workers (2000) showed a 25-percent increase in nonreassuring fetal heart rate patterns when women with oligohydramnios were compared with normal controls. Despite this, the cesarean delivery rate for pregnancies with this finding increased only from 3 to 5 percent (see Table 21-5).

Amnioinfusion

Numerous studies have evaluated whether intrapartum amnioinfusion may prevent fetal morbidity from meconium-stained fluid—often associated with oligohydramnios. Pierce and colleagues (2000) performed meta-analysis of 13 such studies of more than 1900 women. They found that amnioinfusion resulted in significantly decreased adverse outcomes that included meconium beneath the cords (OR 0.18), meconium aspiration syndrome (OR 0.30), neonatal acidemia (OR 0.42), and cesarean delivery rate (0.74). Conversely, Spong and associates (1994) found no benefits when they compared therapeutic with prophylactic amnioinfusion for meconium. Indeed, meconium aspiration syndrome occurred only in the group undergoing therapeutic amnioinfusion. Surprisingly, only 16 percent of the group randomized to expectant therapy ultimately required amnioinfusion for variable fetal heart rate decelerations. These findings are in agreement with reviews of outcomes before and after amnioinfusion protocols were implemented (De Meeus, 1997; Rogers, 1996; Usta, 1995, and all their colleagues).

Fraser and associates (2005) reported results from a 56-center, 13-country international trial of amnioinfusion in 1998 women at term in labor and with thick meconium. They found that amnioinfusion did not reduce the risk of meconium aspiration syndrome, cesarean delivery, or other major indicators of maternal or neonatal morbidity. The incidence of perinatal death or meconium aspiration syndrome was not significantly different—4.5 versus 3.4 percent in the amnioinfused women compared with controls. Finally, Xu and colleagues (2007) recently performed a meta-analysis of 12 trials that included more than 4000 women randomly assigned to amnioinfusion versus no treatment. When outcomes in 1999 women undergoing

amnioinfusion were compared with those in 2031 control women, there was no evidence that amnioinfusion reduced the risk of meconium aspiration syndrome (RR 0.59, 95% CI 0.28–1.25), 5-minute Apgar score <7 (RR 0.9, 95% CI 0.58–1.41), or cesarean delivery (RR 0.89, 95% CI 0.73–1.1).

Finally, a number of maternal deaths have been associated with amnioinfusion in pregnancies complicated by thick meconium-stained fluid (Dibble and Elliot, 1992; Maher and colleagues, 1994). In at least seven of these cases, rapid labor was thought to play a major role (Dorairajan and Soundararaghavan, 2005).

Taken together, these results suggest that routine prophylactic amnioinfusion for labors complicated by meconium-stained amnionic fluid is not warranted. Indeed, the American College of Obstetricians and Gynecologists (2006) concluded that routine prophylactic amnioinfusion for this reason is not recommended. The College, however, concluded that amnioinfusion is a reasonable approach in the treatment of repetitive variable decelerations, regardless of amnionic fluid meconium status. Amnioinfusion is discussed in greater detail in Chapter 29 (p. 628), and the technique is described in Chapter 18 (p. 433).

CHAPTER 22

Labor Induction

LABOR INDUCTION 500
PREINDUCTION CERVICAL RIPENING 501
LABOR INDUCTION AND AUGMENTATION WITH OXYTOCIN 505
ACTIVE MANAGEMENT OF LABOR 508

Induction implies stimulation of contractions before the spontaneous onset of labor, with or without ruptured membranes. *Augmentation* refers to stimulation of spontaneous contractions that are considered inadequate because of failed cervical dilation and fetal descent. According to the National Center for Health Statistics, the incidence of labor induction in the United States more than doubled from 9.5 percent in 1991 to 22.5 percent in 2006 (Martin and associates, 2009). The incidence is variable between practices. For example, at Parkland Hospital approximately 35 percent of labors are induced or augmented. By comparison, at the University of Alabama at Birmingham Hospital, labor is induced in about 20 percent of women, and another 35 percent are given oxytocin for augmentation—a total of 55 percent. This chapter includes an overview of indications for labor induction and augmentation, as well as a description of various techniques to effect pre-induction cervical ripening.

LABOR INDUCTION

Indications

Induction is indicated when the benefits to either mother or fetus outweigh those of continuing the pregnancy. Indications include immediate conditions such as ruptured membranes with chorioamnionitis or severe preeclampsia. The more common indications include membrane rupture without labor, gestational hypertension, nonreassuring fetal status, postterm pregnancy, and various maternal medical conditions such as chronic hypertension and diabetes (American College of Obstetricians and Gynecologists, 1999a).

There are a number of techniques available to induce or augment labor, and these are discussed separately. Importantly, and as recommended in *Guidelines for Perinatal Care*, each obstetrical department should have its own written protocols that describe administration of oxytocin and other uterotonics (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2007).

Contraindications

Contraindications to induction are similar to those that preclude spontaneous labor or delivery. Fetal factors include appreciable macrosomia, multifetal gestation, severe hydrocephalus, malpresentation, or nonreassuring fetal status. The few maternal contraindications are related to prior uterine incision type, contracted or distorted pelvic anatomy, abnormal placentation, and conditions such as active genital herpes infection or cervical cancer.

Risks

Maternal complication rates that are increased in association with labor induction include cesarean delivery, chorioamnionitis, and uterine atony.

Cesarean Delivery Rate

This is especially increased in nulliparas undergoing induction (Luthy and colleagues, 2004; Yeast and associates, 1999). A number of investigators have reported two- to threefold risks (Hoffman and Sciscione, 2003; Maslow and Sweeny, 2000; Smith and colleagues, 2003). Moreover, these rates are inversely

related with favorability of the cervix at induction, that is, the Bishop score (Vahratian and colleagues, 2005; Vrouenraets and associates, 2005).

However, pre-induction cervical ripening may not lower the cesarean delivery rate in a nullipara with an unfavorable cervix (Mercer, 2005). In a retrospective cohort study, Hamar and associates (2001) found that the rate of cesarean delivery following elective induction was significantly increased in women without antepartum complications and with a Bishop score of 7 or greater compared with those with spontaneous labor.

In nulliparas more than 41 weeks with an unengaged vertex, the risk of cesarean delivery increases 12-fold compared with that of those with an engaged vertex (Shin and associates, 2004). There is no increased risk if the engaged fetal head is occiput posterior at the time of induction (Peregrine and colleagues, 2007).

Chorioamnionitis

Women whose labor is induced have an increased incidence of chorioamnionitis compared with those in spontaneous labor (American College of Obstetricians and Gynecologists, 1999a).

Uterine Atony

Postpartum atony and hemorrhage are more common in women undergoing induction or augmentation. Intractable atony was the indication for a third of all cesarean hysterectomies. This indication was more prevalent in women with induced or augmented labor or in those with chorioamnionitis. Shellhaas and associates (2001) reported data from nearly 137,000 deliveries in the Maternal-Fetal Units Network. There were 146 emergent postpartum hysterectomies done—about 1 per 1000 vaginal deliveries versus 1 per 200 cesarean deliveries. Importantly, 41 percent of all hysterectomies followed primary cesarean delivery. Kastner and colleagues (2002) reported similar findings.

Elective Labor Induction

There can be no doubt that elective induction for convenience of the practitioner or the woman and her family has become more prevalent. Glantz (2003) estimated that a fourth of all labor inductions were elective. Despite this, the American College of Obstetricians and Gynecologists (1999a) does not support this practice, except for logistical reasons such as a risk of rapid labor, a woman who lives a long distance from the hospital, or psychosocial indications. We are also of the opinion that routine elective induction at term is not justified, because of the increased risk for severe, albeit infrequent, adverse maternal outcomes. Tita (2009) and Clark (2009) and their colleagues have reported also significant and appreciable adverse neonatal morbidity with elective delivery prior to 39 completed weeks and without consideration or documentation of the American College of Obstetricians and Gynecologists criteria (2007, 2008) detailed in Chapters 26 (p. 571) and 29 (p. 606). If elective induction is considered at term, these risks must be discussed and informed consent obtained.

Oshiro and associates (2009) implemented guidelines to discourage deliveries prior to 39 completed weeks. Fisch and co-workers (2009) also developed and enforced similar guidelines at their institution. Both groups of investigators reported significant decreases in rates of elective deliveries following initiation of guidelines.

Expectations of Labor Induction

Several factors increase the success of labor induction and include multiparity, body mass index (BMI) <30, favorable cervix, and birthweight <3500 g (Peregrine and associates, 2006; Pevzner and co-workers, 2009). In many cases, it seems that the uterus is simply poorly prepared for labor. One example is an "unripe cervix." It is also likely that the increase in cesarean deliveries associated with induction is strongly influenced by the duration of the induction attempt, especially in the circumstance of an unfavorable cervix. Rouse and colleagues (2000) reported characteristics of failed labor induction in a prospective management protocol for 509 women, of whom 360 were nulliparas. The cesarean delivery rate was 9 percent in parous women but 25 percent in nulliparas. The authors concluded that by requiring a minimum of 12 hours of uterine stimulation with oxytocin after membrane rupture, many nulliparas who remained in the latent phase of labor at 6 and 9 hours eventually entered active labor and had a safe vaginal delivery. Simon and Grobman (2005) reported that only 2 percent of nulliparas never achieved active phase labor before cesarean delivery. They concluded that a latent phase as long as 18 hours during induction allowed most of these women to achieve a vaginal delivery without a significantly increased risk of maternal or neonatal morbidity.

The duration for either labor induction or augmentation and successful delivery has received too little attention. More precise data are needed to understand the wide range of individual management. For example, Garcia and associates (2001), after adjustment for case mix, reported that the cesarean delivery rate was about 30 percent lower at academic medical centers compared with that at community hospitals. Doyle and colleagues (2002) reported that cesarean deliveries in a community hospital were twice that of a county hospital.

PREINDUCTION CERVICAL RIPENING

The condition of the cervix—or "favorability"—is important to successful labor induction.

Cervical "Favorability"

One quantifiable method used to predict outcomes of labor induction is the score described by Bishop (1964) and presented in **Table 22-1**. A *Bishop score* of 9 conveys a high likelihood for a successful induction. Most practitioners would consider that a woman whose cervix is 2 cm dilated, 80 percent effaced, soft, and midposition and a fetal occiput at –1 station would have a successful labor induction. For research purposes, a Bishop score of 4 or less identifies an unfavorable cervix and may be an indication for cervical ripening.

As an alternate to the Bishop score, Hatfield and associates (2007) performed a meta-analysis of 20 trials in which cervical length was assessed by transvaginal sonography and used to

TABLE 22-1. Bishop Scoring System Used for Assessment of Inducibility

	Factor				
Score	Dilatation (cm)	Effacement (Percent)	Station (−3 to +2)	Cervical Consistency	Cervical Position
0	Closed	0–30	−3	Firm	Posterior
1	1–2	40–50	−2	Medium	Midposition
2	3–4	60–70	−1	Soft	Anterior
3	≥5	≥80	+1, +2	—	—

predict successful induction. Because of the heterogeneity of study criteria—including the definition of "successful induction"—the authors concluded that the question was still unanswered. They, as did Crane (2006), found that cervical length determination by sonography was not superior to use of the Bishop score.

Unfortunately, women too frequently have an indication for induction but with an unfavorable cervix. As favorability or Bishop score decreases, there is an increasingly unsuccessful induction rate. Thus, considerable research has been directed toward various techniques to "ripen" the cervix prior to stimulation of uterine contractions. In many cases, the techniques used to improve cervical favorability also stimulate contractions. Thus, they may be used to induce labor. Methods used for cervical ripening include pharmacological preparations and various forms of mechanical cervical distension.

Pharmacological Techniques

Prostaglandin E_2

Local application of prostaglandin E_2—dinoprostone—is commonly used for cervical ripening (American College of Obstetricians and Gynecologists, 1999a, b). Its gel form—Prepidil—is available in a 2.5-mL syringe for an intracervical application of 0.5 mg of dinoprostone. With the woman supine, the tip of a pre-filled syringe is placed intracervically, and the gel is deposited just below the internal cervical os. After application she remains reclined for at least 30 minutes. Doses may be repeated every 6 hours, with a maximum of three doses recommended in 24 hours.

Owen and colleagues (1991) did a meta-analysis of 18 studies with 1811 women. They found that prostaglandin E_2 improved Bishop scores and when coupled with oxytocin, lowered induction-to-delivery times compared with those of women treated with oxytocin alone. Unfortunately, they found no benefit in lowering the cesarean delivery rate.

A 10-mg dinoprostone vaginal insert—Cervidil—is also approved for cervical ripening. This is a thin, flat, rectangular polymeric wafer held within a small, white mesh polyester sac (Fig. 22-1). The sac has a long attached tail to allow easy removal from the vagina. The insert provides slower release of medication—0.3 mg/hr—than the gel form. Combined with oxytocin, these inserts have been reported to shorten the induction-to-delivery interval (Bolnick and associates, 2004). Cervidil is used as a single dose placed transversely in the posterior vaginal fornix. Lubricant should be used sparingly, if at all, with insertion. Excessive lubricant can coat and hinder the release of dinoprostone. Following insertion, a woman should remain recumbent for at least 2 hours. The insert is removed after 12 hours or with labor onset.

Administration. Prostaglandin preparations should only be administered in or near the delivery suite, and uterine activity and fetal heart rate monitoring should be performed (American College of Obstetricians and Gynecologists, 1995b). These guidelines stem from the risk that prostaglandin preparations may cause uterine tachysystole. When contractions begin, they are usually apparent in the first hour and show peak activity in the first 4 hours (Bernstein, 1991; Miller and colleagues, 1991). When Perry and Leaphart (2004) compared intracervical gel with the intravaginal insert, they found that intravaginal placement resulted in quicker delivery—11.7 versus 16.2 hours. However, when more than two sequential doses of a prostaglandin E_2 insert were used, Chan and associates (2004) reported that 59 percent of women required emergency cesarean delivery. According to manufacturer guidelines, oxytocin induction that follows prostaglandin use for cervical ripening should be delayed for 6 to 12 hours following prostaglandin E_2 administration.

Side Effects. Uterine tachysystole has been reported to follow vaginally administered prostaglandin E_2 in 1 to 5 percent of women (Brindley and Sokol, 1988; Rayburn, 1989). Although

FIGURE 22-1 Cervidil vaginal insert contains 10 mg of dinoprostone designed to release approximately 0.3 mg/hr over a 10-hour period. (Used with permission of Forest Laboratories, Inc., New York, New York).

definitions may vary among studies, most use the terms defined by the American College of Obstetricians and Gynecologists (1999a) to describe increased uterine activity as follows:

1. *Uterine tachysystole* is defined as ≥6 contractions in a 10-minute period.
2. *Uterine hypertonus* is described as a single contraction lasting longer than 2 minutes.
3. *Uterine hyperstimulation* is when either condition leads to a nonreassuring fetal heart rate pattern.

Because hyperstimulation that can cause fetal compromise may develop when prostaglandins are used with preexisting spontaneous labor, such use is not recommended. If hyperstimulation occurs with the 10-mg insert, its removal by pulling on the tail of the surrounding net sac will usually reverse this effect. Irrigation to remove the gel preparation has not been helpful.

Contraindications to prostaglandin agents in general include asthma, glaucoma, or increased intraocular pressure. Moreover, manufacturer recommendations caution against its use in women with ruptured membranes.

Prostaglandin E_1

Misoprostol—Cytotec—is a synthetic prostaglandin E_1, approved as a 100- or 200-μg tablet for prevention of peptic ulcers. It has been used "off label" for preinduction cervical ripening and may be administered orally or vaginally. The tablets are stable at room temperature.

Although it has become widespread, the off-label use of misoprostol is controversial (Wagner, 2005; Weeks and associates, 2005). In 2000, G. D. Searle & Company notified physicians that misoprostol is not approved for labor induction or abortion. Despite this, the American College of Obstetricians and Gynecologists (2000) quickly reaffirmed its recommendation for use of the drug because of proven safety and efficacy. It currently is the prostaglandin of choice for these purposes at both Parkland Hospital and the University of Alabama at Birmingham Hospital.

Vaginal Administration. Several investigators have reported that misoprostol tablets placed into the vagina were either of equivalent or superior efficacy compared with intracervical prostaglandin E_2 gel (von Gemund and associates, 2004; Wing and co-workers, 1995a, b). The American College of Obstetricians and Gynecologists (1999b) reviewed 19 randomized trials in which more than 1900 women were given intravaginal misoprostol in doses ranging from 25 to 200 μg. They recommended the 25-μg dose—a fourth of a 100-μg tablet. The drug is evenly distributed among these quartered tablets.

Misoprostol use may decrease the need for oxytocin induction and reduce induction-to-delivery intervals (Sanchez-Ramos and colleagues, 1997). Hofmeyr and associates (2003) reviewed the Cochrane database and support these recommendations, but caution that rates of uterine hyperstimulation with adverse fetal heart rate changes are increased with their use. A 50-μg misoprostol intravaginal dose has been associated with significantly increased uterine tachysystole, meconium passage, and meconium aspiration compared with prostaglandin E_2 gel (Wing and co-workers, 1995a, b). A 25-μg intravaginal dose was found comparable to dinoprostone regarding adverse neonatal outcome (von Gemund and associates, 2004).

Uterine rupture has been reported by Wing and colleagues (1998) with prostaglandin E_1 use in women with a prior cesarean delivery. Indeed, Plaut and associates (1999) reported uterine rupture in 5 of 89—6 percent—of women who had a prior cesarean incision and who were induced with misoprostol. This is compared with only 1 of 423 such women not given misoprostol. Currently, the consensus is that prior uterine surgery, including cesarean delivery, precludes the use of misoprostol (American College of Obstetricians and Gynecologists, 2004).

Oral Administration. Prostaglandin E_1 tablets are also effective when given orally. Windrim and associates (1997) reported oral misoprostol administration to be of similar efficacy as intravaginal administration for cervical ripening. Wing (2000) and Hall (2002) and their associates reported that a 100-μg oral dose was as effective as a 25-μg intravaginal dose.

Labor Induction with Prostaglandin E_1. Both vaginal and oral misoprostol may be used for either cervical ripening or labor induction. Hofmeyer and Gulmezoglu (2007) performed a Cochrane systematic review and found vaginal misoprostol, followed by oxytocin if needed, to be superior to oxytocin alone for labor induction. Rates of cesarean delivery section were variable. Some studies showed decreased rates with misoprostol, whereas others found no difference in rates.

It appears that 100 μg of oral or 25 μg of vaginal misoprostol is similar in efficacy to intravenous oxytocin for labor induction in women at or near term with either prematurely ruptured membranes or a favorable cervix (Lin and co-workers, 2005; Lo and associates, 2003). Misoprostol may be associated with an increased rate of hyperstimulation. In addition, induction with PGE_1 may prove ineffective and require subsequent augmentation with oxytocin. Thus, there are trade-offs regarding the risks, costs, and ease of administration of the two drugs, but either is suitable for labor induction. For *labor augmentation*, results of a pilot study showed oral misoprostol, 75 μg given at 4-hour intervals for a maximum of two doses, to be safe and effective (Villano and colleagues, 2010).

Nitric Oxide Donors

Several findings have led to a search for agents that stimulate nitric oxide (NO) production locally to be used for clinical purposes (Chanrachakul and co-workers, 2000). First, nitric oxide is likely a mediator of cervical ripening (see Chap. 3, p. 138). Also, cervical NO metabolites are increased at the beginning of uterine contractions. Lastly, cervical NO production is very low in postterm pregnancy (Väisänen-Tommiska and colleagues, 2003, 2004).

Bullarbo and colleagues (2007) recently reviewed rationale and use of the NO donors *isosorbide mononitrate* and *glyceryl trinitrate*. Isosorbide mononitrate induces cervical cyclo-oxygenase 2 (Ekerhovd and colleagues, 2002). It also induces cervical ultrastructure rearrangement similar to that seen with spontaneous cervical ripening (Thomson and associates, 1997; Ekerhovd and colleagues, 2003).

Clinical trials have not shown NO donors to be as effective as prostaglandin E_2 to effect cervical ripening (Chanrachakul

and associates, 2001; Osman and colleagues, 2006). And the addition of isosorbide mononitrate to either dinoprostone or misoprostol did not enhance cervical ripening either in early pregnancy or at term and did not shorten time to vaginal delivery (Collingham, 2009; Ledingham, 2001; Wölfler, 2006, and all their co-workers).

Mechanical Techniques

Transcervical Catheter

A Foley catheter may be placed through the internal cervical os. Downward tension that is created by taping the catheter to the thigh can lead to cervical ripening. A modification of this, termed *extra-amnionic saline infusion (EASI),* consists of a constant saline infusion through the catheter into the space between the internal cervical os and placental membranes (Fig. 22-2). Catheter placement, with or without continuous saline infusion, results in improved cervical favorability and frequently stimulates contractions (Guinn and associates, 2004). Sherman and colleagues (1996) summarized the results of 13 trials with balloon-tipped catheters to effect cervical dilatation. They concluded that, with or without saline infusion, the method led to rapid improvement in Bishop scores and shorter labors. Karjane and co-workers (2006) reported that chorioamnionitis was less frequent when infusion was done compared with no infusion—6 versus 16 percent.

Labor Induction. Especially with saline infusion, the transcervical catheter technique is also effective for initiating labor, and several comparative studies have been done. Chung and colleagues (2003) randomized 135 women to labor induction with vaginal misoprostol, extra-amnionic Foley catheter with bulb inflation to 30 mL, or both therapies. Outcomes were similar in all three groups, and there was no apparent benefit of combining these two techniques. Conversely, Culver and colleagues (2004) compared oxytocin plus an intracervical Foley catheter with 25-μg vaginal misoprostol every 4 hours in women with a Bishop score less than 6. The mean induction-to-delivery time was significantly shorter in the catheter-plus-oxytocin group—16 versus 22 hours. Levy and associates (2004) reported that the use of an 80-mL Foley transcervical catheter balloon compared with that of a 30-mL for cervical ripening was significantly more effective.

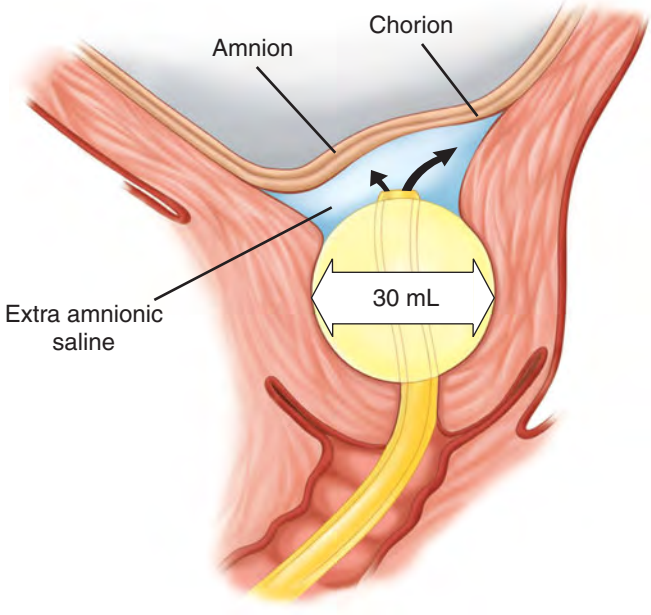

FIGURE 22-2 Extra-amnionic saline infusion (EASI) through 26F Foley catheter is placed through the cervix. The 30-mL balloon is inflated with saline and pulled snugly against the internal os, and the catheter taped to the thigh. Room-temperature normal saline is infused through the catheter port of the Foley at 30 or 40 mL/hour by intravenous infusion pump.

Extra-amnionic Saline Infusion (EASI)

This technique has been reported to significantly improve the Bishop score and decrease induction-to-delivery times compared with: (1) 50-μg intravaginal misoprostol tablets, (2) 0.5 mg of intracervical prostaglandin E_2, (3) 50-μg oral misoprostol (Goldman and Wigton, 1999; Vengalil and colleagues, 1998). In another study, Guinn and colleagues (2000) randomized women to intracervical prostaglandin E_2, laminaria plus intravenous oxytocin, or EASI plus oxytocin. The cesarean delivery rate was similar with all three interventions. The mean induction-to-delivery time of 18 hours with catheter infusion was significantly less than the 21 hours with laminaria plus oxytocin or the 25 hours with prostaglandin E_2 gel.

In one follow-up study, Sciscione and co-workers (2004) concluded that cervical ripening with a Foley catheter did not increase the risk of preterm birth in a subsequent pregnancy.

Hygroscopic Cervical Dilators

Cervical dilatation can be accomplished using hygroscopic osmotic cervical dilators, as described for early pregnancy termination (see Chap. 9, p. 229). These mechanical dilators have long been successfully used when inserted prior to pregnancy termination (Hale and Pion, 1972). More recently, they have also been used for cervical ripening before labor induction. Intuitive concerns of ascending infection have not been verified. Thus, their use appears to be safe, although anaphylaxis has followed laminaria insertion (Cole and Bruck, 2000; Nguyen and Hoffman, 1995). Dilators are attractive because of their low cost and easy placement and removal.

Gilson and associates (1996) reported a rapid improvement of cervical favorability in women randomized to hygroscopic dilators prior to oxytocin induction. There was, however, no beneficial effect on the vaginal delivery rate or induction-to-delivery times compared with those of women given oxytocin only. In the randomized study cited earlier, Guinn and co-workers (2000) reported a longer induction-to-delivery time with cervical dilators plus oxytocin compared with that of EASI plus oxytocin.

Membrane Stripping for Labor Induction

Induction of labor by membrane "stripping" is a common practice (see Fig. 6-4, p. 142). McColgin and colleagues (1990) reported that stripping was safe and decreased the incidence of postterm gestation. They documented significantly increased serum levels of endogenous prostaglandins with stripping (McColgin and associates, 1993). Allott and Palmer (1993)

randomized 195 women with normal pregnancies beyond 40 weeks to digital cervical examination either with or without membrane stripping. The women were examined as outpatients. Two thirds of those who underwent stripping entered spontaneous labor within 72 hours compared with one third of the other group. The incidence of ruptured membranes, infection, and bleeding was not increased. Importantly, subsequent induction for postterm pregnancy at 42 weeks was significantly decreased with stripping.

Summary of Preinduction Cervical Ripening

These techniques are widely used when labor induction is indicated for a woman with an "unripe cervix." Some of the preinduction techniques described may have benefits when compared with oxytocin induction alone (Table 22-2). Some are quite successful for induction. That said, there are few data to support the premise that any of these techniques results in a reduction in cesarean delivery rates or in lower maternal or neonatal morbidity compared with those of women in whom such techniques are not used.

LABOR INDUCTION AND AUGMENTATION WITH OXYTOCIN

In most instances, pre-induction cervical ripening and labor induction are simply a continuum. Often, as described above, "ripening" will also stimulate labor. If not, however, induction or augmentation may be continued with diluted intravenous solutions of oxytocin given by infusion pump.

TABLE 22-2. Some Commonly Used Regimens for Pre-induction Cervical Ripening and/or Labor Induction

Techniques	Agent	Route/Dose	Comments
Pharmacological			
Prostaglandin E_2	Dinoprostone gel, 0.5 mg (Prepidil)	Cervical 0.5 mg; repeat in 6 hr; permit 3 doses total	1. Shorter I-D times with oxytocin infusion than oxytocin alone
	Dinoprostone insert, 10 mg (Cervidil)	Posterior fornix, 10 mg	2. Insert has shorter I-D times than gel 3. 6–12 hr interval from last insert to oxytocin infusion
Prostaglandin E_1[a]	Misoprostol tablet, 100–200 μg (Cytotec)	Vaginal, 25 μg; repeat 3–6 hr prn Oral, 50–100 μg; repeat 3–6 hr prn	1. Contractions within 30–60 min 2. Comparable success with oxytocin for ruptured membranes at term and/or favorable cervix 3. Tachysystole common with doses >25 μg dosed vaginally
Mechanical			
Transcervical 36F Foley catheter	30-mL balloon		1. Improves Bishop scores rapidly 2. 80-mL balloon more effective 3. Combined with oxytocin infusion is superior to PGE_1 vaginally 4. Results improved with EASI
Hygroscopic dilators		Laminaria, magnesium sulfate	1. Rapidly improves Bishop score 2. May not shorten I-D times with oxytocin

[a]Off-label use.
EASI = extra-amnionic saline infusion at 30–40 mL/hr; I-D = induction-to-delivery.

Synthetic oxytocin is one of the most commonly used medications in the United States. It was the first polypeptide hormone synthesized, an achievement for which the 1955 Nobel Prize in chemistry was awarded (du Vigneaud and co-workers, 1953). Regarding labor, it may be used for induction or for augmentation of labor.

With oxytocin use, the American College of Obstetricians and Gynecologists (1999a) recommends fetal heart rate and contraction monitoring similar to that for any high-risk pregnancy. Contractions can be monitored either by palpation or by electronic means of recording uterine activity (see Chap. 18, p. 437). One caveat with palpation is that contraction pressures cannot be accurately quantified (Arrabal and Nagey, 1996).

Techniques

Intravenous Oxytocin Administration

The goal of induction or augmentation is to effect uterine activity sufficient to produce cervical change and fetal descent, while avoiding development of a nonreassuring fetal status. In general, oxytocin should be discontinued if the number of contractions persists with a frequency greater than five in a 10-minute period or seven in a 15-minute period or with a persistent nonreassuring fetal heart rate pattern. Discontinuation of oxytocin nearly always rapidly decreases the frequency of contractions. When oxytocin is stopped, its concentration in plasma rapidly falls because the mean half-life is approximately 5 minutes. Seitchik and co-workers (1984) found that the uterus contracts within 3 to 5 minutes of beginning an oxytocin infusion and that a plasma steady-state is reached in 40 minutes. Response is highly variable and depends on preexisting uterine activity, cervical status, pregnancy duration, and individual biological differences. Caldeyro-Barcia and Poseiro (1960) reported that the uterine response to oxytocin increases from 20 to 30 weeks and increases rapidly at term (see Chap. 18, p. 437).

Oxytocin Dosage. A 1-mL ampule containing 10 units usually is diluted into 1000 mL of a crystalloid solution and administered by infusion pump. A typical infusate consists of 10 or 20 units—or 10,000 to 20,000 mU—mixed into 1000 mL of lactated Ringer solution. This mixture results in an oxytocin concentration of 10 or 20 mU/mL, respectively. To avoid bolus administration, the infusion should be inserted into the main intravenous line close to the venipuncture site.

A number of oxytocin regimens for labor stimulation are recommended by the American College of Obstetricians and Gynecologists (1999a). These and others are shown in **Table 22-3**. Initially, only variations of low-dose protocols were used in the United States. In 1984, O'Driscoll and colleagues (1984) from Dublin described a protocol for the active management of labor that called for oxytocin at a starting dosage of 6 mU/min and advanced in 6-mU/min increments. Subsequent comparative trials during the 1990s were done to compare high-dose—4 to 6 mU/min—versus conventional low-dose—0.5 to 1.5 mU/min—regimens both for labor induction and for augmentation.

From Parkland Hospital, Satin and colleagues (1992) evaluated an oxytocin regimen using an initial and incremental dosage of 6 mU/min compared with one using 1 mU/min. Increases at 20-minute intervals were provided as needed. Among 1112 women undergoing induction, the 6-mU/min regimen resulted in a shorter mean admission-to-delivery time, fewer failed inductions, and no cases of neonatal sepsis. Among 1676 women who had labor augmentation, those who received the 6-mU/min regimen had a shorter duration-to-delivery time, fewer forceps deliveries, fewer cesarean deliveries for dystocia, and decreased intrapartum chorioamnionitis or neonatal sepsis. With this protocol, uterine hyperstimulation is managed by oxytocin discontinuation followed by resumption when indicated and at half the stopping dosage. Thereafter, the dosage is increased at 3 mU/min when appropriate instead of the usual 6-mU/min increase for women without hyperstimulation. No adverse neonatal effects were observed.

Xenakis and colleagues (1995) reported benefits using an incremental oxytocin regimen starting at 4 mU/min. In a comparative study of 1307 women by Merrill and Zlatnik (1999), 816 were randomized for labor induction and 816 for augmentation with incremental oxytocin given at either 1.5 or 4.5 mU/min. Women randomized to the 4.5 mU/min dosage had significantly decreased mean durations of induction-to-second-stage labor and induction-to-delivery. Nulliparas randomized to the 4.5 mU/min dosage had a significantly lower

TABLE 22-3. Various Low- and High-Dose Oxytocin Regimens Used for Labor Induction

Regimen	Starting Dose (mU/min)	Incremental Increase (mU/min)	Interval (min)
Low-Dose	0.5–1.5	1	15–40
	2	4, 8, 12, 16, 20 25, 30	15
High-Dose	4	4	15
	4.5	4.5	15–30
	6	6[a]	20–40[b]

[a]With hyperstimulation and after oxytocin infusion is discontinued, it is restarted at ½ the previous dose and increased at 3 mU/min incremental doses.
[b]Hyperstimulation is more common with shorter intervals.
Data from Merrill and Zlatnik (1999), Satin and associates (1992, 1994), and Xenakis and colleagues (1995).

cesarean delivery rate for dystocia compared with those given 1.5 mU/min dosage—5.9 versus 11.9 percent.

Thus, benefits favor higher-dose regimens of 4.5 to 6 mU/min compared with lower dosages of 0.5 to 1.5 mU/min. In 1990, routine use of the 6-mU/min oxytocin beginning and incremental dosage was incorporated at Parkland Hospital and continues through today. At the University of Alabama at Birmingham, a 2-mU/min beginning and incremental oxytocin regimen is administered. In both cases, these dosages are employed for either labor induction or augmentation.

Interval between Incremental Dosing

Intervals to increase oxytocin doses vary from 15 to 40 minutes (see Table 22-2). Satin and colleagues (1994) addressed this aspect with a 6-mU/min regimen providing increases at either 20- or 40-minute intervals. Women assigned to the 20-minute interval regimen for labor augmentation had a significant reduction in the rate of cesarean delivery for dystocia compared with that for the 40-minute interval regimen—8 versus 12 percent. As perhaps expected, uterine hyperstimulation was significantly more frequent with the 20-minute regimen.

Other investigators report even more frequent incremental increases. Frigoletto and associates (1995) and Xenakis and coworkers (1995) began oxytocin at 4 mU/min with increases as needed every 15 minutes. Merrill and Zlatnik (1999) started with 4.5 mU/min with increases every 30 minutes. López-Zeno and colleagues (1992) began at 6 mU/min with increases every 15 minutes. Thus, there are a number of acceptable oxytocin protocols that at least appear dissimilar. But a comparison of protocols from two of our institutions indicates that this is not so:

1. The Parkland Hospital protocol calls for a starting dose of oxytocin at 6 mU/min, with 6-mU/min increases every 40 minutes, but employs flexible dosing based on hyperstimulation.
2. The University of Alabama at Birmingham Hospital protocol begins oxytocin at 2 mU/min and increases it as needed every 15 minutes to 4, 8, 12, 16, 20, 25, and 30 mU/min.

Thus, although the regimens at first appear disparate, if there is no uterine activity, either regimen is delivering 12 mU/min by 45 minutes into the infusion.

Maximal Dosage

The *maximal* effective dose of oxytocin to achieve adequate contractions in all women is different. Wen and colleagues (2001) studied 1151 consecutive nulliparas and found that the likelihood of progression to a vaginal delivery decreased at and beyond an oxytocin dosage of 36 mU/min. At a dosage of 72 mU/min, however, half of the nulliparas were delivered vaginally. Thus, if contractions are not adequate—less than 200 Montevideo units—and if the fetal status is reassuring and labor has arrested, an oxytocin infusion dose greater than 48 mU/min has no apparent risks.

Risks versus Benefits

Unless the uterus is scarred, uterine rupture associated with oxytocin infusion is rare, even in parous women (see Chap. 35, p. 784). Flannelly and associates (1993) reported no uterine ruptures, with or without oxytocin, in 27,829 *nulliparas*. There were eight instances of overt uterine rupture during labor in 48,718 *parous* women—but only one of these was associated with oxytocin use.

Oxytocin has amino-acid homology similar to arginine vasopressin. Thus, not surprisingly, it has significant antidiuretic action, and when infused at dosages of 20 mU/min or more, renal free water clearance decreases markedly. If aqueous fluids are infused in appreciable amounts along with oxytocin, *water intoxication* can lead to convulsions, coma, and even death. In general, if oxytocin is to be administered in high doses for a considerable period of time, its concentration should be increased rather than increasing the flow rate of a more dilute solution. Consideration also should be given to use of either normal saline or lactated Ringer solution in these circumstances.

Uterine Contraction Pressures

Contraction forces in spontaneously laboring women range from 90 to 390 Montevideo units. As discussed in Chapter 20 (p. 467), the latter are calculated by subtracting the baseline uterine pressure from the peak contraction pressure for each contraction in a 10-minute window. The pressures generated by each contraction are then summed. Caldeyro-Barcia and associates (1950) and Seitchik and colleagues (1984) found that the mean or median spontaneous uterine contraction pattern resulting in a progression to a vaginal delivery was between 140 and 150 Montevideo units.

In the management of active-phase arrest, and with no contraindication to intravenous oxytocin, decisions must be made with knowledge of the safe upper range of uterine activity. Hauth and co-workers (1986) described an effective and safe protocol for oxytocin augmentation for active-phase arrest with which greater than 90 percent of women achieved an average of at least 200 to 225 Montevideo units. Hauth and associates (1991) later reported that nearly all women in whom active-phase arrest persisted, despite oxytocin, generated more than 200 Montevideo units. Importantly, despite no labor progression, there were no adverse maternal or perinatal effects in those undergoing cesarean delivery. There are no data regarding safety and efficacy of contraction patterns in women with a prior cesarean delivery, with twins, or with an overdistended uterus.

Duration of Oxytocin Administration—Active Phase Arrest

First-stage arrest of labor is defined by the American College of Obstetricians and Gynecologists (1989, 1995a) as a completed latent phase along with contractions exceeding 200 Montevideo units for more than 2 hours without cervical change. Some investigators have attempted to define a more accurate duration for active-phase arrest. Arulkumaran and associates (1987) extended the 2-hour limit to 4 hours and reported a 1.3-percent cesarean delivery rate in women who continued to have adequate contractions and progressive cervical dilatation of at least 1 cm/hr. In women without progressive cervical dilatation who were allowed another 4 hours of labor, half required cesarean delivery.

Rouse and colleagues (1999) prospectively managed 542 women at term with active-phase arrest and no other complications. Their protocol was to achieve a sustained pattern of at least 200 Montevideo units for a *minimum* of 4 hours. This time frame was extended to 6 hours if activity of 200 Montevideo

units or greater could not be sustained. Almost 92 percent of these women were delivered vaginally. As discussed in Chapter 20 (p. 467), these and other studies support the practice to allow an active-phase arrest of 4 hours (Rouse and associates, 2001). Solheim and colleagues (2009) also support the quality and cost effectiveness of allowing an active-phase arrest of 4 hours.

Zhang and co-workers (2002) analyzed labor duration from 4 cm to complete dilatation in 1329 nulliparas at term. They found that before dilatation of 7 cm was reached, lack of progress for more than 2 hours was not uncommon in those who delivered vaginally. Alexander and colleagues (2002) reported that epidural analgesia prolonged active labor by 1 hour compared with duration of the active phase as defined by Friedman (1955). Consideration of these changes in the management of labor, especially in nulliparas, may safely reduce the cesarean delivery rate.

Amniotomy

A common indication for artificial rupture of the membranes—*surgical amniotomy*—includes the need for direct monitoring of the fetal heart rate or uterine contractions, or both. During amniotomy, to minimize the risk of cord prolapse, care should be taken to avoid dislodging the fetal head. Fundal or suprapubic pressure or both may reduce the risk of cord prolapse. Some clinicians prefer to rupture membranes during a contraction. If the vertex is not well applied to the lower uterine segment, a gradual egress of amnionic fluid can sometimes be accomplished by several membrane punctures with a 26-gauge needle held with a ring forceps and with direct visualization using a vaginal speculum. In many of these, however, membranes tear and fluid is lost rapidly. The fetal heart rate should be assessed before and immediately after amniotomy.

Elective Amniotomy

Membrane rupture with the intention of accelerating labor is commonly performed. In the investigations presented in Table 22-4, amniotomy at about 5 cm dilation accelerated spontaneous labor by 1 to 2 hours. Importantly, neither the need for oxytocin stimulation nor the overall cesarean delivery rate was increased. Although mild and moderate cord compression patterns were increased following amniotomy, cesarean delivery for fetal distress was not increased. Most importantly, there were no adverse perinatal effects.

Amniotomy Induction

Artificial rupture of the membranes—sometimes called surgical induction—can be used to induce labor, and it always implies a commitment to delivery. The main disadvantage of amniotomy used alone for labor induction is the unpredictable and occasionally long interval to labor onset. That said, in a randomized trial, Bakos and Bäckström (1987) found that amniotomy alone or combined with oxytocin was superior to oxytocin alone. Mercer and colleagues (1995) randomized 209 women undergoing oxytocin induction to either early amniotomy at 1 to 2 cm, or late amniotomy at 5 cm. Early amniotomy was associated with significant 4-hour shorter labor. With early amniotomy, however, there was an increased incidence of chorioamnionitis.

Amniotomy Augmentation

It is common practice to perform amniotomy when labor is abnormally slow. Rouse and co-workers (1994) found that amniotomy with oxytocin augmentation for arrested active-phase labor shortened the time to delivery by 44 minutes compared with that of oxytocin alone. Although amniotomy did not affect the route of delivery, one drawback was that it significantly increased the incidence of chorioamnionitis.

ACTIVE MANAGEMENT OF LABOR

This term describes a codified approach to the management of labor, which is discussed in detail in Chapter 17 (p. 405).

TABLE 22-4. Randomized Clinical Trials of Elective Amniotomy in Early Spontaneous Labor at Term

		Effects of Amniotomy					
Study	Number	Mean Dilatation at Amniotomy	Mean Shortening of Labor	Need for Oxytocin	Cesarean Delivery Rate	Abnormal Tracing	Neonatal Effects
Fraser and co workers (1993)	925	<5 cm	125 min	None	None[a]	None	None
Garite and associates (1993)	459	5.5 cm	81 min	Decreased	None	Increased[b]	None
UK Amniotomy Group (1994)	1463	5.1 cm	60 min	None	None	NA	None

[a]No effect on overall rate; cesarean delivery for fetal distress significantly increased.
[b]Increased mild and moderate umbilical cord compression patterns.
NA = not assessed.

CHAPTER 23

Forceps Delivery and Vacuum Extraction

FORCEPS DELIVERY 511
VACUUM EXTRACTION 522
COMPARISON OF VACUUM EXTRACTION WITH FORCEPS 524

The precise incidence of operative vaginal delivery in the United States is unknown. According to the National Vital Statistics Report, forceps or vacuum delivery was coded on the birth certificate as the method of delivery for 4.5 percent of vaginal births in the United States in 2006 (Martin and colleagues, 2009).

FORCEPS DELIVERY

True forceps were first devised in the late 16th or beginning of the 17th century. The reader is referred to the 19th and earlier editions of *Williams Obstetrics* regarding their history.

Forceps Designs

These instruments basically consist of two crossing branches. Each branch has four components: blade, shank, lock, and handle. Each blade has two curves: The *cephalic curve* conforms to the shape of the fetal head, and the *pelvic curve* corresponds more or less to the axis of the birth canal (Fig. 23-1). Some varieties are *fenestrated* or *pseudofenestrated* to permit a firmer grasp of the fetal head.

The blades are connected to the handles by the *shanks.* The common method of articulation, the *English lock,* consists of a socket located on the shank at the junction with the handle, into which fits a socket similarly located on the opposite shank (Figs. 23-1 and 23-2). A *sliding lock* is used in some forceps, such as Kielland forceps (Fig. 23-3).

Classification of Forceps Deliveries

The current classification of the American College of Obstetricians and Gynecologists (2000, 2002) for forceps and vacuum operations is summarized in Table 23-1. It emphasizes the two most important discriminators of risk for both mother and infant: *station* and *rotation.* Station is measured in centimeters, −5 to 0 to +5. Deliveries are categorized as outlet, low, and midpelvic procedures. *High forceps* in which instruments are applied above 0 station have no place in contemporary obstetrics.

Incidence of Forceps Delivery

Over the past decade, as the cesarean delivery rate has risen, the rate of operative vaginal delivery has fallen. The latter was 9.8 percent in 1994, and fell to 4.5 percent of all births in the United States in 2006 (Martin and colleagues, 2009). In a study from the United States National Hospital Discharge Survey, Kozak and Weeks (2002) reported that forceps deliveries decreased 17.7 to 4.0 per 100 vaginal deliveries from 1980 to 2000. During this same 20-year period, the vacuum delivery rate increased from 0.7 to 8.4 per 100 vaginal deliveries.

Effects of Regional Analgesia

Epidural analgesia may be associated with failure of spontaneous rotation to an occiput anterior position. It also may slow second-stage labor and decrease maternal expulsive efforts. Both of these may predispose to instrumented delivery. Sharma and colleagues (2004) analyzed the outcomes of 2703 nulliparas who were enrolled in one of five randomized trials performed at Parkland Hospital to ascertain the effects of labor analgesia. Women given epidural analgesia had a twofold increased rate of forceps delivery compared with those given intravenous

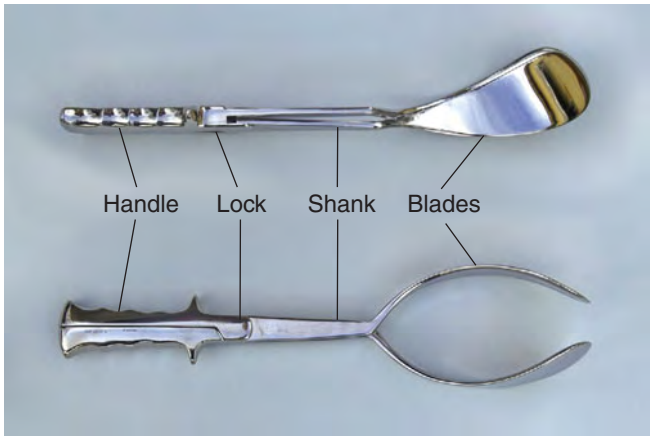

FIGURE 23-1 Tucker–McLane forceps. The blade is solid and the shank is narrow.

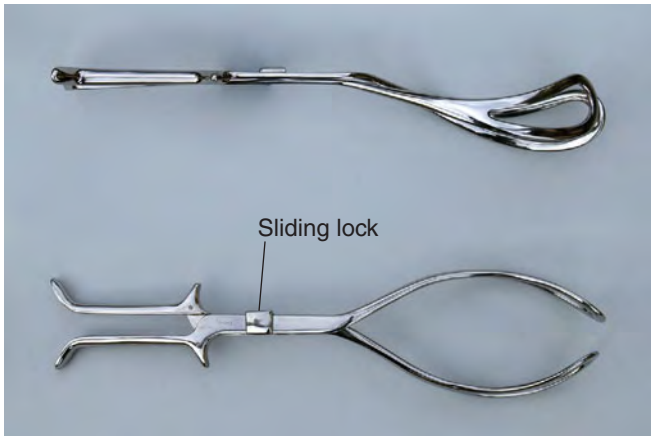

FIGURE 23-3 Kielland forceps. The characteristic features are the sliding lock, minimal pelvic curvature, and light weight.

analgesia—13 versus 7 percent. Similarly, in their meta-analysis of epidural versus opioid analgesia, Halpern and colleagues (1998) reported that women receiving epidural analgesia were twice as likely to have an instrumented delivery. Both studies are consistent with a comprehensive systematic review performed by Lieberman and O'Donoghue (2002).

Training

As the rate of operative vaginal delivery has declined, so have opportunities for training. In 1999, Hankins and colleagues reported that fewer than half of the residency directors expected proficiency with midforceps delivery, and today, far fewer would. From a training standpoint, in many programs even low and outlet forceps procedures have reached critically low levels. Thus, traditional hands-on training will likely evolve. For example, Dupuis and colleagues (2006, 2009) have developed a sophisticated forceps simulation system that utilizes spatial location sensors to track the trajectories of forceps blades. Leslie and associates (2005) used an isometric strength testing unit with real-time visual feedback to optimize traction force exerted by residents during simulated forceps deliveries. Cheong and co-workers (2004) reported lowered rates of maternal and neonatal morbidity associated with instrumented delivery in their hospital after the implementation of a formal instrumented delivery education program that included a manikin and pelvic model.

FIGURE 23-2 Simpson forceps. **A.** Note the ample pelvic curve in the blades. **B.** The cephalic curve is evident in the articulated blades. The fenestrated blade and the wide shank in front of the English-style lock characterize the Simpson forceps.

Function of Forceps

Although the most important function of forceps is *traction*, forceps may be invaluable for *rotation*, particularly for occiput transverse and posterior positions. In general, Simpson forceps are used to deliver the fetus with a molded head, as is common in nulliparous women. The Tucker-McLane instrument is often used for the fetus with a rounded head, which more characteristically is seen in multiparas. In most situations, however, either instrument is appropriate.

Forces Exerted by the Forceps

The force produced by the forceps on the fetal skull is a complex function of both traction and compression by the forceps, as well as friction produced by maternal tissues. It is impossible to ascertain the amount of force exerted by forceps for an individual patient.

Indications for Forceps

When it is technically feasible and can be safely accomplished, termination of second-stage labor by forceps or vacuum extraction delivery is indicated in any condition threatening the mother or fetus that is likely to be relieved by delivery. Some *maternal indications* include heart disease, pulmonary injury or compromise, intrapartum infection, certain neurological conditions, exhaustion, or prolonged second-stage labor. For nulliparas, the latter is defined by the American College of Obstetricians and Gynecologists (2002) as more than 3 hours with, and more than 2 hours without, regional analgesia. In the parous woman, a prolonged second stage is defined as more than 2 hours with, and more than 1 hour without, regional analgesia. Shortening of second-stage labor for maternal reasons should generally be performed from either a low or outlet station.

TABLE 23-1. Classification of Forceps Delivery according to Station and Rotation[a]

Procedure	Criteria
Outlet forceps	1. Scalp is visible at the introitus without separating the labia 2. Fetal skull has reached pelvic floor 3. Sagittal suture is in anteroposterior diameter or right or left occiput anterior or posterior position 4. Fetal head is at or on perineum, and 5. Rotation does not exceed 45 degrees
Low forceps	Leading point of fetal skull is at station ≥ +2 cm, and not on the pelvic floor, and: • Rotation is 45 degrees or less, *or* • Rotation is greater than 45 degrees.
Midforceps	Station is between 0 and +2 cm.
High	Not included in classification.

[a]Classification for the vacuum delivery system is the same as for forceps except that vacuum is used for traction but not rotation.

Presuming that all prerequisites for instrumented delivery are met, some *fetal indications* for operative vaginal delivery include prolapse of the umbilical cord, premature separation of the placenta, or a nonreassuring fetal heart rate pattern.

Elective and Outlet Forceps

Forceps generally should not be used electively until the criteria for outlet forceps have been met. The fetal head must be on the perineal floor with the sagittal suture no more than 45 degrees from the anteroposterior diameter. In these circumstances, forceps delivery is a simple and safe operation (Hagadorn-Freathy and associates, 1991). That said, however, there is no evidence that use of prophylactic forceps is *beneficial* in the otherwise normal term labor and delivery.

Prophylactic Outlet Forceps for Low-Birthweight Fetuses

In the past, it was taught that forceps delivery was somewhat protective of the fragile head of the preterm infant. Fairweather (1981) reported no significant differences in outcomes in neonates who weighed 500 to 1500 g between those delivered spontaneously and those by outlet forceps. Schwartz and colleagues (1983) reported similar findings. Thus, it appears that there is no obvious advantage to routine outlet forceps delivery of a small fetus.

Prerequisites for Forceps Application

There are at least six prerequisites for successful application of forceps:

1. The cervix must be completely dilated.
2. The membranes must be ruptured.
3. The head must be engaged. Extensive caput succedaneum formation and molding sometimes make determination of the station difficult. With difficulties of station assignment, it is important to realize that what is assumed to be a low-forceps procedure may actually be a more difficult midforceps operation.
4. The fetus must present a vertex, or present a face with the chin anterior.
5. The position of the fetal head must be precisely known.
6. There should be no suspected cephalopelvic disproportion.

Preparation for Forceps Delivery

Although pudendal block analgesia may prove adequate for outlet forceps operations, regional analgesia or general anesthesia is preferable for low-forceps or midpelvic procedures. The bladder should be emptied.

The exact position of the fetal head must be known for a proper cephalic application. With the head low in the pelvis, position is determined by examination of the sagittal suture and the fontanels. When the head is at a higher station, an absolute determination can be made by locating the posterior ear.

Outlet Forceps Delivery

Forceps Application

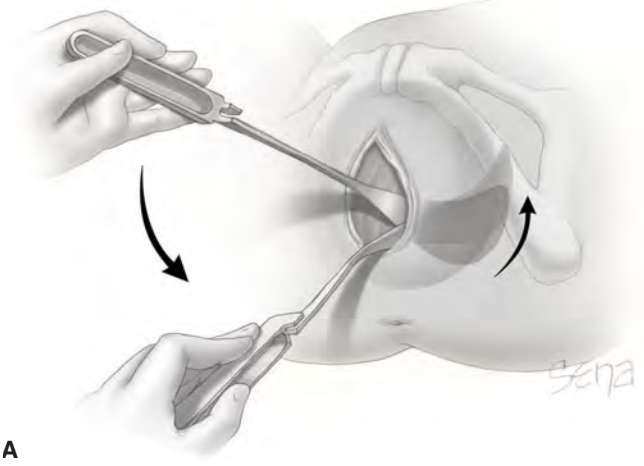
Delivery by outlet forceps of the occiput anterior fetal head is illustrated in Figures 23-4 through 23-7. In such circumstances, the small (posterior) fontanel is directed toward the symphysis pubis. The forceps, if applied to the sides of the pelvis, grasp the head ideally. The forceps are applied as follows: Two or more fingers of the right hand are introduced inside the left posterior portion of the vulva and into the vagina beside the fetal head. The handle of the left branch is then grasped between the thumb and two fingers of the left hand. The tip of the blade is then gently

FIGURE 23-4 The left handle of the forceps is held in the left hand. The blade is introduced into the left side of the pelvis between the fetal head and fingers of the operator's right hand.

passed into the vagina between the fetal head and the palmar surface of the fingers of the right hand (see Fig. 23-4). For application of the right blade, two or more fingers of the left hand are introduced into the right, posterior portion of the vagina to serve as a guide for the right blade. This blade is held in the right hand and introduced into the vagina as described for the left blade. After positioning, the branches are articulated (see Fig. 23-7).

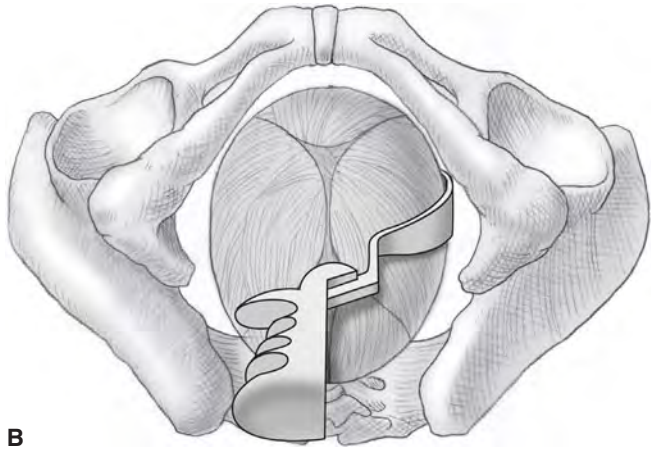
The blades are constructed so that their cephalic curve is closely adapted to the sides of the fetal head. The biparietal diameter of the fetal head corresponds to the greatest distance between the appropriately applied blades. Consequently, the head of the fetus is perfectly grasped only when the long axis of the blades corresponds to the occipitomental diameter. Thus, the major portion of the blade is lying over the face. If the fetus is in an occiput anterior position, then the concave margins of the blades are directed toward the sagittal suture. If the fetus is in an occiput posterior position, then the concave margins are directed toward the fetal face.

Applied as such, the forceps should not slip, and traction may be applied most advantageously. With most forceps, if one blade is applied over the brow and the other over the occiput, the instrument cannot be locked, or if locked, the blades will slip off when traction is applied (**Fig. 23-8**). For these reasons, the forceps must be applied directly to the sides of the fetal head along the occipitomental diameter.



Appropriateness of Application

For the occiput anterior position, appropriately applied blades are equidistant from the sagittal suture. In the occiput posterior position, the blades are equidistant from the midline of the face and brow.



Traction

If necessary, rotation to occiput anterior is performed before traction is applied (**Fig. 23-9**). When it is certain that the blades are placed satisfactorily, then gentle, intermittent, horizontal traction is exerted until the perineum begins to bulge (**Fig. 23-10**). With traction, as the vulva is distended by the occiput, an episiotomy may be performed if indicated (**Fig. 23-11**).

Additional horizontal traction is applied, and the handles are gradually elevated, eventually pointing almost directly upward as the parietal bones emerge (**Figs. 23-12** and **23-13**). As the handles are raised, the head is extended. During the birth of the head, spontaneous delivery should be simulated as closely as possible. Traction should therefore be intermittent, and the

FIGURE 23-5 A. Continued insertion of the left blade. Note the arc of the handles as they rotate to be applied to the mother's left. **B.** First blade in place.

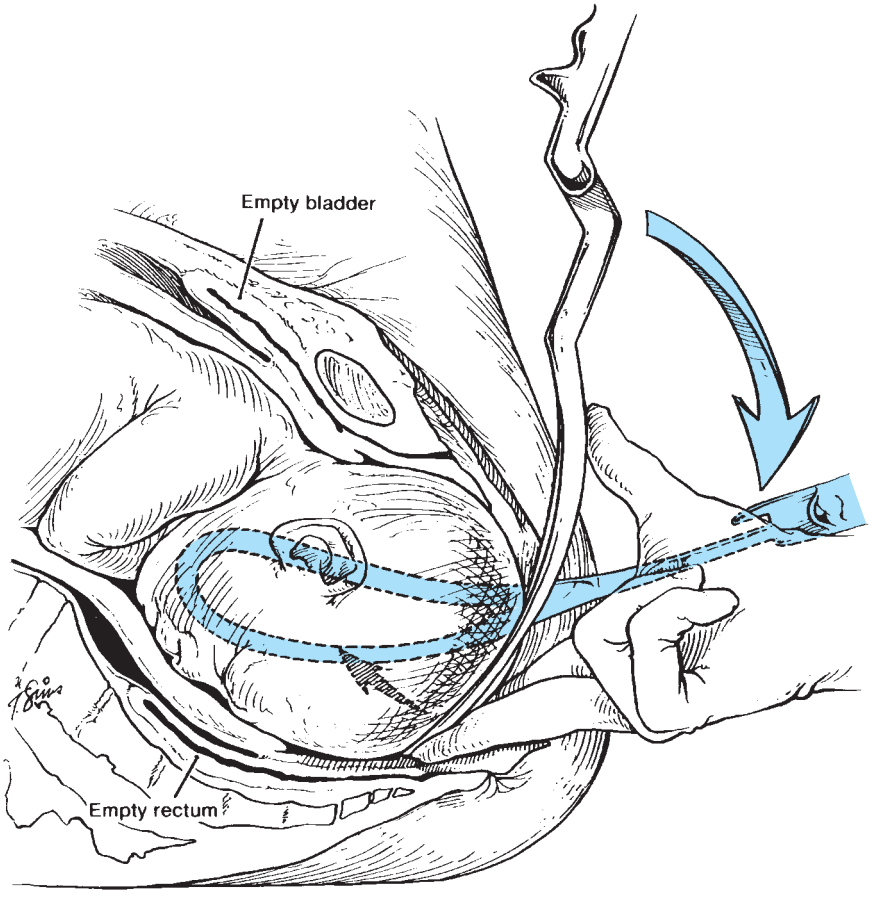

FIGURE 23-6 Sagittal view of first-blade application. The fetus is presenting as vertex with occiput anterior crowning. The application of the left blade of the Simpson forceps is shown. Next, the right blade is applied and the blades are articulated.

head should be allowed to recede in intervals, as in spontaneous labor. Except when urgently indicated, as in severe fetal bradycardia, delivery should be sufficiently slow, deliberate, and gentle to prevent undue head compression. It is preferable to apply traction only with each uterine contraction.

After the vulva has been well distended by the head, the delivery may be completed in several ways. Some clinicians keep the forceps in place to control the advance of the head. However, the thickness of the blades adds to the distension of the vulva, thus increasing the likelihood of laceration or necessitating a large episiotomy. To prevent this, the forceps may be removed and delivery completed by the modified Ritgen maneuver (Fig. 23-14). If the forceps are removed prematurely, the modified Ritgen maneuver may prove to be ineffective or unduly difficult.

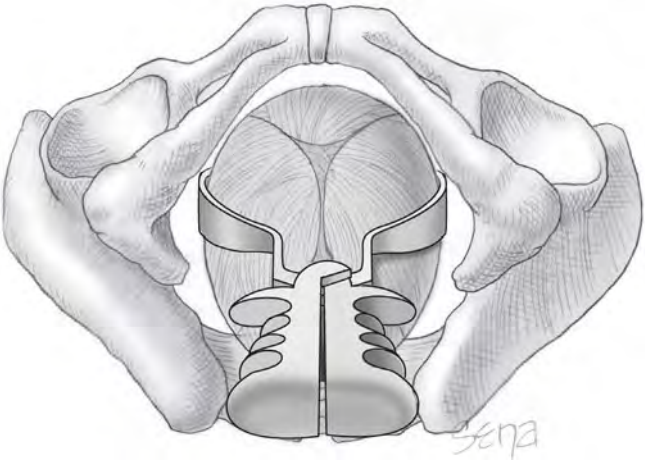

FIGURE 23-7 The vertex is now occiput anterior, and the forceps are symmetrically placed and articulated.

Low- and Midforceps Operations

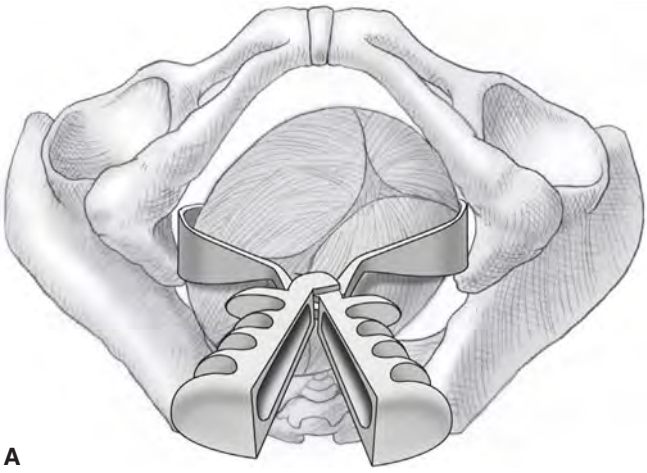
When the head lies above the perineum, the sagittal suture usually occupies an oblique or transverse diameter of the pelvis. In such cases, the forceps should always be applied to the sides of the head.

Left Occiput Anterior Position

The right hand, introduced into the left posterior segment of the vagina, should identify the posteriorly located left ear. At the same time, the right hand serves as a guide for introduction of the left branch of the forceps, which is held in the left hand and applied over the left ear. Two fingers of the left hand are then introduced into the right posterior portion of the pelvis.

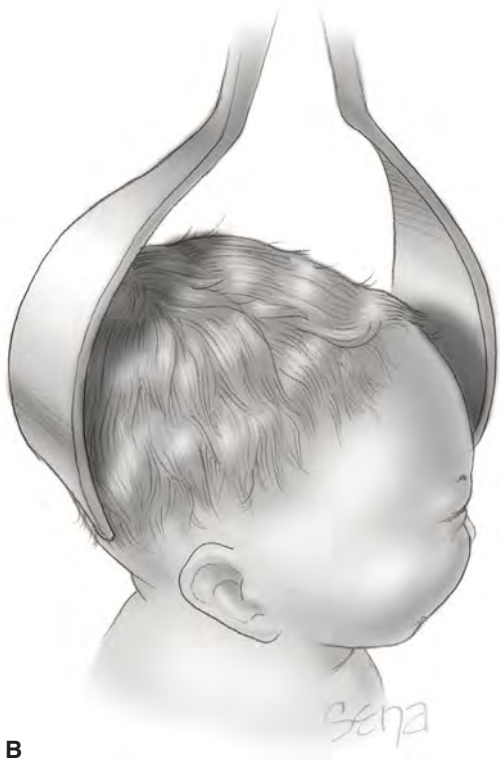
The right branch of the forceps, held in the right hand, is then introduced along the left hand as a guide. It must then be applied over the anterior ear of the fetus by gently sweeping the blade anteriorly until it lies directly opposite the blade that was introduced first.

Right Occiput Anterior Position



The blades are introduced similarly as above, but in the opposite directions off the vertical. After the blades have been applied to the sides of the head, the left handle and shank lie above the right. Consequently, the forceps do not immediately articulate. Locking of the branches is easily effected, however, by rotating the left around the right to bring the lock into proper position.

Occiput Transverse Positions



The forceps are introduced similarly, as described, but with the first blade applied over the posterior ear and the second rotated anteriorly to a position opposite the first. In this case, one blade lies in front of the sacrum and the other behind the symphysis. Simpson or Tucker-McLane forceps or one of their modifications is generally used. In some cases the specialized Kielland forceps may be used.

Rotation from Anterior and Transverse Positions

When the occiput is obliquely anterior, it gradually rotates spontaneously to the symphysis pubis as traction is exerted.

A

B

FIGURE 23-8 Incorrect application of forceps. **A.** One blade over the occiput and the other over the brow. Forceps cannot be locked. **B.** With incorrect placement, blades tend to slip off with traction.

When it is directly transverse, however, a rotary motion of the forceps is required. Rotation counterclockwise from the left side toward the midline is required when the occiput is directed toward the left, and in the reverse direction when it is directed toward the right side of the pelvis. Infrequently, when forceps are used in transverse positions in anteroposteriorly flattened—platypelloid—pelves, rotation should not be attempted until the fetal head has reached or approached the pelvic floor. Regardless of the original position of the head, delivery eventually is accomplished by exerting traction downward until the occiput appears at the vulva. After this, the rest of the operation is completed as previously described.

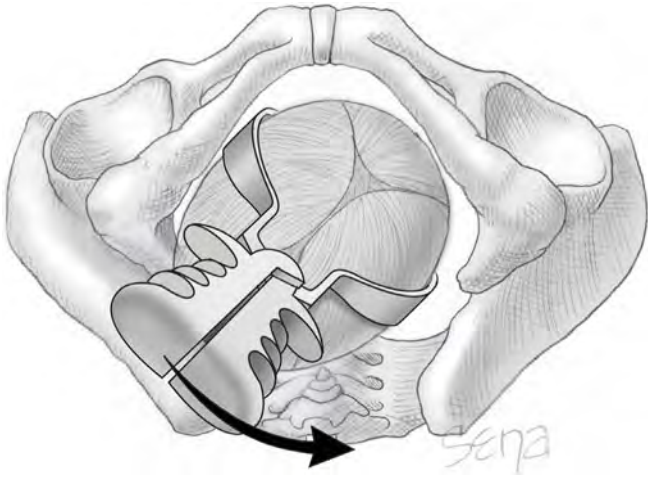


FIGURE 23-9 Forceps have been locked. Vertex is rotated from left occiput anterior to occiput anterior (*arrow*).

Occiput Posterior Positions

Prompt delivery may at times become necessary when the small occipital fontanel is directed toward one of the sacroiliac synchondroses, that is, in right occiput posterior or left occiput posterior positions. When delivery is required in either instance, the head is often imperfectly flexed. In some cases, when the hand is introduced into the vagina to locate the posterior ear, the occiput rotates spontaneously toward the anterior, indicating that manual rotation of the fetal head might easily be accomplished.

Manual Rotation

A hand with the palm upward is inserted into the vagina and the fingers are brought in contact with the side of the fetal head that is to be rotated toward the anterior position, while the thumb is placed over the opposite side of the head. With the occiput in a right posterior position, the left hand is used to rotate the occiput anteriorly in a clockwise direction. The right hand is used for the left occiput posterior position. The head must not be disengaged during rotation. After the occiput has reached the anterior position, labor may be allowed to continue, or forceps can be used. Le Ray and colleagues (2007) reported a success rate of greater than 90 percent, and two thirds required only one attempt.

Forceps Delivery of Occiput Posterior

If manual rotation cannot be easily accomplished, application of the blades to the head in the posterior position and delivery from the occiput posterior position may be the safest procedure (Fig. 23-15). In many cases, the cause of the persistent occiput posterior position and of the difficulty in accomplishing

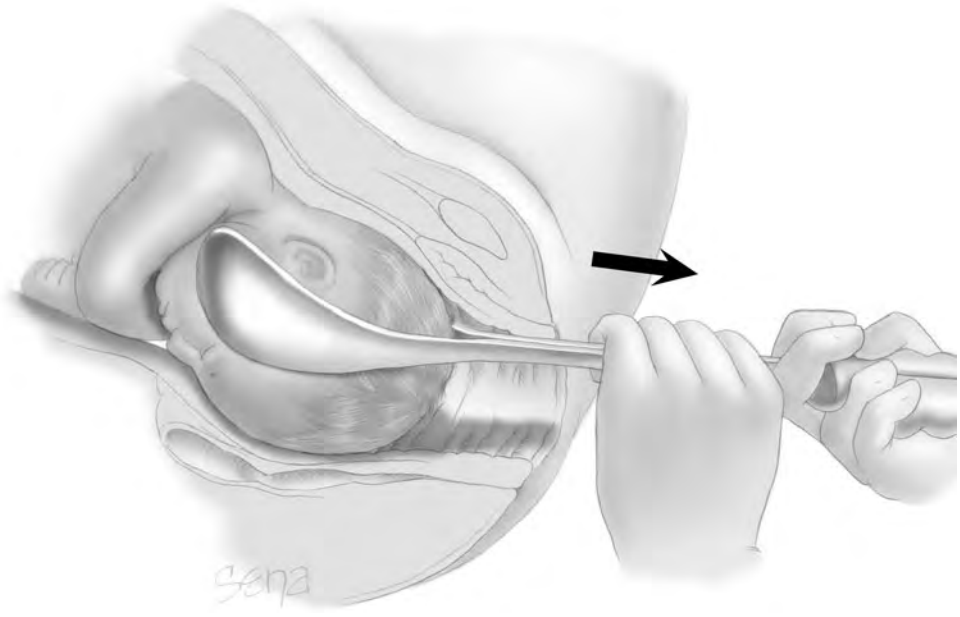

FIGURE 23-10 Occiput anterior. Delivery by low forceps. The direction of gentle traction for delivery of the head is indicated.

rotation is an anthropoid pelvis, the architecture of which opposes rotation and predisposes to posterior delivery. When the occiput is directly posterior, horizontal traction should be applied until the base of the nose is under the symphysis. The handles should then be slowly elevated until the occiput gradually emerges over the anterior margin of the perineum. Then, the forceps are directed in a downward motion, and the nose, face, and chin successively emerge from the vulva.

Occiput posterior delivery causes greater distension of the vulva, and a large episiotomy may be needed. Pearl and associates (1993) reviewed 564 occiput posterior deliveries and compared them with 1068 controls. The occiput posterior group had a higher incidence of severe perineal lacerations and extensive episiotomy compared with that of the occiput anterior group. Within the occiput posterior group, operative delivery was associated with a higher incidence of severe perineal lacerations—35 versus 16 percent; vaginal lacerations—18 versus 7 percent; and episiotomy—95 versus 74 percent, than was spontaneous delivery. Damron and Capeless (2004) reported a third- or fourth-degree perineal laceration in 72 percent of 118 women with occiput posterior forceps deliveries. From The Netherlands, de Leeuw and collaborators (2008) studied more than 28,500 operative vaginal deliveries and reported similar findings. Consequences of these perineal tears are discussed in Chapter 17 (p. 400). Infants delivered from the occiput posterior position had a higher incidence of Erb and facial nerve palsies, 1 and 2 percent, respectively, than did those delivered from the occiput anterior position.

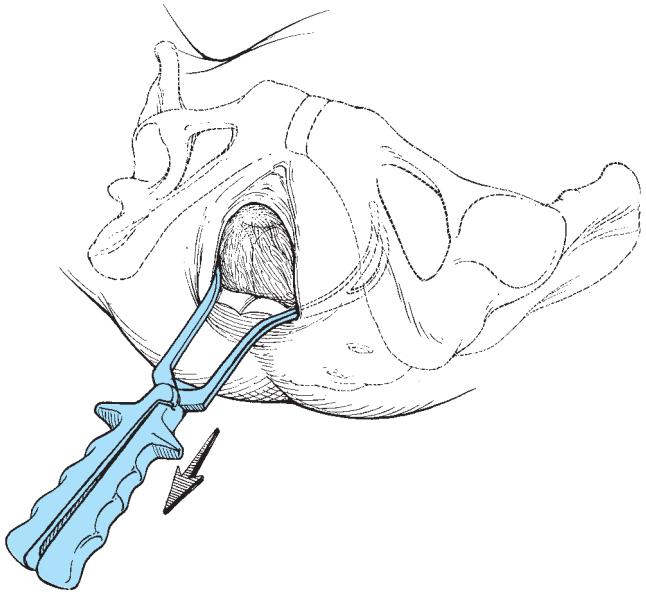

FIGURE 23-11 Horizontal traction.

Forceps Rotations of Occiput Oblique Posterior

For rotations, either Tucker-McLane, Simpson, or Kielland forceps may be used. The oblique occiput may be rotated 45 degrees to the posterior position, or 135 degrees to the anterior position (**Fig. 23-16**). If rotation is performed with Tucker-McLane or Simpson forceps, the head must be flexed, but this is not necessary with Kielland forceps because they have a less pronounced pelvic curve. In rotating the occiput anteriorly with Tucker-McLane or Simpson forceps, the pelvic curvature, originally directed upward, is, at the completion of rotation, inverted and directed posteriorly. Attempted delivery with the instrument in that position is likely to cause vaginal sulcus tears and sidewall lacerations. To avoid such trauma, it is essential to remove and reapply the instrument as described below.

Occiput Transverse Rotation

Specialized skill and training are essential when performing this technically difficult operative vaginal procedure. Either standard forceps, such as pseudofenestrated Simpson, or specialized forceps, such as Kielland, are employed. The latter have a sliding lock and almost no pelvic curve (see Fig. 23-3). On each handle is a small knob that indicates the direction of the occiput. The station of the fetal head must be accurately ascertained to be at, or preferably below, the level of the ischial spines, especially in the presence of extreme molding.

Kielland described two methods of applying the anterior blade:

1. With the *wandering* or *gliding* method, the anterior blade is introduced at the side of the pelvis over the brow or face. The blade is then arched around the brow or face to an anterior position, with the handle of the blade held close to

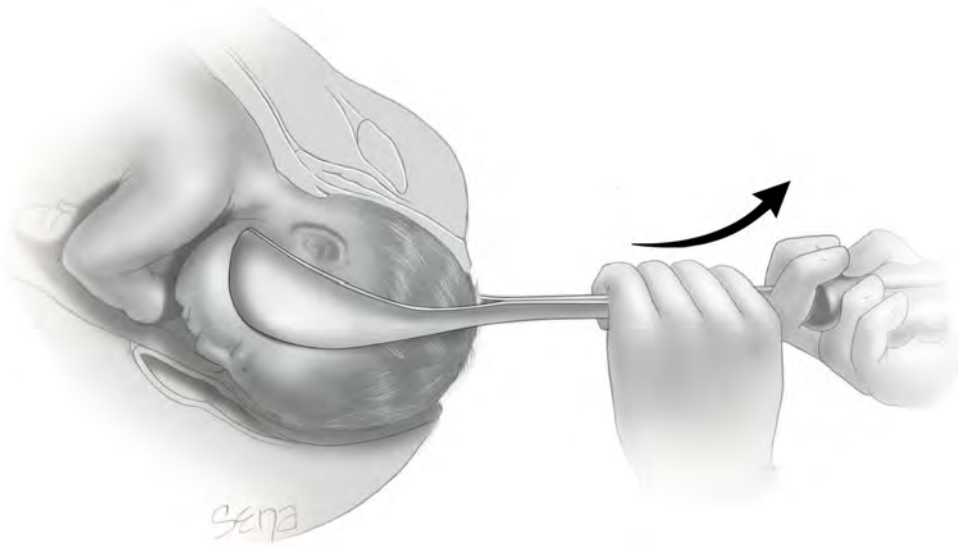

FIGURE 23-12 Upward arching traction (*arrow*) is used as the head is delivered.

the opposite maternal buttock throughout the maneuver. The second blade is introduced posteriorly and the branches are locked.

2. With the *direct* or *classical* application, the anterior blade is introduced first with its cephalic curve directed upward, curving under the symphysis. After it has been advanced far enough into the lower uterine cavity, it is turned on its axis through 180 degrees to adapt the cephalic curvature to the head. For a more detailed description Kielland forceps procedures, see the second edition of *Operative Obstetrics* (Gilstrap, 2002).

Face Presentation Forceps Delivery

With a mentum anterior face presentation, forceps can be used to effect vaginal delivery. The blades are applied to the sides of the head along the occipitomental diameter, with the pelvic curve directed toward the neck. Downward traction is exerted until the chin appears under the symphysis. Then, by an upward movement, the face is slowly extracted, with the nose, eyes, brow, and occiput appearing in succession over the anterior margin of the perineum (**Fig. 23-17**). Forceps should not be applied to the mentum posterior presentation because vaginal delivery is impossible.

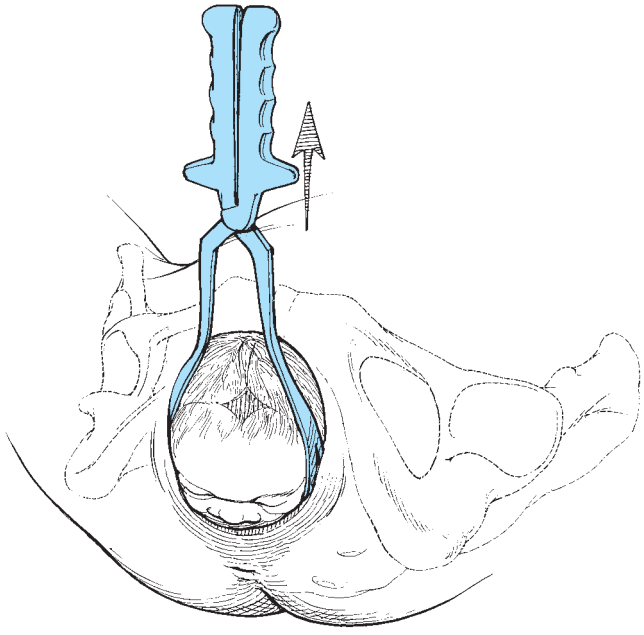

FIGURE 23-13 Upward traction (*arrow*) is continued as the head is delivered.

Morbidity from Forceps Operations

Maternal Morbidity

The relationship of maternal morbidity to forceps deliveries should be considered on two levels. First, and overall, the maternal morbidity from indicated forceps delivery is most properly compared with the morbidity from cesarean delivery, and not to that from spontaneous vaginal delivery. This is because

FIGURE 23-14 Forceps may be disarticulated as the head is delivered. Modified Ritgen maneuver may be used to complete delivery of the head.

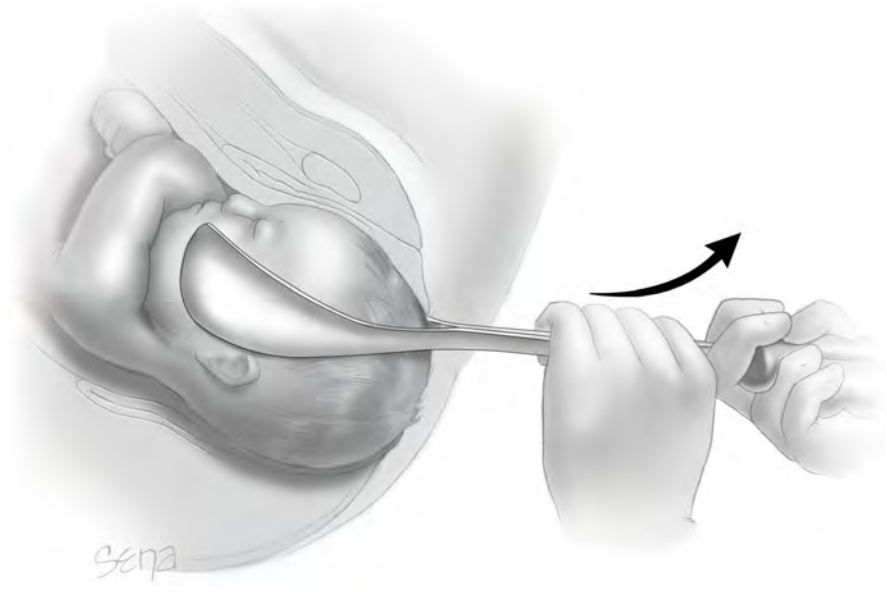

FIGURE 23-15 Outlet forceps delivery from an occiput posterior position. The head should be flexed after the bregma passes under the symphysis.

the alternative to indicated forceps delivery is cesarean delivery. Second, among women undergoing forceps delivery, the higher the station, and/or the greater the degree of rotation, the more likely it is that morbidity in the form of lacerations and blood loss will occur.

Lacerations and Episiotomy. As documented by a number of studies, the very conditions that lead to indications for operative vaginal delivery also increase the need for episiotomy and the likelihood of lacerations (de Leeuw and colleagues, 2008). Moreover, station and degree of instrumented rotation correlate with morbidity. Hagadorn-Freathy and co-workers (1991) reported a 13-percent rate of third- and fourth-degree episiotomy extensions and vaginal lacerations for outlet forceps, 22 percent for low forceps with less than 45 degrees rotation, 44 percent for low forceps with more than 45 degrees rotation, and 37 percent for midforceps deliveries. Bofill and colleagues (1996a, b) found a significant association of moderate and severe perineal injuries with indicated operative deliveries, use of forceps versus vacuum extractor, the need for episiotomy, and delivery from other than outlet station. These findings are consistent with the recent report of FitzGerald and associates (2007).

Coincidental with overall efforts to reduce routine episiotomy use, Ecker and colleagues (1997) reported a significant decrease in the episiotomy rate with both forceps—96 to 30 percent—as well as vacuum—89 to 39 percent—deliveries from 1984 to 1994. During this time, there was a decrease in fourth-degree but no change in third-degree lacerations. In a review of more than 34,000 vaginal births by Goldberg and colleagues (2002), episiotomy rates decreased from 70 percent in 1983 to 19 percent in 2000. Forceps deliveries, however, were associated with higher episiotomy rates as well as third- and fourth-degree lacerations compared with those of spontaneous delivery.

Urinary and Fecal Incontinence. *Short-term effects* of forceps and vacuum deliveries, especially midcavity deliveries, include postpartum urinary retention and bladder dysfunction (Carley and co-workers, 2002). Arya and colleagues (2001) reported that urinary incontinence after forceps delivery was more likely to persist than incontinence associated with vacuum or spontaneous delivery.

Regarding *long-term effects*, there are a now a number of studies indicating that even spontaneous vaginal delivery will, in some women, be followed by urinary and fecal incontinence. Incontinence is temporary and improves with time in some of these. In others, however, it persists and may worsen over years. Extensive episiotomies or lacerations, especially of the anal sphincter, are more likely to cause problems with incontinence than spontaneous vaginal delivery alone (Pollack and associates, 2004; Pregazzi and colleagues, 2002). Because forceps deliveries are associated with an increased incidence of episiotomy and extension or laceration, it is not surprising that forceps use has been associated in some reports with higher rates of anal and urinary incontinence (Baydock and coworkers, 2009; Fitzpatrick and colleagues, 2003; Viktrup and Lose, 2001). Thus, the anterior compartment—responsible for bladder function, or the posterior

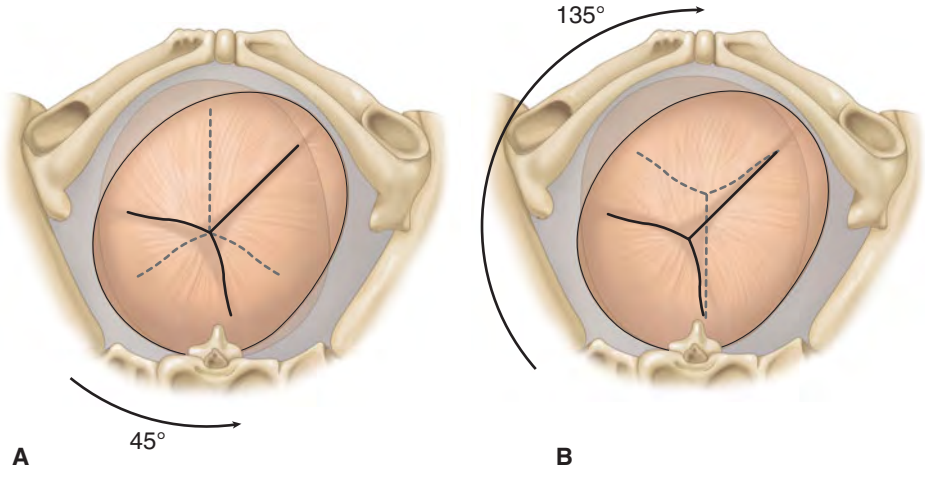

FIGURE 23-16 Rotation of obliquely posterior occiput to sacrum **(A)** or to symphysis pubis **(B)**.

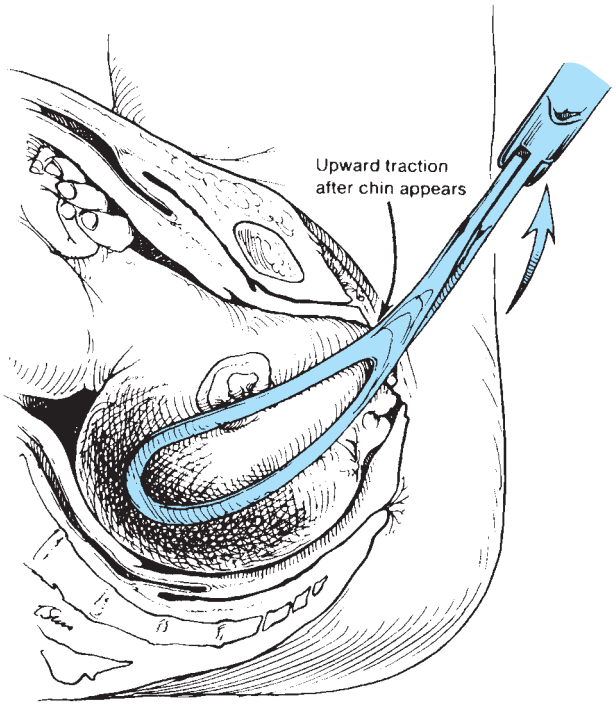

FIGURE 23-17 Face presentation, mentum (chin) anterior. Delivery with outlet forceps (Simpson).

compartment—responsible for anal function, or both may be involved.

Anal sphincter dysfunction, although associated with spontaneous delivery, is increased with instrumental vaginal delivery, episiotomy extensions, and deep lacerations. Eason and colleagues (2000, 2002) evaluated 949 Canadian women 3 months after delivery. Three percent had fecal incontinence, and more than a fourth had flatus incontinence. Both were more common in women who had had anal sphincter injuries and forceps delivery. Sultan and colleagues (1993) reported defecatory symptoms in 38 percent of women after forceps delivery, 12 percent following vacuum delivery, and 4 percent after spontaneous delivery with either a mediolateral episiotomy or second-degree lacerations. Pretlove and associates (2008) performed a systematic Cochrane Library review that included more than 12,000 deliveries. Within the year following delivery, women delivered by forceps had a twofold increased incidence of anal incontinence. Muscle injury is responsible for most anal dysfunction, however, pudendal nerve damage also plays a role (Tetzschner and colleagues, 1998).

Although the short-term effects on anorectal function associated with operative vaginal delivery are of concern, studies of long-term morbidity are conflicting. For example, in a 34-year follow-up after forceps delivery, Bollard and colleagues (2003) reported that significant fecal and urinary incontinence was no more likely after forceps delivery than after vaginal delivery. In a 30-year follow-up study, Nygaard and co-workers (1997) documented incontinence of flatus in 31, 43, and 36 percent of women who had experienced a disrupted sphincter, an episiotomy, or cesarean delivery, respectively. Conversely, in a 6-year follow-up of 3813 women, MacArthur and associates (2005) found an overall 3.6-percent prevalence of anal incontinence. First delivery by forceps was associated with a doubled risk of anal incontinence relative to spontaneous vaginal delivery. They also reported that cesarean delivery was not protective.

Febrile Morbidity. Postpartum uterine infection and pelvic cellulitis are more frequent, and often more severe, in women following cesarean delivery compared with that following operative vaginal delivery (Robertson and colleagues, 1990).

Perinatal Morbidity

Direct morbidity to the fetus caused by forceps is usually from trauma. Facial nerve palsy was reported by Falco and Eriksson (1990) in 0.9 percent of 8415 infants delivered by forceps compared with 0.02 percent among 35,877 delivered spontaneously or by cesarean. The former included infants delivered by high and midforceps. Importantly, almost 90 percent of these facial palsies underwent complete spontaneous resolution. Brachial plexus injury was reported by Gilbert and co-workers (1999) to be more frequent among infants delivered with forceps or vacuum than those delivered spontaneously. They analyzed data from more than 1 million deliveries in California and described rates of injury of 5, 4, and 1.5 per thousand with forceps, vacuum, and spontaneous delivery, respectively.

Forceps and vacuum deliveries were associated with intracranial hemorrhage more commonly than spontaneous delivery in a study by Towner and colleagues (1999). They reviewed 583,340 term nulliparous women delivered in California between 1992 and 1994. A third of these underwent cesarean, forceps, or vacuum delivery, and they were compared with those delivered spontaneously. As shown in **Table 23-2**, the incidence of intracranial hemorrhage was highest in infants delivered by forceps, vacuum, or cesarean after labor had started, and comparable across these groups. Combined attempts with vacuum and forceps had the highest rate. These investigators concluded that abnormal labor, and not the method of delivery per se, was the common risk factor.

Morbidity from Midforceps Deliveries

Numerous reports have described the association of neonatal morbidity and midforceps operations. Several factors must be considered when interpreting these studies. First and foremost, most were conducted prior to the redefined classification of

TABLE 23-2. Effect of Method of Delivery on Incidence of Neonatal Intracranial Hemorrhage (ICH)

Delivery	ICH
Vacuum and forceps	1:280
Forceps	1:664
Vacuum	1:860
Cesarean with labor	1:907
Spontaneous	1:1900
Cesarean without labor	1:2750

Data from Towner and colleagues (1999).

forceps in 1988 by the American College of Obstetricians and Gynecologists (2000). Thus, in these earlier studies, midforceps were not defined clearly and included deliveries from relatively high stations (0 to +1), as well as those with difficult forceps rotations. Second, spontaneous vaginal deliveries are not appropriate controls for midforceps. Supportive of this is the study of Towner and colleagues (1999) in which infants delivered by cesarean after commencement of labor had the same risk of intracranial hemorrhage as those delivered by forceps. Finally, there is no uniformity in the criteria used to define immediate fetal morbidity.

There are only a few studies done applying the updated 1988 classification. In one, Robertson and associates (1990) reported significantly higher neonatal morbidity in the midforceps group compared with infants born by cesarean delivery.

The study cited earlier by Hagadorn-Freathy and colleagues (1991) was a prospective investigation designed to test the validity of the 1988 classification for fetal risk discrimination. They classified 357 forceps deliveries using both the pre-1988 and 1988 classifications and compared outcomes. Facial nerve palsy developed in 1.3 percent of infants delivered by outlet forceps and 3.2 percent of those delivered by midforceps using the pre-1988 classification. This compared with rates of 0.9 percent for outlet forceps, 1.7 percent for low forceps, and 9.2 percent for midforceps using the 1988 classification. Thus, the 1988 classification seems to usefully discriminate among the risks associated with outlet, low-, and midpelvic forceps deliveries. Because of increased maternal and neonatal morbidity rates compared with those for low-forceps operations, midforceps deliveries are seldom performed now.

Long-Term Infant Morbidity

For many decades, controversy has attended forceps vis-à-vis their relationship to long-term neurodevelopmental outcomes. Particularly controversial has been the possible association between forceps delivery and decreased measures of intelligence. Some of the early studies used data from the Collaborative Perinatal Project. In one, Broman and co-workers (1975) controlled for socioeconomic status, race, and gender. They reported that infants delivered by midforceps had slightly higher intelligence scores at age 4 years compared with those of children delivered spontaneously. Using the same database, Friedman and associates (1977, 1984) analyzed intelligence assessments at or after age 7 years. They concluded that children delivered by midforceps had lower mean intelligence quotients (IQs) compared with children delivered by outlet forceps. In yet another report from this same database, Dierker and colleagues (1986) compared long-term outcomes of children delivered by midforceps with those of children delivered by cesarean after dystocia. The strength of this study is the appropriateness of the control group. These investigators reported that delivery by midforceps was not associated with neurodevelopmental disability.

In another study of long-term morbidity of midforceps deliveries, Nilsen (1984) evaluated 18-year-old men when they were drafted into the Norwegian Army. The study found that those delivered by Kielland forceps had higher intelligence scores than those delivered spontaneously, by vacuum extraction, or by cesarean. Similar data reported by Seidman and colleagues (1991) from more than 32,000 Israeli Defense Forces draftees are shown in Table 23-3. Likewise, Wesley and colleagues (1992) assessed 1746 children and found no significant differences in intelligence test scores at age 5 years in spontaneous, forceps, or vacuum deliveries. Murphy and co-workers (2004) found no association between forceps delivery and epilepsy in a cohort of 21,441 adults, 9 percent of whom had been delivered by forceps. Finally, Bahl and associates (2007) performed a prospective cohort study of the children of 264 women who underwent operative delivery. Their incidence of adverse outcomes was similar whether delivered by successful forceps delivery, failed forceps with cesarean delivery, or immediate cesarean delivery.

TABLE 23-3. Intelligence Test Scores at Age 17 for Subjects Born in Jerusalem between 1964 and 1970

	Mean Intelligence Score (±SE)	
Type of Delivery	**Unadjusted**	**Adjusted[a]**
Spontaneous (n = 29,136)	105.4 (0.1)	105.7 (0.1)
Forceps (n = 567)	108.2 (0.7)	104.6 (0.4)
Vacuum extraction (n = 1207)	109.6 (0.5)	105.9 (0.4)
Cesarean delivery (n = 1335)	105.4 (0.4)	103.7 (0.1)

SE = standard error.

Conclusions Regarding Morbidity From Forceps

Although it is clear that midforceps operations are associated with the most significant maternal and neonatal risks, the bulk of studies in which morbid events were reported are from an era when cesarean delivery rates were around 5 percent. Thus, they undoubtedly included many difficult and even ill-advised forceps deliveries that would, in all likelihood, never be attempted today.

Also relevant to contemporary instrumented delivery is the widespread use of epidural analgesia (Lieberman and O' Donoghue, 2002). The need for forceps or vacuum delivery in women using this form of labor pain relief often results from inadequate maternal expulsive forces against a relaxed pelvic sling. Because of this, such deliveries are not usually associated with either relative or absolute cephalopelvic disproportion. Although it is prudent in these cases to allow a longer second-stage labor, in some circumstances, delivery is indicated sooner. Forceps deliveries for epidural-associated labor abnormalities are likely to be safer than the same operation performed in women with prolonged labor or midpelvic arrest unassociated with conduction analgesia.

It seems reasonable to conclude that outlet and low-forceps operations, as classified by the scheme proposed by the American College of Obstetricians and Gynecologists (2000), can be performed safely for both mother and fetus if the basic guidelines set forth in this chapter are carefully observed.

Trial of Forceps and Failed Forceps

If an attempt at operative vaginal delivery is anticipated to be difficult, the attempt should be considered a trial. With an operating room both equipped and staffed for immediate cesarean delivery, the trial may proceed. If a satisfactory application of the forceps cannot be achieved, then the procedure is abandoned and delivery accomplished by use of either vacuum extraction or cesarean. Once application has been achieved and in conjunction with contractions and maternal expulsive efforts, gentle downward pulls are made on the forceps. If there is no descent, the procedure should be abandoned and cesarean delivery performed.

In a study of 122 women who had a trial of midcavity forceps or vacuum extraction in a setting with full preparations to proceed to cesarean section, Lowe (1987) found no significant difference in immediate neonatal or maternal morbidity compared with that of 42 women delivered for similar indications by cesarean but without such a trial of instrumentation. Conversely, neonatal morbidity was higher in 61 women who had "unexpected" forceps or vacuum failure in which there was no prior preparation for immediate cesarean delivery. Ben-Haroush and colleagues (2007) reported a 1.3-percent failed forceps rate in 821 attempts. This compares with a 10-percent failed vacuum rate during 4299 attempts. Factors associated with failure were persistent occiput posterior position, absence of regional or general anesthesia, and birthweight greater than 4000 g.

To avoid morbidity with failed forceps or vacuum delivery, the American College of Obstetricians and Gynecologists (2000) cautions that these trials should be attempted only if the clinical assessment is highly suggestive of a successful outcome. We also emphasize proper training.

VACUUM EXTRACTION

In the United States, the device is referred to as the vacuum extractor, whereas in Europe it is commonly referred to as a *ventouse*—from French, literally, *soft cup* (**Fig. 23-18A**). Theoretical advantages of the vacuum extractor compared with forceps include: (1) avoidance of insertion of space-occupying steel blades within the vagina, (2) no requirement for precise positioning over the fetal head, (3) less maternal trauma, and (4) less intracranial pressure during traction. All previously described instruments were unsuccessful until Malmström (1954) applied a new principle, that is, traction on a metal cap designed so that the suction creates an artificial caput—chignon—within the cup that holds firmly and allows adequate traction.

As with forceps choice, the decision to use a metal or a soft cup appears regional. In the United States, the metal cup generally has been replaced by newer soft-cup vacuum extractors. As emphasized by Duchon and associates (1998), however, high-pressure vacuum generates large amounts of force regardless of the cup used. A wide variety of soft-cup extractors and vacuum devices are available. The former differ in their shape, size, rigidity, and reusability. The main difference among the latter is whether the device is handheld and actuated by the operator, or whether an assistant holds and operates the pump. Shown in Figure 23-18A is the system currently used at the University of Alabama at Birmingham Hospital.

A number of investigators have studied outcome in rigid and soft cups. Loghis and colleagues (1992) compared results of 200 women delivered using a metal cup with those of 200 women in whom a pliable cup was used. No differences were found in the rate of birth canal trauma—11 versus 13 percent; major neonatal scalp trauma—6.5 versus 5.5 percent; neonatal jaundice—15.5 versus 13.5 percent; or Apgar scores. Kuit and co-workers (1993) found that the only advantage of the soft cups was a lower incidence of scalp injury. They reported a 14-percent episiotomy extension rate with both rigid and pliable cups. Associated perineal lacerations developed with 16 percent of rigid cup extractions and 10 percent with the pliable cup. Johanson and Menon (2000a) analyzed results from nine randomized trials. They found that soft cups had an almost twofold failure rate but half the number of scalp injuries compared with rigid cups. In a similar review, Vacca (2002) concluded that there were fewer scalp lacerations with the soft cup, but that the rate of cephalohematomas and subgaleal hemorrhage was similar between soft and rigid cups.

Indications and Prerequisites for Vacuum Delivery

Generally, vacuum extraction is reserved for fetuses who have attained a gestational age of at least 34 weeks. Otherwise, the indications and prerequisites for its use are the same as for forceps delivery (American College of Obstetricians and Gynecologists, 2000). From their review of vacuum extraction, Koscica and Gimovsky (2002) concluded that contraindications include

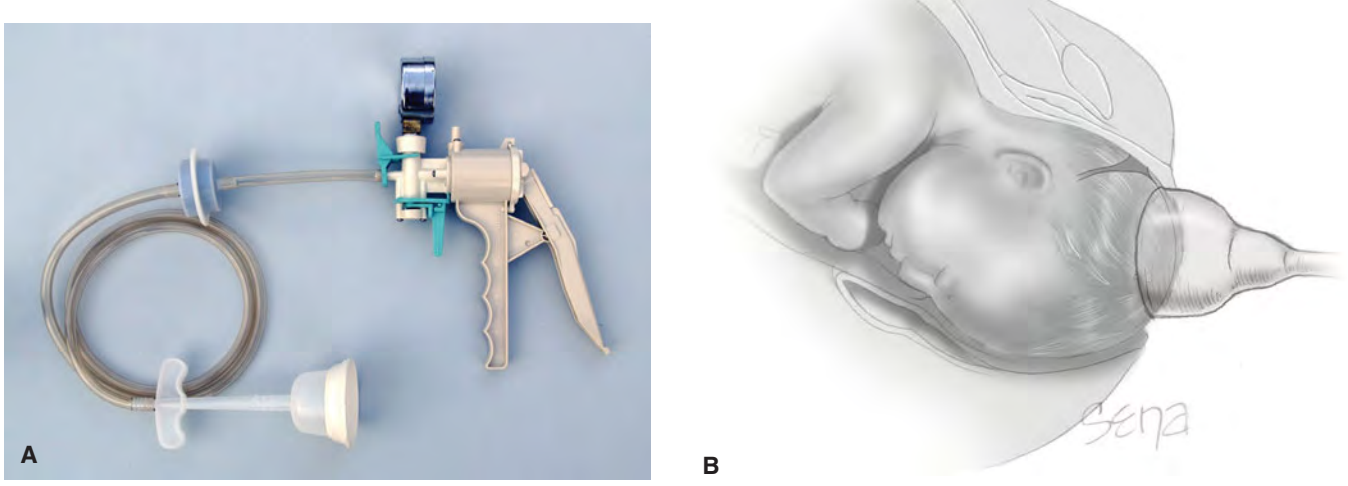

FIGURE 23-18 A. Vacuum delivery system: The Mityvac pump is attached to a disposable MitySoft Bell vacuum-assist delivery cup with tubing and filter. **B.** Cup in place.

operator inexperience, inability to assess fetal position, high station, and suspicion of cephalopelvic disproportion. Contraindications for delivery using vacuum extraction include face or other nonvertex presentations, or fetal coagulopathy. Recent scalp blood sampling is a relative contraindication, however, this sampling is infrequently used.

Technique

Proper cup placement is the most important determinant of success in vacuum extraction. The center of the cup should be over the sagittal suture and about 3 cm in front of the posterior fontanel toward the face (Fig. 23-18B). Anterior placement on the fetal cranium—near the anterior fontanel rather than over the occiput—will result in cervical spine extension unless the fetus is small. Similarly, asymmetrical placement relative to the sagittal suture may worsen asynclitism. Cup placement for elective use in occiput anterior positions is seldom difficult. In contrast, when the indication for delivery is failure to descend caused by occipital malposition, with or without asynclitism or deflexion, cup placement can be difficult.

Entrapment of maternal soft tissue predisposes the mother to lacerations and hemorrhage and virtually ensures cup dislodgement. The full circumference of the cup should be palpated both before and after the vacuum has been created as well as prior to traction to ensure that such entrapment has not occurred. When using rigid cups, it is recommended that the vacuum be created gradually by increasing the suction by 0.2 kg/cm^2 every 2 minutes until a negative pressure of 0.8 kg/cm^2 is reached. With soft cups, negative pressure can be increased to 0.8 kg/cm^2 over as little as 1 minute (Hankins and associates, 1995; Kuit and colleagues, 1993). Some authors suggest that 0.6 kg/cm^2 is the optimal peak pressure (Lucas, 1994). Listed in Table 23-4 are conversions of various units of pressures used by different instruments.

Traction should be intermittent and coordinated with maternal expulsive efforts. Traction may be initiated by using a two-handed technique, that is, the fingers of one hand are placed against the suction cup, while the other hand grasps the handle of the instrument. Manual torque to the cup should be avoided as it may cause cephalohematomas and with metal cups, "cookie-cutter"–type scalp lacerations. Vacuum extraction should be considered a trial, and without early and clear evidence of descent toward delivery, an alternate delivery approach should be considered. As a general guideline, progressive descent should accompany each traction attempt. Neither data nor consensus are available regarding the number of pulls required to effect delivery, the maximum number of cup pop-offs that can be tolerated, or optimal total duration of the procedure. Cup dislodgement due to technical failure or less than optimal placement should not be equated with dislodgement under ideal conditions of exact cup placement and optimal vacuum maintenance. The former may merit either additional attempts at placement and delivery or alternatively, a trial of forceps (Ezenagu and colleagues, 1999; Williams and co-workers, 1991). As with forceps procedures, there should be a willingness to abandon attempts at vacuum extraction if satisfactory progress is not made (American College of Obstetricians and Gynecologists, 2000).

TABLE 23-4. Table of Vacuum Pressure Conversions

mm Hg	in Hg	lb/in^2	kg/cm^2
100	3.9	1.9	0.13
200	7.9	3.9	0.27
300	11.8	5.8	0.41
400	15.7	7.7	0.54

600	23.6	11.6	0.82

Reprinted from MJ Lucas, The role of vacuum extraction in modern obstetrics [Review], *Clinical Obstetrics & Gynecology,* Vol. 37, No. 4, pp. 794–805, 1994, with permission.

Complications

Complications of the vacuum extractor include scalp lacerations and bruising, subgaleal hematomas, cephalohematomas, intracranial hemorrhage, neonatal jaundice, subconjunctival hemorrhage, clavicular fracture, shoulder dystocia, injury of sixth and seventh cranial nerves, Erb palsy, retinal hemorrhage, and fetal death (Broekhuizen and associates, 1987; Galbraith, 1994; Govaert and colleagues, 1992). That said, Berkus and associates (1985) found no increase in rates of serious neonatal morbidity, including retinal hemorrhage, for the Silastic vacuum extractor compared with that associated with spontaneous delivery.

The Food and Drug Administration (FDA) issued a Public Health Advisory in 1998 regarding the possible association of vacuum-assisted delivery with serious fetal complications, including death. During a 4-year period, the FDA received reports of nine serious fetal injuries and 12 newborn deaths, which was a significant increase over the preceding 11 years. In a response to this advisory, the American College of Obstetricians and Gynecologists (1998) issued a Committee Opinion recommending the continued use of vacuum-assisted delivery devices when appropriate. They estimated that there is approximately one adverse event per 45,455 vacuum extractions per year.

Subsequently, Ross and colleagues (2000) reviewed the FDA Manufacturer and User Facility Device Experience (MAUDE) Database for the six months after the FDA advisory. These investigators concluded that adverse events due to the vacuum may in fact occur at a substantially higher rate than previously reported. Simonson and co-workers (2007) employed systematic radiographic and sonographic screening in 913 successful term vacuum-assisted deliveries and reported a fairly high reservoir of complications, including a 5-percent rate of skull fracture, and a 1-percent rate of intracranial hemorrhage. Complications were more frequent among nulliparas, midcavity deliveries, after more than three traction attempts, and after cup dislodgement. Reassuringly, all infants with skull fracture were asymptomatic, as were seven of the eight infants with intracranial hemorrhage. There were no cases of subgaleal hemorrhage.

Recommendations Regarding Vacuum Delivery

Considering the 1998 FDA Public Health Advisory, the following recommendations seem reasonable:

1. The classification of vacuum deliveries should be the same as that used for forceps deliveries (including station).
2. The same indications and contraindications used for forceps deliveries should be applied to vacuum-assisted deliveries.
3. The vacuum should not be applied to an unengaged vertex, that is, above 0 station.
4. The individual performing or supervising the procedure should be an experienced operator.
5. The operator should be willing to abandon the procedure if it does not proceed easily or if the cup dislodges more than three times.

COMPARISON OF VACUUM EXTRACTION WITH FORCEPS

There have been numerous studies comparing vacuum extraction with forceps deliveries. Vacca and associates (1983) conducted a randomized, prospective study comparing metal cup vacuum extraction with forceps delivery. They reported a higher frequency of maternal trauma and blood loss in the forceps group, but an increase in the incidence of neonatal jaundice in the vacuum group. Macleod and co-workers (2008) found lower episiotomy rates with vacuum delivery compared with forceps delivery. Bofill and colleagues (1996b) randomized 637 women to forceps versus vacuum extraction with the Mityvac M-cup. There were significantly more third- and fourth-degree lacerations—29 versus 12 percent—in the forceps-delivered group. Conversely, the incidence of both shoulder dystocia and cephalohematoma was approximately doubled in the vacuum group—15 versus 6 percent, and 37 versus 19 percent, respectively. Caughey and associates (2005) reported lower overall rates of shoulder dystocia, but the same relative relationship between the vacuum and forceps—3.5 percent versus 1.5 percent. Fitzpatrick and colleagues (2003) randomized 130 women to vacuum or forceps delivery. At 3 months, symptoms of fecal incontinence were more common in women delivered with forceps than with vacuum—59 versus 33 percent.

Although retinal hemorrhage occasionally is seen with vacuum usage, it has no apparent long-term effects. Johanson and Menon (2000b) analyzed 10 randomized trials and confirmed that vacuum extraction was associated with less maternal but more fetal trauma, for example, cephalohematoma and retinal hemorrhage.

The data are sparse regarding long-term neurological outcome in newborns delivered by vacuum extraction. In the report of an 18-year follow-up by Nilsen (1984), the mean intelligence score of 38 male infants delivered by vacuum was not different from the national average. Seidman and associates (1991) reported in their adjusted analysis that mean IQ score at age 17 in those delivered by vacuum or forceps was virtually the same as those delivered spontaneously (see Table 23-3). Johanson and colleagues (1999) performed a 5-year follow-up of a randomized trial of forceps versus vacuum delivery in more than 600 women and reported that there were no significant differences in child development in the two groups.

CHAPTER 24

Breech Presentation and Delivery

ASSOCIATED FACTORS 527
DIAGNOSIS 527
COMPLICATIONS 529
PROGNOSIS 529
TECHNIQUES FOR BREECH DELIVERY 532
ANALGESIA AND ANESTHESIA 538
VERSION 539

When the buttocks of the fetus enter the pelvis before the head, the presentation is *breech.* The term probably derives from the same word as *britches,* which described a cloth covering the loins and thighs. Breech presentation is more common remote from term because the bulk of each fetal pole is more similar. Most often, however, as term approaches, the fetus turns spontaneously to a cephalic presentation because the increasing bulk of the buttocks seeks the more spacious fundus. But, breech presentation persists in 3 to 4 percent of singleton deliveries at term (Fig. 24-1). For example, the annual rate of breech presentation at delivery in nearly 270,000 singleton newborns at Parkland Hospital has varied from only 3.3 to 3.9 percent during the past 20 years.

ASSOCIATED FACTORS

As term approaches, the uterine cavity usually accommodates the fetus in a longitudinal lie with the vertex presenting. Factors other than gestational age that predispose to breech presentation include hydramnios, high parity with uterine relaxation, multiple fetuses, oligohydramnios, hydrocephaly, anencephaly, previous breech delivery, uterine anomalies, placenta previa, fundal placental implantation, and pelvic tumors. Vendittelli and colleagues (2008) recently described a twofold incidence of breech presentation and prior cesarean delivery.

DIAGNOSIS

Definitions

The varying relations between the lower extremities and buttocks of breech presentations form the categories of frank, complete, and incomplete breech presentations. With a *frank breech* presentation, the lower extremities are flexed at the hips and extended at the knees, and thus the feet lie in close proximity to the head (Fig. 24-2). A *complete breech* presentation differs in that one or both knees are flexed (Fig. 24-3). With *incomplete breech* presentation, one or both hips are not flexed, and one or both feet or knees lie below the breech, such that a foot or knee is lowermost in the birth canal (Fig. 24-4). *Footling breech* is an incomplete breech with one or both feet below the breech.

In perhaps 5 percent of term breech presentations, the fetal head may be in extreme hyperextension. These presentations have been referred to as the *stargazer fetus*, and in Britain as the *flying foetus*. With such hyperextension, vaginal delivery may result in injury to the cervical spinal cord. Thus, if present after labor has begun, this is an indication for cesarean delivery (Svenningsen and associates, 1985).

Abdominal Examination

Use of the *Leopold maneuvers* to ascertain fetal presentation is discussed in Chapter 17 (p. 377). The accuracy of palpation varies (Lydon-Rochelle, 1993; Nassar, 2006, and all their coworkers; Thorp, 1991). Thus, with suspected breech presentation—or any presentation other than cephalic—sonographic evaluation is indicated.

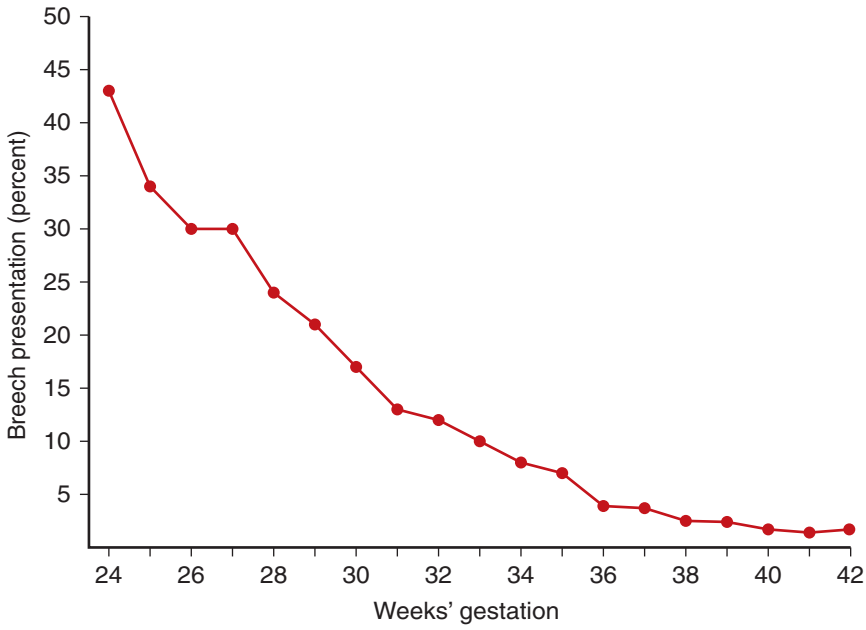

FIGURE 24-1 Prevalence of breech presentation by gestational age at delivery in 58,842 singleton pregnancies at the University of Alabama at Birmingham Hospitals, 1991 to 2006. (Used with permission from the Center for Women's Reproductive Health, University of Alabama at Birmingham.)

With the first Leopold maneuver, the hard, round, readily ballottable fetal head may be found to occupy the fundus. The second maneuver indicates the back to be on one side of the abdomen and the small parts on the other. With the third maneuver, if not engaged, the breech is movable above the pelvic inlet. After engagement, the fourth maneuver shows the firm breech to be beneath the symphysis.

Vaginal Examination

With the frank breech presentation, both ischial tuberosities, the sacrum, and the anus usually are palpable, and after further fetal descent, the external genitalia may be distinguished. Especially when labor is prolonged, the buttocks may become markedly swollen, rendering differentiation of a face and breech difficult. In some cases, the anus may be mistaken for the mouth and the ischial tuberosities for the malar eminences. With careful examination, however, the finger encounters muscular resistance with the anus, whereas the firmer, less yielding jaws are felt through the mouth. The finger, upon removal from the anus, may be stained with meconium. The mouth and malar eminences form a triangular shape, whereas the ischial tuberosities and anus lie in a straight line.

The sacrum and its spinous processes are palpated to establish the position and presentation. As with cephalic presentations and as described in Chapter 17 (p. 375), fetal positions are designated as left sacrum anterior (LSA), right sacrum anterior (RSA), left sacrum posterior (LSP), right sacrum posterior (RSP), or sacrum transverse (ST) to reflect the relationship of the fetal sacrum to the maternal pelvis.

Regarding presentation, with a complete breech, the feet may be felt alongside the buttocks. In footling presentations, one or both feet are inferior to the buttocks. When the breech has descended farther into the pelvic cavity, the genitalia may be felt.

FIGURE 24-2 Frank breech presentation.

FIGURE 24-3 Complete breech presentation.

FIGURE 24-4 Incomplete breech presentation.

Imaging Techniques

Because most are preterm, in many fetuses, the breech is smaller than the aftercoming head. Moreover, unlike cephalic presentations, the head of a breech-presenting fetus is not permitted to undergo molding during labor. Thus to avoid trapping of the head following delivery of the breech, pelvic dimensions should be assessed prior to vaginal delivery. In addition, the type of breech and degree of neck flexion or extension should be identified. To evaluate these, there are several imaging techniques.

Sonography

The best confirmation of a suspected breech presentation is with sonography. It also can provide information regarding the breech type and neck angle (Fontenot and associates, 1997; Rojansky and colleagues, 1994).

Other Methods

Computed tomographic (CT) scanning also can be used and will also provide pelvic measurements and configuration with lower doses of radiation than standard radiographs (see Chap. 20, p. 472). *Magnetic resonance (MR) imaging* provides reliable information about pelvic capacity and architecture without ionizing radiation, but it is not always readily available (van Loon and colleagues, 1997).

Pelvimetry. The role of radiographic pelvimetry to help determine the mode of delivery for breech presentation is controversial. Cheng and Hannah (1993) reviewed 15 studies of term-presenting breeches in which either radiographic or CT pelvimetry was used. They concluded that the utility of pelvimetry was difficult to assess because "permissible" pelvic dimensions varied among studies. Also, in most of these studies, there was no correlation between pelvic measurements and labor outcome. At Parkland Hospital, we use CT pelvimetry when possible to assess the *critical dimensions* of the pelvis (see Chap. 2, p. 31).

COMPLICATIONS

In the persistent breech presentation, an increased frequency of the following complications can be anticipated:

- Prolapsed cord
- Placenta previa
- Congenital anomalies
- Uterine anomalies and tumors
- Difficult delivery
- Increased maternal and perinatal morbidity

PROGNOSIS

Adverse pregnancy outcomes may be increased for both mother and fetus.

Maternal Morbidity

Because of the greater frequency of operative delivery, there is a higher rate of maternal morbidity for pregnancies complicated by persistent breech presentation. The most worrisome are genital tract lacerations. Intrauterine maneuvers, especially with a thinned lower uterine segment, or delivery of the aftercoming head through an incompletely dilated cervix, may cause rupture of the uterus, lacerations of the cervix and vaginal walls, or both. Such manipulations also may lead to extensions of the episiotomy and deep perineal tears. Anesthesia sufficient to induce appreciable uterine relaxation may cause uterine atony and in turn, postpartum hemorrhage. Finally, manual manipulations within the birth canal increase the risk of infection.

The maternal mortality rate may even be increased. Schutte and colleagues (2007) reported the deaths of four women in the Netherlands from 2000 to 2002 as a result of elective cesarean delivery for breech presentation—a case fatality rate of 0.47 maternal deaths per 1000 births.

Perinatal Morbidity and Mortality

The major contributors to perinatal loss are preterm delivery, congenital anomalies, and birth trauma. In their study reported more than 30 years ago, Brenner and associates (1974) found that at every stage of gestation, neonatal deaths were significantly greater among breeches. One reason was that congenital abnormalities were identified in 6.3 percent of breech-presenting fetuses compared with 2.4 percent of those who were not breech. However, in an analysis of 57,819 pregnancies in the Netherlands, corrected for gestational age, congenital defects, and birthweight, Schutte and colleagues (1985) reported that the perinatal mortality rate was higher in breech—compared with cephalic—presenting newborns. These investigators concluded that breech presentation may not be coincidental, but rather is a consequence of poor fetal quality.

More contemporaneous outcomes are improved because of careful assessment before attempted vaginal delivery and because of increased cesarean delivery rates, which generally exceed 60 percent. For example, Albrechtsen and colleagues (1997) reported that the perinatal mortality rate in 45,579 breech deliveries decreased from 9 percent in the period from 1967 through 1976 to 3 percent from 1987 through 1994. Herbst (2005) analyzed 22,549 term breech deliveries from 1991 to 2001 and reported a remarkably low combined perinatal and infant mortality rate of 0.63 percent.

Fetal Injuries

Several specific injuries are associated with vaginal breech deliveries. Fracture of the humerus and clavicle cannot always be avoided, and fracture of the femur may be sustained during difficult breech extractions. Such fractures are associated with both vaginal and cesarean deliveries (Awwad and colleagues, 1993; Vasa and Kim, 1990). Neonatal perineal tears have been reported as a complication of spinal electrode use (Freud and associates, 1993). Hematomas of the sternocleidomastoid muscles occasionally develop after delivery, although they usually disappear spontaneously. More serious problems, however, may follow separation of the epiphyses of the scapula, humerus, or femur. There is no evidence that the incidence of congenital hip dislocations is increased (Clausen and Nielsen, 1988).

Upper extremity paralysis may follow pressure on the brachial plexus by the fingers in exerting traction, but more frequently it is caused by overstretching the neck while freeing the arms. Geutjens and colleagues (1996) described 36 newborns with brachial plexus injury following vaginal breech delivery. In 80 percent, there was avulsion of the upper cervical spine roots. This injury cannot be treated adequately by microsurgical nerve grafting and carries a poor prognosis for shoulder function. When the fetus is extracted forcibly through a contracted pelvis, spoon-shaped depressions or actual fractures of the skull may result. Occasionally, even the fetal neck may be broken when great force is employed. Testicular injury, in some cases severe enough to result in anorchia, may follow vaginal breech delivery (Tiwary, 1989).

Term Breech Fetus

Cheng and Hannah (1993) conducted a comprehensive review of 24 studies encompassing 11,721 women. Studies were selected that compared *planned* vaginal with *planned* cesarean delivery for the term, singleton breech fetus. The corrected perinatal mortality rate ranged from 0 to 48 per 1000 births. All but two of the 77 perinatal deaths were in women allowed to deliver vaginally. The main causes of death were head entrapment, cerebral injury and intracranial hemorrhage, cord prolapse, and intrapartum asphyxia. The overall neonatal mortality and morbidity rates resulting from trauma were increased almost fourfold in the planned vaginal delivery groups. Similarly, Gifford and co-workers (1995) performed a meta-analysis of outcomes after term breech delivery, and they too reported that a trial of labor was associated with an increased risk of perinatal injury or death. Their analysis included only two randomized trials. Although these two trials concluded that vaginal breech delivery was relatively safe, only 110 women were actually allowed a trial of labor. This small number does not provide sufficient power to demonstrate differences in outcomes such as perinatal death and birth injury (Eller and Van Dorsten, 1995).

Preterm Breech Fetus

There are no randomized studies regarding delivery of the preterm breech fetus. A number of older retrospective studies yielded conflicting results. Studies published since 1990, however, generally report no excessive risks (Gravenhorst and co-workers, 1993; Wolf and colleagues, 1999). In a multicenter study, Malloy and co-workers (1991) described findings from the National Institute of Child Health and Human Development-sponsored Neonatal Research Network of 437 very-low-birthweight breech newborns. After adjusting for several variables, the risk of intraventricular hemorrhage and death was not significantly affected by the mode of delivery for fetuses weighing less than 1500 g. In a similar report from France, Kayem and co-workers (2008) described neonatal outcomes in 169 breech deliveries from 26 to 30 weeks. The neonatal death risk—11 versus 7 percent—was similar in infants undergoing planned vaginal versus planned cesarean delivery.

Current Status of Vaginal Breech Delivery

There are a number of events during the past decade that have had a marked influence on the mode of delivery for the breech-presenting fetus. Some of these changes are now summarized.

The Randomised Multicentre Trial

The multinational study performed by the Term Breech Trial Collaborative Group reported by Hannah and colleagues (2000) had a significant impact on obstetrical management. The trial included 1041 women randomly assigned to planned cesarean and 1042 to planned vaginal delivery. In the planned vaginal delivery group, 57 percent were actually delivered vaginally. Overall, planned cesarean delivery was associated with a lower risk of perinatal mortality compared with planned vaginal delivery—3 per 1000 versus 13 per 1000. Planned cesarean delivery was also associated with a lower risk of "serious" neonatal morbidity—1.4 versus 3.8 percent. Maternal complications were similar between the groups.

As subsequently discussed, the almost immediate effect of these results was an abrupt and almost complete decline in the rate of attempted vaginal breech deliveries. For example, in the Netherlands, the cesarean delivery rate for term breeches increased from 50 percent in the 33 months preceding the publication of the trial to 80 percent in the 25 months after its publication (Rietberg and associates, 2005).

United States, 2000–2005

In 2001, the American College of Obstetricians and Gynecologists published Committee Opinion No. 265, which concluded that except in cases of "advanced labor" and "imminent delivery"—not otherwise defined—women with persistent singleton breech presentation at term should undergo a planned cesarean delivery. These opinions arose from the previously discussed study by Hannah and colleagues (2000). Since that time, the number of vaginal breech deliveries has diminished. For example, in 2004, 87 percent of breech fetuses in the United States were born by

cesarean delivery. As a result, the number of skilled operators with the ability to safely select and vaginally deliver breech fetuses continues to dwindle. Obvious medicolegal concerns make it difficult to train new physicians to perform such deliveries.

For a number of reasons, we took issue with Committee Opinion No. 265 (Hauth and Cunningham, 2002). Our objections primarily centered on reliance on the Randomized Multicentre Trial. More recently, Glezerman (2006) again codified some of these criticisms:

1. Among the 1025 women enrolled from countries with low perinatal mortality rates, perinatal deaths were infrequent and did not differ significantly between groups—none in 514 women in the planned cesarean compared with 3 of 511 in the planned vaginal delivery group.
2. Most outcomes included in the "serious" neonatal morbidity composite do not actually portend long-term disability.
3. Fewer than 10 percent of women in the trial underwent pelvimetry using plain radiography, CT scanning, or MR imaging.
4. In more than 30 percent of women, the attitude of the fetal head was determined only by clinical methods.

As it happens, these criticisms subsequently were proven valid. Whyte and colleagues (2004) reported the 2-year outcomes for children born during the original multicenter trial. They found that planned cesarean delivery was not associated with a reduction in the rate of death or developmental delay. Specifically in the planned cesarean delivery group, the rate was 3.1 percent compared with 2.8 percent in the vaginal delivery group. Similar results were reported from Norway by Eide and associates (2005), who analyzed findings from more than 390,000 men who had intelligence testing at mandatory military registration. More than 8000 of these men—2 percent—were delivered from the breech position. The investigators concluded that presentation at birth did not affect intellectual performance. They also found that cesarean delivery of breech-presenting fetuses was not associated with *improved* intelligence-testing performance.

There are also a number of contemporaneous single-center studies that support a trial of vaginal delivery for selected breech-presenting term fetuses. Irion and associates (1998) reported significantly fewer maternal complications, but no difference in corrected neonatal morbidity or mortality rates between 385 *attempted* vaginal breech deliveries—70 percent of whom were delivered vaginally—and 320 planned cesarean deliveries. Giuliani and associates (2002) reported that in their institution, vaginal breech delivery was performed in half of 699 consecutive, term, breech-presenting fetuses. There were no short- or long-term differences in outcomes for fetuses delivered by either route. Alarab and associates (2004) reported no serious adverse neonatal outcomes in the fourth of 146 term breech fetuses delivered vaginally over a 3½-year period. Excellent outcomes for singleton breech fetuses after planned vaginal birth have also been reported by Uotila (2005), Krupitz (2005), Pradhan (2005), and their colleagues.

Results from a large prospective European study were reported by Goffinet and co-workers (2006). They analyzed outcomes of 8105 term singleton breech-presenting fetuses from 174 French and Belgium hospitals. The decision on mode of delivery and the management of those who labored followed fairly stringent guidelines put forth by the French College of Obstetricians and Gynecologists and which are consistent with those outlined below. Vaginal delivery was planned in about a third—2526—of these women, and it was successful in 1796 of these—71 percent. The perinatal mortality or serious neonatal morbidity rates were low. Importantly, they did not differ between the planned vaginal and planned cesarean group—1.6 versus 1.5 percent, respectively. The single neonatal death was a nonmalformed newborn who was in the planned cesarean group.

United States, after 2005

In response to the 2-year outcomes from the Multicentre International Trial, as well as some of the other reports cited above, the American College of Obstetricians and Gynecologists (2006) modified its stance concerning breech delivery. Specifically, Committee Opinion No. 340 states that "the decision regarding the mode of delivery should depend on the experience of the health care provider" and that "planned vaginal delivery of a term singleton breech fetus may be reasonable under hospital-specific protocol guidelines."

These newer guidelines seem more reasonable to define state-of-the-art practices. The problem of a continuing source of experienced operators is real (Chinnock and Robson, 2007). Some institutions have responded to diminished training opportunities in innovative ways. For example, Deering and colleagues (2006) utilized a birth simulator to improve resident competence in vaginal breech delivery. Finally, as aptly stated by Gimovsky and associates (2007), the "understandable but elusive desire to be 100-percent correct complicates the issue"!

Recommendations for Delivery

A diligent search for any other complications, actual or anticipated, that might justify cesarean delivery has become a feature of most philosophies for managing singleton breech delivery. Cesarean delivery is commonly, but not exclusively, used in the following circumstances:

1. A large fetus
2. Any degree of contraction or unfavorable shape of the pelvis determined clinically or with CT pelvimetry
3. A hyperextended head
4. When delivery is indicated in the absence of spontaneous labor
5. Uterine dysfunction—some would use oxytocin augmentation
6. Incomplete or footling breech presentation
7. An apparently healthy and viable preterm fetus with the mother in either active labor or in whom delivery is indicated
8. Severe fetal-growth restriction
9. Previous perinatal death or children suffering from birth trauma
10. A request for sterilization
11. Lack of an experienced operator.

For a favorable outcome with any breech delivery, at the very minimum, the birth canal must be sufficiently large to allow passage of the fetus without trauma. The cervix must be fully dilated, and if not, then a cesarean delivery nearly always is the

more appropriate method of delivery when suspected fetal compromise develops.

TECHNIQUES FOR BREECH DELIVERY

Labor and Spontaneous Delivery

There are important fundamental differences between labor and delivery in cephalic and breech presentations. With a cephalic presentation, once the head is delivered, the rest of the body typically follows without difficulty. With a breech, however, successively larger and very much less compressible parts are born. Spontaneous complete expulsion of the fetus that presents as a breech, as subsequently described, is seldom accomplished successfully. Therefore, as a rule, vaginal delivery requires skilled participation for a favorable outcome.

Methods of Vaginal Delivery

There are three general methods of breech delivery through the vagina:

1. *Spontaneous breech delivery.* The fetus is expelled entirely spontaneously without any traction or manipulation other than support of the newborn.
2. *Partial breech extraction.* The fetus is delivered spontaneously as far as the umbilicus, but the remainder of the body is extracted or delivered with operator traction and assisted maneuvers, with or without maternal expulsive efforts.
3. *Total breech extraction.* The entire body of the fetus is extracted by the obstetrician.

Labor Induction and Augmentation

Induction or augmentation of labor in women with a breech presentation is controversial. Many years ago, Brenner and associates (1974) found similar perinatal outcomes in newborns with induced versus spontaneous labor. In oxytocin-augmented labor, however, infant mortality rates were higher and Apgar scores were lower. Fait and colleagues (1998) reported that 12 of 23 women with an unripe cervix who underwent induction had a successful breech vaginal delivery with no neonatal complications. Su and colleagues (2003) reported that avoiding labor augmentation and having an experienced obstetrician present at birth significantly reduces the risk of adverse perinatal outcomes.

At Parkland Hospital, cesarean delivery is preferred to oxytocin induction or augmentation with a viable fetus. Amniotomy induction is suitable. At the University of Alabama at Birmingham, oxytocin is employed if clinical factors are favorable for vaginal delivery and if CT pelvimetry confirms an adequate pelvis.

Management of Labor

On arrival, rapid assessment should be made to establish the status of the membranes, labor, and fetal condition. Surveillance of fetal heart rate and uterine contractions is begun at admission. Immediate recruitment of necessary staff should include:

1. An obstetrician skilled in the art of breech extraction
2. An associate to assist with the delivery
3. Anesthesia personnel who can ensure adequate analgesia or anesthesia when needed
4. An individual trained newborn resuscitation.

In addition, the nursery is notified. For the mother, an intravenous catheter is inserted, and an infusion begun. Emergency induction of anesthesia or maternal resuscitation following hemorrhage from lacerations or from uterine atony are but two of many reasons that may require immediate intravenous access.

Stage of Labor

Assessment of cervical dilatation and effacement and the station of the presenting part is essential for planning the route of delivery. If labor is too far advanced, there may not be sufficient time to obtain pelvimetry. This alone, however, should not force the decision for cesarean delivery. Biswas and Johnstone (1993) found that among 267 term breech presentations, satisfactory progress in labor was the best indicator of pelvic adequacy. Nwosu and colleagues (1993) reported similar findings.

Fetal Condition

In many cases, sonographic fetal evaluation was done as part of prenatal care. If not, the presence of gross fetal abnormalities, such as hydrocephaly or anencephaly, can be rapidly ascertained with the use of sonography. This will help to ensure that a cesarean delivery is not performed under emergency conditions for an anomalous fetus with no chance of survival. For vaginal delivery, the fetal head should not be extended. As discussed, it is usually possible to ascertain head flexion and to exclude extension with sonography (Fontenot and colleagues, 1997; Rojansky and co-workers, 1994). If not possible, then simple two-view radiography of the abdomen can be used.

Fetal Monitoring

Additional help is required for managing labor and delivery of a breech presentation. One-on-one nursing is ideal during labor because of the risk of cord prolapse or occlusion, and physicians must be readily available should there be an emergency. Guidelines for monitoring the high-risk fetus are applied as discussed in Chapter 17 (p. 393). During the first stage of labor, the fetal heart rate is recorded at least every 15 minutes. Most clinicians prefer continuous electronic monitoring.

When membranes are ruptured, either spontaneously or artificially, the risk of cord prolapse is appreciably increased. The frequency of cord prolapse is increased when the fetus is small or when the breech is not frank (Barrett, 1991; Collea and colleagues, 1978. Therefore, a vaginal examination should be performed following rupture to check for cord prolapse. To detect occult cord prolapse, special attention should be directed to the fetal heart rate for the first 5 to 10 minutes following membrane rupture.

Soernes and Bakke (1986) confirmed earlier observations that umbilical cord length is significantly shorter in breech presentations. Moreover, multiple coils of cord entangling the fetus are more common with breech presentations (Spellacy and associates, 1966). These umbilical cord abnormalities likely play a role both in the development of breech presentation and in the

relatively high incidence of nonreassuring fetal heart rate patterns in labor.

Route of Delivery

The choice of abdominal or vaginal delivery is based on factors discussed on page 531. As outlined by the American College of Obstetricians and Gynecologists (2006), risks versus benefits are discussed with the woman. If possible, this is done before admission.

Cardinal Movements with Breech Delivery

Engagement and descent of the breech usually take place with the bitrochanteric diameter in one of the oblique pelvic diameters. The anterior hip usually descends more rapidly than the posterior hip, and when the resistance of the pelvic floor is met, internal rotation of 45 degrees usually follows, bringing the anterior hip toward the pubic arch and allowing the bitrochanteric diameter to occupy the anteroposterior diameter of the pelvic outlet. If the posterior extremity is prolapsed, however, it, rather than the anterior hip, rotates to the symphysis pubis.

After rotation, descent continues until the perineum is distended by the advancing breech, and the anterior hip appears at the vulva. By lateral flexion of the fetal body, the posterior hip then is forced over the perineum, which retracts over the buttocks, thus allowing the infant to straighten out when the anterior hip is born. The legs and feet follow the breech and may be born spontaneously or require aid.

After the birth of the breech, there is slight external rotation, with the back turning anteriorly as the shoulders are brought into relation with one of the oblique diameters of the pelvis. The shoulders then descend rapidly and undergo internal rotation, with the bisacromial diameter occupying the anteroposterior plane. Immediately following the shoulders, the head, which is normally sharply flexed upon the thorax, enters the pelvis in one of the oblique diameters and then rotates in such a manner as to bring the posterior portion of the neck under the symphysis pubis. The head is then born in flexion.

The breech may engage in the transverse diameter of the pelvis, with the sacrum directed anteriorly or posteriorly. The mechanism of labor in the transverse position differs only in that internal rotation is through an arc of 90 rather than 45 degrees. Infrequently, rotation occurs in such a manner that the back of the fetus is directed posteriorly instead of anteriorly. Such rotation should be prevented if possible. Although the head may be delivered by allowing the chin and face to pass beneath the symphysis, the slightest traction on the body may cause extension of the head, which increases the diameter of the head that must pass through the pelvis.

Partial Breech Extraction

Delivery is easier, and in turn, morbidity and mortality rates are probably lower, when the breech is allowed to deliver spontaneously to the umbilicus. Delivery of the breech draws the umbilicus and attached cord into the pelvis, which compresses the cord. Therefore, once the breech has passed beyond the vaginal introitus, the abdomen, thorax, arms, and head must be delivered promptly. If a nonreassuring fetal heart rate pattern develops before this time, however, a decision must be made whether to perform manual extraction or cesarean delivery.

FIGURE 24-5 The hips of the frank breech are delivering over the perineum.

With all breech deliveries, unless there is considerable relaxation of the perineum, an episiotomy should be made. The episiotomy is an important adjunct to any type of breech delivery. The posterior hip will deliver, usually from the 6 o'clock position, and often with sufficient pressure to evoke passage of thick meconium at this point (Fig. 24-5). The anterior hip then delivers, followed by external rotation to a sacrum anterior position. The mother should be encouraged to continue to push, as the cord is now drawn well down into the birth canal and likely is being compressed or stretched causing fetal bradycardia. As the fetus continues to descend, the legs are sequentially delivered by splinting the medial aspect of each femur with the operator's fingers positioned parallel to each femur, and by exerting pressure laterally to sweep each leg away from the midline.

FIGURE 24-6 Delivery of the body. The hands are applied, but not above the pelvic girdle. Gentle downward rotational traction is accomplished until the scapulas are clearly visible.

Following delivery of the legs, the fetal bony pelvis is grasped with both hands, using a cloth towel moistened with warm water. The fingers should rest on the anterior superior iliac crests and the thumbs on the sacrum, minimizing the chance of fetal abdominal soft tissue injury (Fig. 24-6). Maternal expulsive efforts are used in conjunction with continued gentle downward operator rotational traction to effect delivery. Gentle downward traction is combined with an initial 90-degree rotation of the fetal pelvis through one arc and then a 180-degree rotation to the other, to effect delivery of the scapulas and arms (Figs. 24-7 and 24-8).

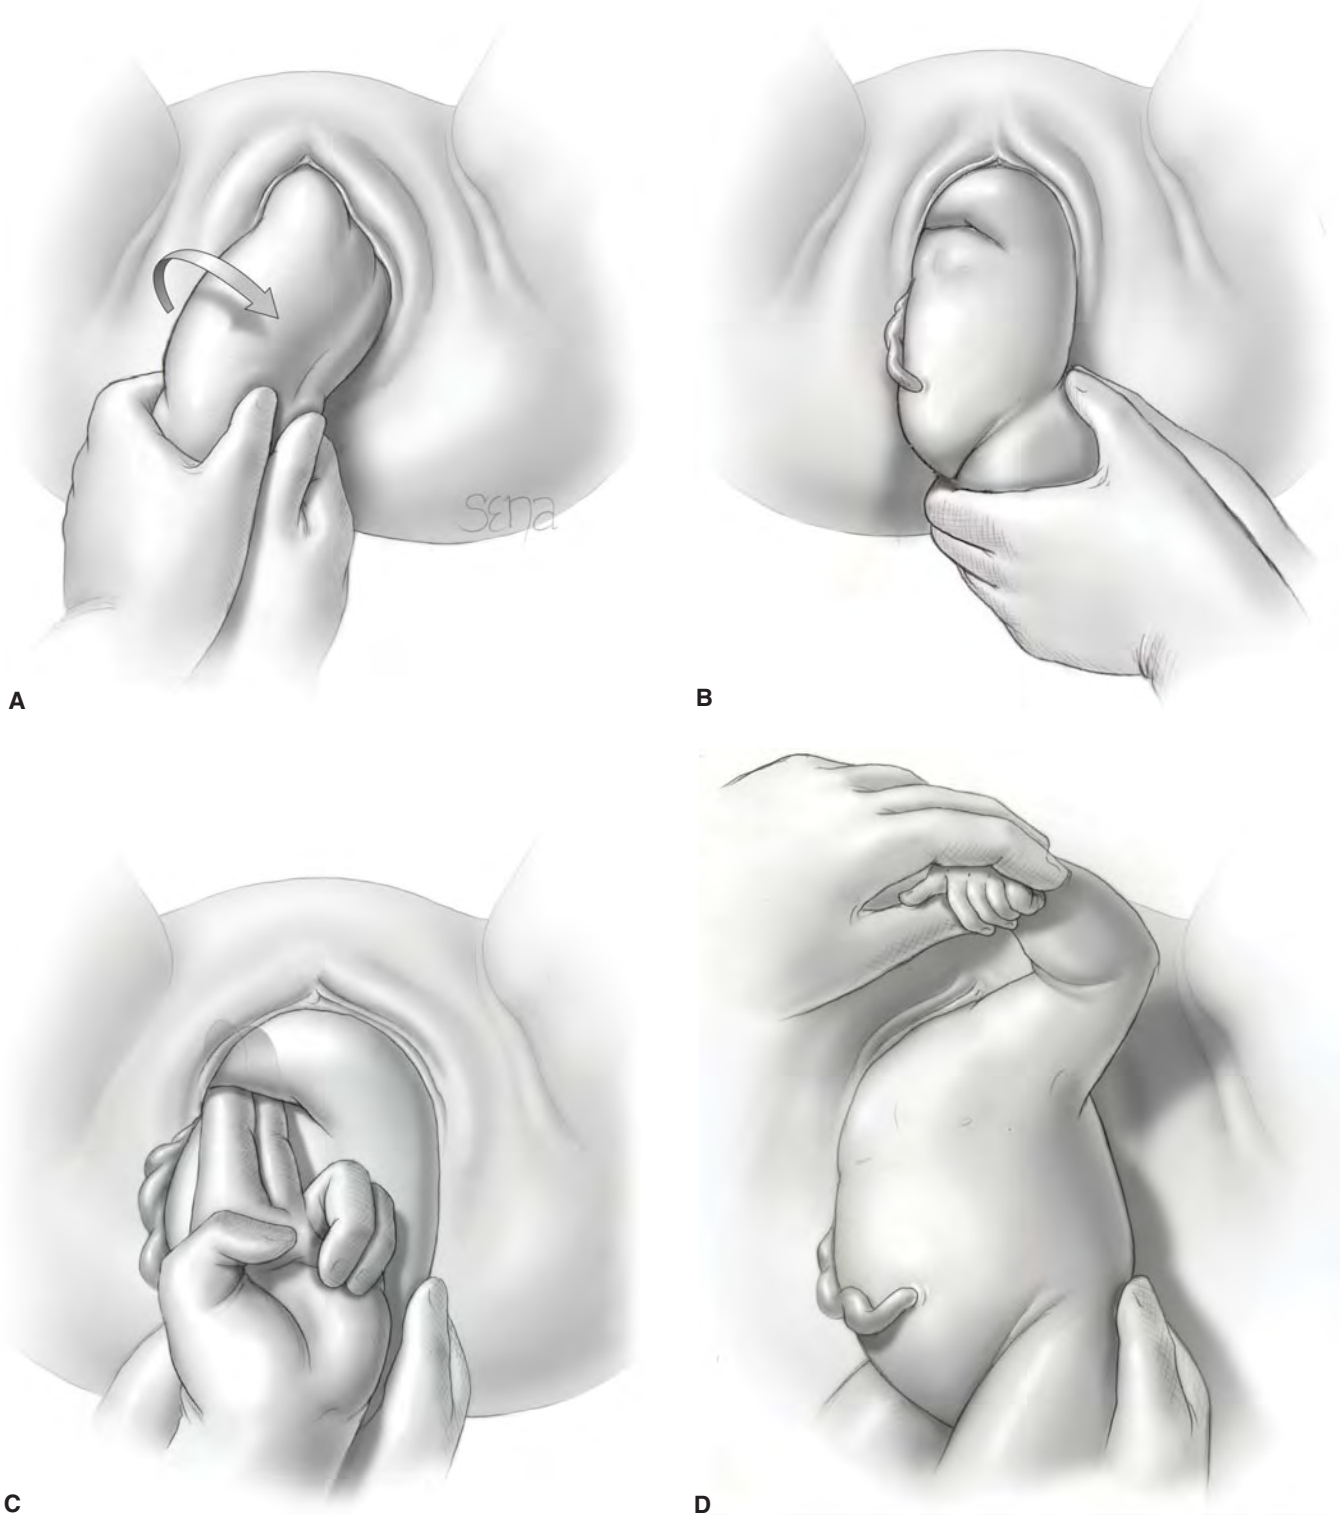

FIGURE 24-7 Clockwise rotation of the fetal pelvis 90 degrees brings the sacrum from anterior to left sacrum transverse. Simultaneously, the application of gentle downward traction effects delivery of the scapula **(A)** and arm **(B–D)**.

FIGURE 24-8 Counterclockwise rotation from sacrum anterior to right sacrum transverse along with gentle downward traction effects delivery of the right scapula.

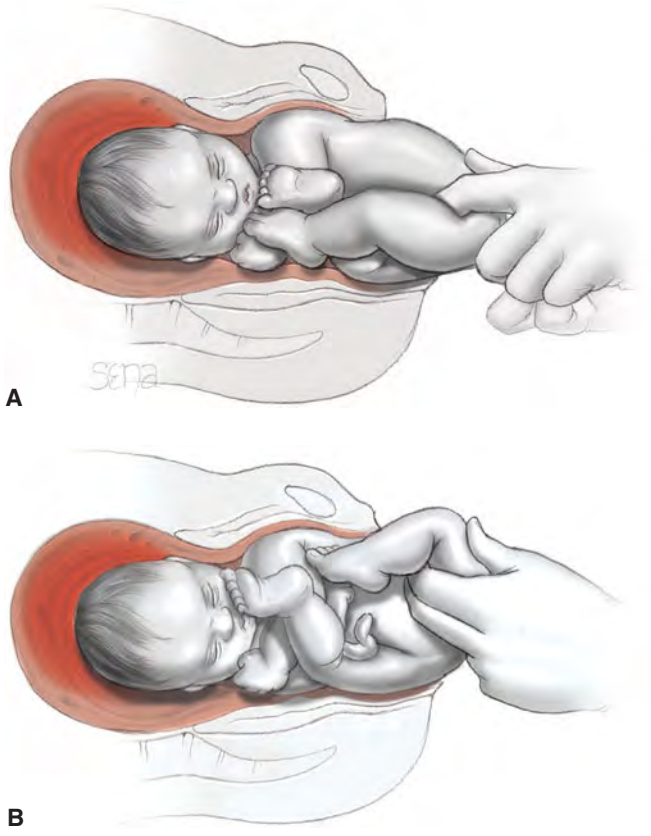

FIGURE 24-9 **A.** Extraction of frank breech using fingers in groins. **B.** Once the hips are delivered, each hip and knee is flexed to deliver them from the vagina.

These rotational and downward traction maneuvers will decrease the persistence of nuchal arms, which can prevent further descent and may result in a traumatic delivery. These maneuvers are frequently most easily effected with the operator at the level of the maternal pelvis and with one knee on the floor. When the scapulas are clearly visible, delivery is then completed as subsequently described for the complete or incomplete breech (p. 536).

Total Breech Extraction

Frank Breech Extraction

At times, extraction of a frank breech may be required and can be accomplished by moderate traction exerted by a finger in each groin and aided by a generous episiotomy (Fig. 24-9). If moderate traction does not affect delivery, then vaginal delivery can be accomplished only by breech decomposition. This procedure involves manipulation within the birth canal to convert the frank breech into a footling breech. It is accomplished more readily if the membranes have ruptured recently, and it becomes extremely difficult if there is minimal amnionic fluid. In such cases, the uterus may have become tightly contracted around the fetus. Pharmacological relaxation by general anesthesia, intravenous magnesium sulfate, or a betamimetic such as terbutaline, 250 μg subcutaneously, may be required.

Breech decomposition is accomplished by the maneuver attributed to Pinard (1889). It aids in bringing the fetal feet within reach of the operator. As shown in Figure 24-10, two fingers are carried up along one extremity to the knee to push it away from the midline. Spontaneous flexion usually follows, and the foot of the fetus is felt to impinge on the back of the hand. The fetal foot then may be grasped and brought down.

FIGURE 24-10 Frank breech decomposition using the Pinard maneuver. Two fingers are inserted along one extremity to the knee, which is then pushed away from the midline after spontaneous flexion. Traction is used to deliver a foot into the vagina.

FIGURE 24-11 Complete breech extraction begins with traction on the feet and ankles.

FIGURE 24-12 As breech extraction continues, upward traction is employed, effecting delivery of the posterior shoulder. This is followed by delivery of the posterior arm.

Complete or Incomplete Breech Extraction

During total extraction of a complete or incomplete breech, the hand is introduced through the vagina and both feet of the fetus are grasped. The ankles are held with the second finger lying between them and with gentle traction, the feet are brought through the vulva. If difficulty is experienced in grasping both feet, first one foot should be drawn into the vagina but not through the introitus, and then the other foot is advanced in a similar fashion. Now both feet are grasped and pulled through the vulva simultaneously (Fig. 24-11).

As the legs begin to emerge through the vulva, downward gentle traction is then continued. As the legs emerge, successively higher portions are grasped, first the calves and then the thighs. When the breech appears at the vaginal outlet, gentle traction is applied until the hips are delivered. As the buttocks emerge, the back of the fetus usually rotates to the anterior. The thumbs are then placed over the sacrum and the fingers over the hips, and assisted breech delivery is completed, as described previously (see Fig. 24–6). As the scapulas become visible, the back of the fetus tends to turn spontaneously toward the side of the mother to which it was originally directed.

A cardinal rule in successful breech extraction is to employ steady, gentle, downward rotational traction until the lower halves of the scapulas are delivered, making no attempt at delivery of the shoulders and arms until one axilla becomes visible. The appearance of one axilla indicates that the time has arrived for delivery of the shoulders. It makes little difference which shoulder is delivered first, and there are two methods for delivery of the shoulders:

1. In the first method, with the scapulas visible, the trunk is rotated in such a way that the anterior shoulder and arm appear at the vulva and can easily be released and delivered first (see Fig. 24-7). The body of the fetus is then rotated in the reverse direction to deliver the other shoulder and arm (see Fig. 24-8).
2. The second method is employed if trunk rotation is unsuccessful. With this maneuver, the posterior shoulder is delivered first. The feet are grasped in one hand and drawn upward over the inner thigh of the mother toward which the ventral surface of the fetus is directed (Fig. 24-12). In this manner, leverage is exerted on the posterior shoulder, which slides out over the perineal margin, usually followed by the arm and hand. Then, by depressing the body of the fetus, the anterior shoulder emerges beneath the pubic arch, and the arm and hand usually follow spontaneously. Thereafter, the back tends to rotate spontaneously in the direction of the symphysis. If upward rotation fails to occur, it is completed by manual rotation of the body. Delivery of the head may then be accomplished.

Unfortunately, the process is not always so simple, and it is sometimes necessary first to free and deliver the arms. These maneuvers are less likely to be required if rotational traction is employed and attempts to deliver the shoulders until an axilla becomes visible are avoided. **Attempts to free the arms immediately after the costal margins emerge should be avoided.** There is more space available in the posterior and lateral segments of the normal pelvis than elsewhere. Therefore, in difficult cases, the posterior arm should be freed first. Because the corresponding axilla is already visible, upward traction on the feet is continued, and two fingers of the other hand are passed along the humerus until the elbow is reached (see Fig. 24-12). The fingers are placed parallel to the humerus and used to splint the arm, which is swept downward and delivered through the vulva.

To deliver the anterior arm, depression of the body of the fetus is sometimes all that is required to allow the anterior arm to slip out spontaneously. In other instances, the anterior arm can be swept down over the thorax using two fingers as a splint.

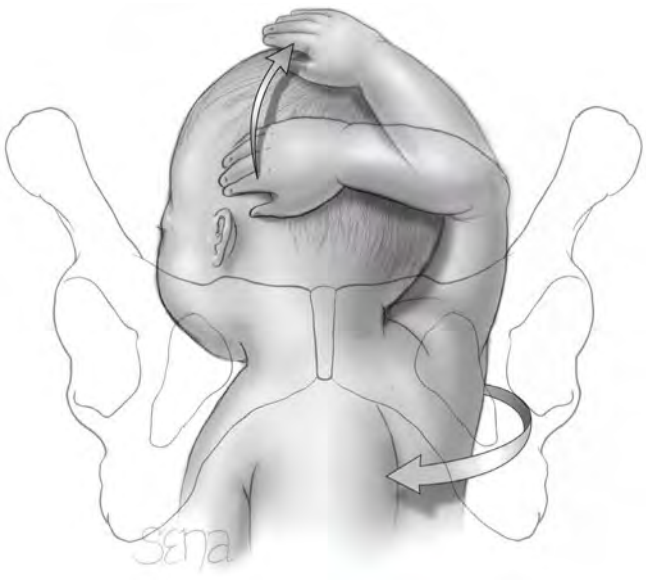

FIGURE 24-13 Reduction of nuchal arm being accomplished by rotating the fetus through half a circle counterclockwise so that the friction exerted by the birth canal will draw the elbow toward the face.

In some cases, the body must be held with the thumbs over the scapulas and rotated to bring the undelivered shoulder near the closest sacrosciatic notch. The legs then are carried upward to bring the ventral surface of the fetus to the opposite inner thigh of the mother. Subsequently, the arm can be delivered as described previously. If the arms have become extended over the head, their delivery, although more difficult, usually can be accomplished by the maneuvers just described. In so doing, particular care must be taken by the operator to carry the fingers up to the elbow and to use them as a splint to prevent fracture of the humerus.

Nuchal Arm. As discussed earlier, one or both fetal arms occasionally may be found around the back of the neck—the nuchal arm—and impacted at the pelvic inlet. In this situation, delivery is more difficult. If the nuchal arm cannot be freed in the manner described, extraction may be aided, especially with a single nuchal arm, by rotating the fetus through half a circle in such a direction that the friction exerted by the birth canal will serve to draw the elbow toward the face (Fig. 24-13). Should rotation of the fetus fail to free the nuchal arm(s), it may be necessary to push the fetus upward in an attempt to release it. If the rotation is still unsuccessful, the nuchal arm often is extracted by hooking a finger(s) over it and forcing the arm over the shoulder, and down the ventral surface for delivery of the arm. In this event, fracture of the humerus or clavicle is very common.

Delivery of the Aftercoming Head

The fetal head may be extracted with forceps or by one of the following maneuvers.

Mauriceau Maneuver

The index and middle finger of one hand are applied over the maxilla, to flex the head, while the fetal body rests on the palm of the hand and forearm (Fig. 24-14). The forearm is straddled by the fetal legs. Two fingers of the other hand then are hooked over the fetal neck, and grasping the shoulders, downward traction is applied until the suboccipital region appears under the symphysis. Gentle suprapubic pressure simultaneously applied by an assistant helps keep the head flexed. The body then is elevated toward the maternal abdomen, and the mouth, nose, brow, and eventually the occiput emerge successively over the perineum. **With this maneuver, the operator uses both hands simultaneously and in tandem to exert continuous downward gentle traction simultaneously on the fetal neck and on the maxilla.** At the same time, appropriate suprapubic pressure applied by an assistant is helpful in delivery of the head (see Fig. 24-14).

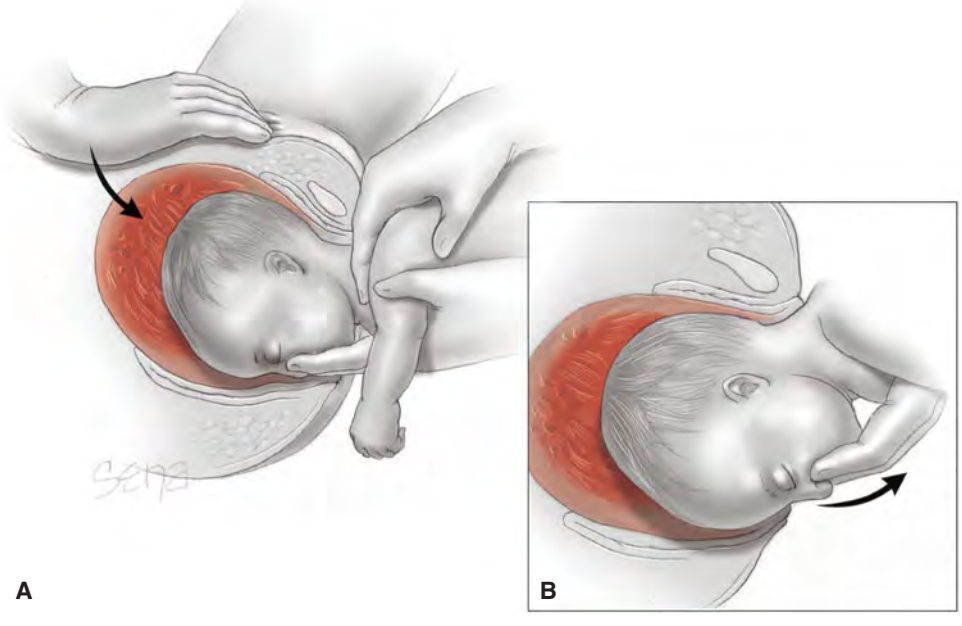

FIGURE 24-14 A. Delivery of the aftercoming head using the Mauriceau maneuver. Note that as the fetal head is being delivered, flexion of the head is maintained by suprapubic pressure provided by an assistant. **B.** Pressure on the maxilla is applied simultaneously by the operator as upward and outward traction is exerted.

Modified Prague Maneuver

Rarely, the back of the fetus fails to rotate to the anterior. When this occurs, rotation of the back to the anterior may be achieved by using stronger traction on the fetal legs or bony pelvis. If the back still remains oriented

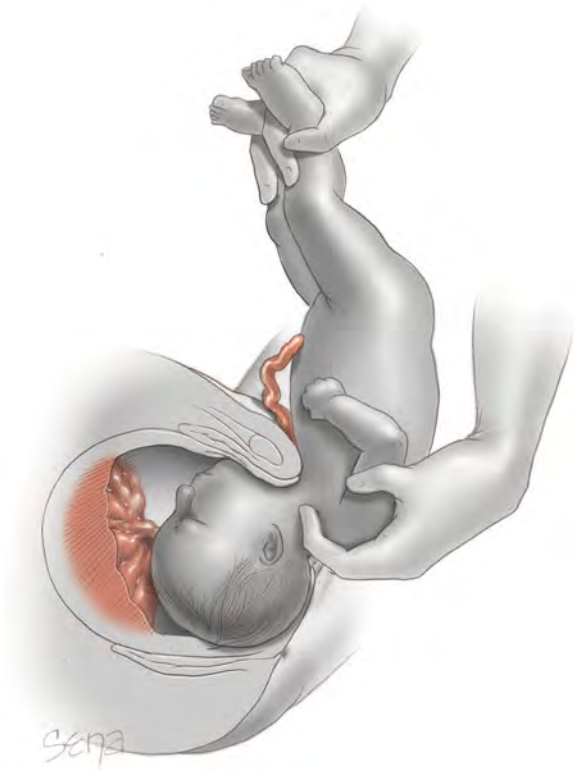

FIGURE 24-15 Delivery of the aftercoming head using the modified Prague maneuver necessitated by failure of the fetal trunk to rotate anteriorly.

posteriorly, extraction may be accomplished using the Mauriceau maneuver and delivering the fetus back down. If this is impossible, the fetus still may be delivered using the modified Prague maneuver, which, as practiced today, consists of two fingers of one hand grasping the shoulders of the back-down fetus from below while the other hand draws the feet up over the maternal abdomen (Fig. 24-15).

Forceps to Aftercoming Head

Specialized forceps can be used to deliver the aftercoming head. *Piper forceps,* shown in Figure 24-16, or divergent *Laufe forceps* may be applied electively or when the Mauriceau maneuver cannot be accomplished easily. The blades of the forceps should not be applied to the aftercoming head until it has been brought into the pelvis by gentle traction, combined with suprapubic pressure, and is engaged. Suspension of the body of the fetus in a towel effectively holds the fetus and helps keep the arms out of the way.

Entrapment of the Aftercoming Head

Occasionally—especially with a small preterm fetus—the incompletely dilated cervix will constrict around the neck and impede delivery of the aftercoming head. At this point, it must be assumed that there is significant and even total cord compression, and thus time is of the essence. With gentle traction on the fetal body, the cervix, at times, may be manually slipped over the occiput. If this is not successful, then *Dührssen incisions* as shown in Figure 24-17 may be necessary. Other alternatives include intravenous nitroglycerin—typically 100 μg—to provide cervical relaxation for relief of head entrapment (Dufour and colleagues, 1997; Wessen and associates, 1995). There is, however, no compelling evidence of its efficacy for this purpose. General anesthesia is another option.

As a last resort, replacement of the fetus higher into the vagina and uterus, followed by cesarean delivery, can be used to rescue an entrapped breech fetus that cannot be delivered vaginally. Steyn and Pieper (1994) described use of the *Zavanelli maneuver*—cesarean delivery after replacement of the fetus back into the uterus—to deliver a healthy 2590-g newborn with head entrapment. Sandberg (1999) reviewed 11 breech deliveries in which this maneuver was used.

In some countries, *symphysiotomy* is used to widen the anterior pelvis. Sunday-Adeoye and colleagues (2004) reported that at the Mater Misericordiae Hospital, in Nigeria, 3.7 percent of 27,477 deliveries from 1982 to 1989 were accomplished with symphysiotomy! In his review, Menticoglou (1990) reported that its use has been associated with good infant outcomes in 80 percent of reported cases. Lack of operator training and the potential to cause serious maternal injury explain its rare use in this country (Goodwin and colleagues, 1997).

ANALGESIA AND ANESTHESIA

Continuous epidural analgesia, as described in Chapter 19 (p. 454), is advocated by some as ideal for women in labor with a breech presentation. Confino and colleagues (1985) reviewed the outcomes of 371 singleton breech fetuses delivered vaginally. About 25 percent of these women had been given continuous epidural analgesia, and oxytocin augmentation was necessary to effect delivery in half of them. Although first-stage labor was not longer than in a control group not given epidural analgesia, the second stage was prolonged significantly in women whose fetuses weighed more than 2500 g. It was doubled if the fetus weighed more than 3500 g. Chadha and associates (1992) reported similar findings. These potential disadvantages must be weighed against the advantages of better pain relief and importantly, increased pelvic relaxation should extensive manipulation be required to complete delivery.

Analgesia for episiotomy and intravaginal manipulations that are needed for breech extraction usually can be accomplished with pudendal block and local infiltration of the perineum. Nitrous oxide plus oxygen inhalation provides further relief from pain. If general anesthesia is required, it can be induced quickly with thiopental plus a muscle relaxant and maintained with nitrous oxide.

Anesthesia for breech decomposition and extraction must provide sufficient relaxation to allow intrauterine manipulations. Although successful decomposition has been accomplished using epidural or spinal analgesia, increased uterine tone may render the operation more difficult. Under such conditions, general anesthesia with a halogenated agent may be required to relax the uterus as well as to provide analgesia.

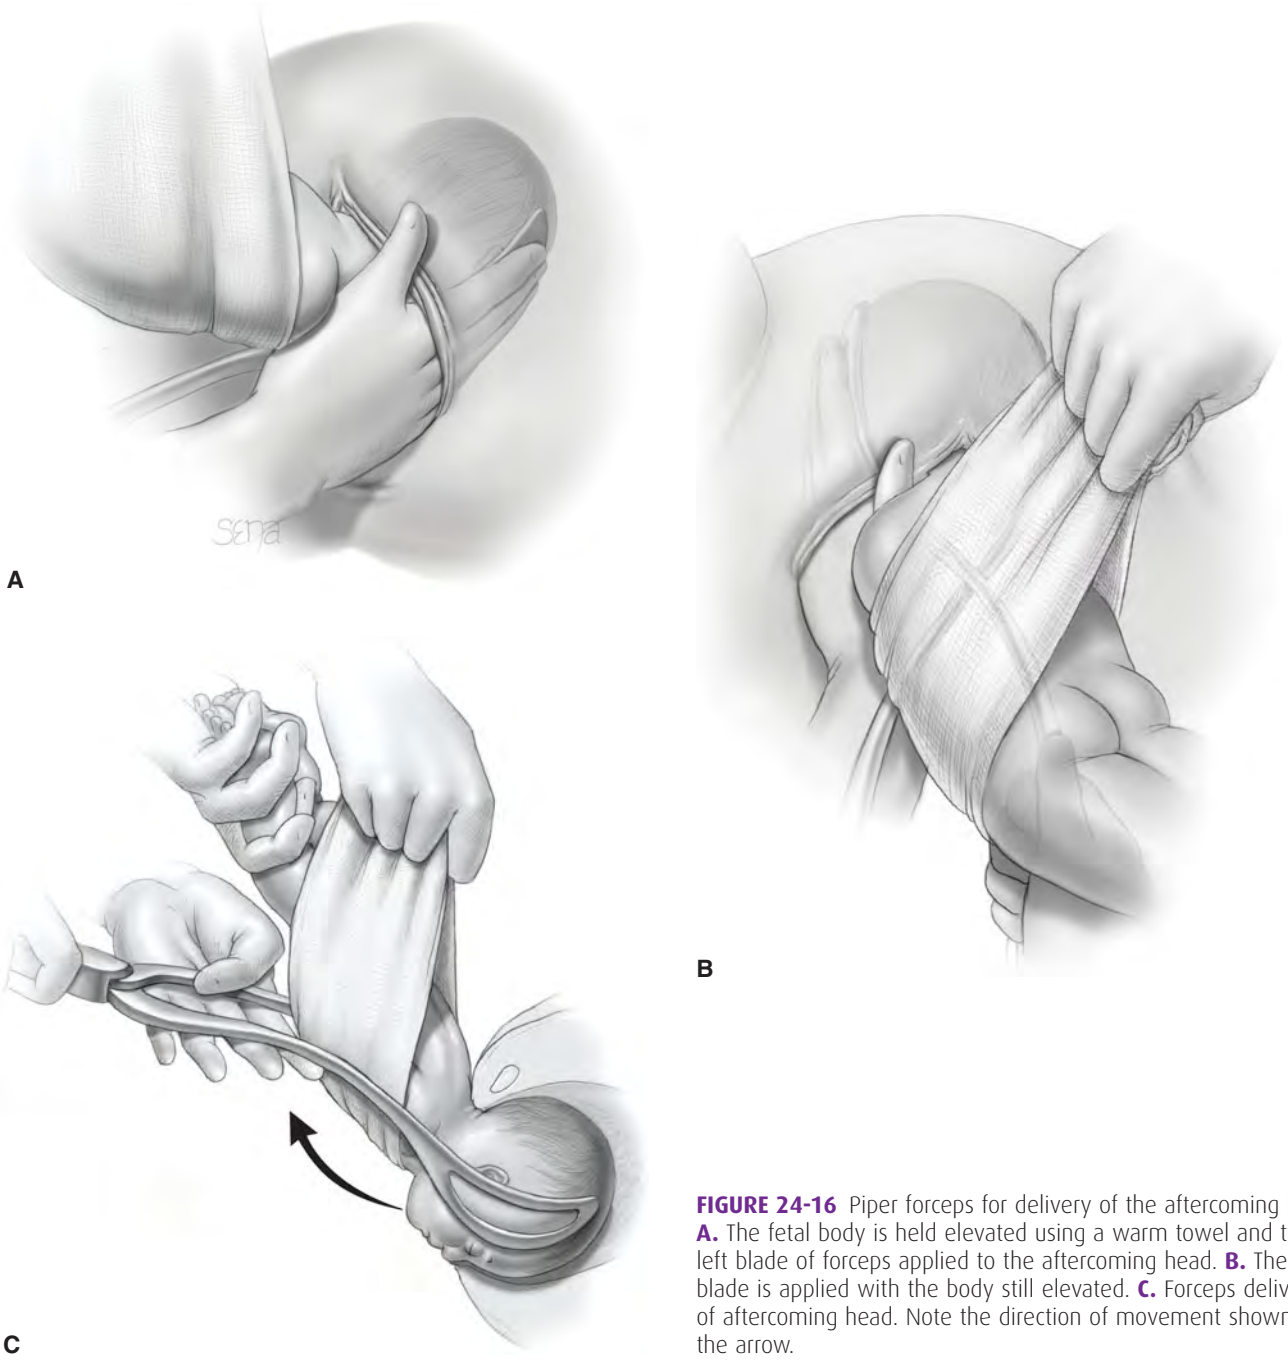

FIGURE 24-16 Piper forceps for delivery of the aftercoming head. **A.** The fetal body is held elevated using a warm towel and the left blade of forceps applied to the aftercoming head. **B.** The right blade is applied with the body still elevated. **C.** Forceps delivery of aftercoming head. Note the direction of movement shown by the arrow.

VERSION

Version is a procedure in which the fetal presentation is altered by physical manipulation, either substituting one pole of a longitudinal presentation for the other, or converting an oblique or transverse lie into a longitudinal presentation. According to whether the head or breech is made the presenting part, the operation is designated *cephalic* or *podalic version,* respectively. In *external version,* the manipulations are performed exclusively through the abdominal wall. In *internal version,* they are accomplished inside the uterine cavity.

External Cephalic Version

In the United States, Van Dorsten and co-workers (1981) rekindled interest in this procedure, and the American College of Obstetricians and Gynecologists (2006) recommends that version should be offered and attempted whenever possible. The

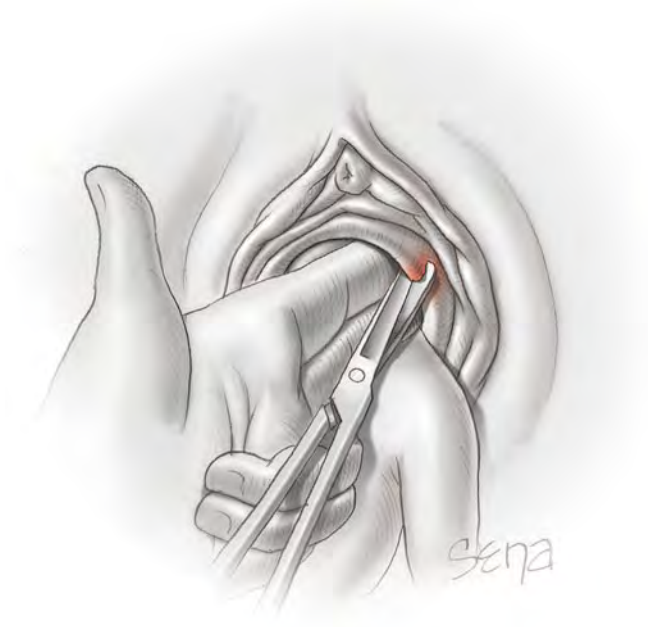

FIGURE 24-17 Dührssen incision being cut at 2 o'clock, which is followed by a second incision at 10 o'clock. Infrequently, an additional incision is required at 6 o'clock. The incisions are so placed as to minimize bleeding from the laterally located cervical branches of the uterine cavity. After delivery, the incisions are repaired as described in Chapter 35 (p. 783).

success rate for external version ranges from 35 to 86 percent, with an average of 58 percent (American College of Obstetricians and Gynecologists, 2000). In their review of 25 reports through 1991, Zhang and co-workers (1993) reported an average success rate of 65 percent. Moreover, they observed that after successful version, almost all fetuses remain cephalic.

Interestingly, several reports suggest that even after successful version, the risk of cesarean delivery does not completely revert to the institutional baseline for vertex presentations, and that dystocia, malpresentation, and nonreassuring fetal heart patterns may be more common after successful version (Chan and colleagues, 2004; Vézina and associates, 2004). Also, failure is not always absolute. Ben-Meir and colleagues (2007) reported a spontaneous version rate of 7 percent among 226 failed versions—2 percent among nulliparas and 13 percent among parous women.

Indications

In general, when a breech presentation is recognized prior to labor in a woman who has reached 36 weeks' gestation, external cephalic version should be considered. Before this time, there is a relatively high incidence of recurrence. After 36 weeks, however, the likelihood of spontaneous version is low (Hickok and colleagues, 1992; Westgren and co-workers, 1985). Moreover, if version results in the need for immediate delivery, complications of iatrogenic preterm delivery generally are not severe.

Version is contraindicated if vaginal delivery is not an option. Examples include placenta previa or nonreassuring fetal status. A prior uterine incision is a relative contraindication, although in small studies external version was not associated with uterine rupture in women who had previously undergone cesarean delivery (Abenhaim, 2009; Flamm, 1991; Sela, 2009, and all their associates). At the University of Alabama at Birmingham, decisions about version in women with a prior cesarean incision are individualized. At Parkland Hospital, external version is not attempted in these women. Obviously, larger studies are needed to better characterize risks versus benefits.

TABLE 24-1. Factors That May Modify the Success of External Cephalic Version

Increase Success
Increasing parity
Ample amnionic fluid
Unengaged fetus
Tocolysis
Decrease Success
Engaged fetus
Tense uterus
Inability to palpate head
Obesity
Anterior placenta
Fetal spine anterior or posterior
Labor

Factors Associated with Successful Version

A number of associated factors can improve or lessen the chances of a successful version attempt (Table 24-1). Increasing parity and increasing amnionic fluid index are consistent factors associated with success (Boucher, 2003; Hutton, 2008; Kok, 2008; Zhang, 1993, and all their co-workers). Kok and colleagues (2009) reported improved success also in those with a posterior placenta and complete breech position.

A number of factors are predictive of *failed version.* Lau and associates (1997) identified three: (1) an engaged presenting part, (2) difficult palpation of the fetal head, and (3) a uterus tense to palpation. When all three were present, there were no successes; with two, success was less than 20 percent; and if none was present, the success rate was 94 percent. In a secondary analysis of a randomized trial that included 178 women undergoing attempted version, Hutton and colleagues (2008) reported that an unengaged presenting part improved the success rate. They recommended consideration for attempted version before engagement, that is, earlier in pregnancy. Other reported determinants of failed version include maternal obesity, anterior placenta, cervical dilatation, and anterior or posterior positioning of the fetal spine (Fortunato and associates, 1988; Newman and colleagues, 1993).

Transverse Lie

Women with a transverse lie usually are excluded from analyses of breech version because the overall success rate approaches 90 percent (Newman and colleagues, 1993).

Technique

External cephalic version should be carried out in an area that has ready access to a facility equipped to perform emergency cesarean deliveries (American College of Obstetricians and

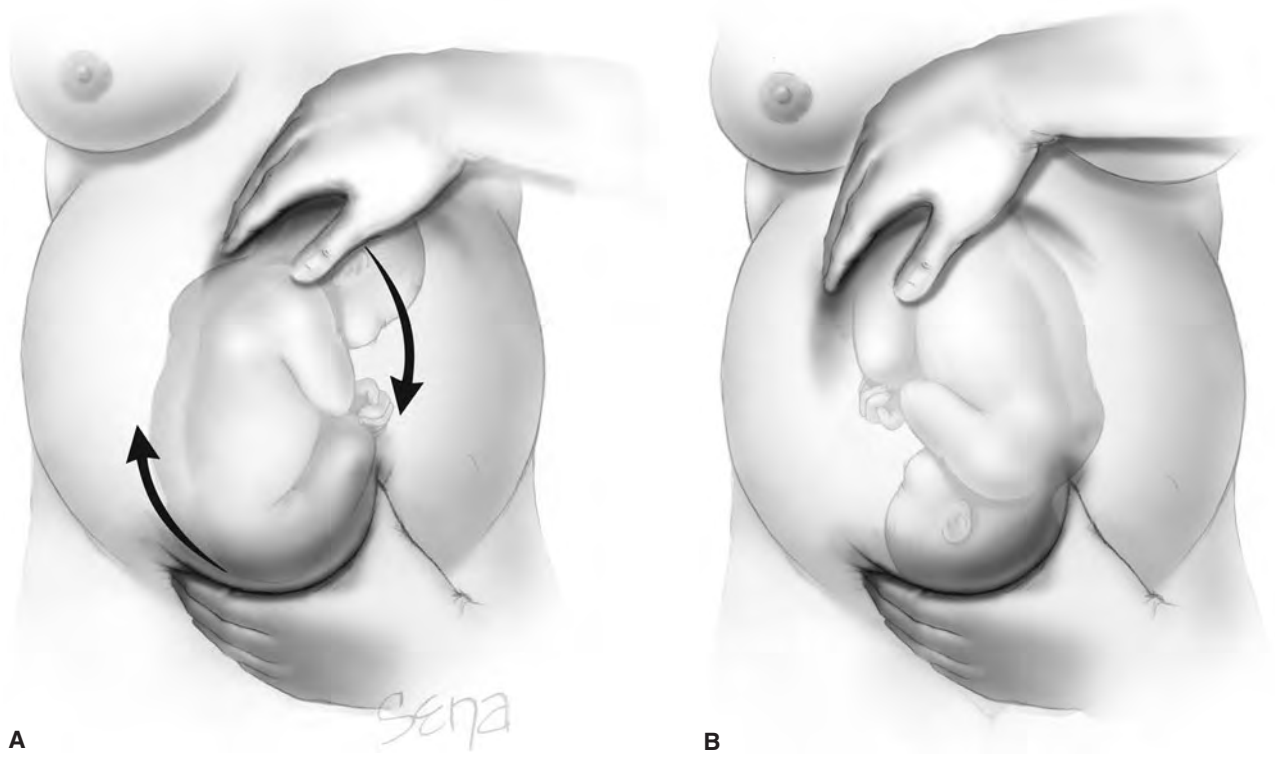

FIGURE 24-18 External cephalic version. **A.** Clockwise pressure is exerted against the fetal poles. **B.** Successful completion is noted by feeling the head above the symphysis during Leopold examination.

Gynecologists, 2000). Sonographic examination is performed to confirm nonvertex presentation and adequacy of amnionic fluid volume, to exclude obvious fetal anomalies if not done previously, and to identify placental location. External monitoring is performed to assess fetal heart rate reactivity. Anti-D immune globulin is given if indicated.

A *forward roll* of the fetus usually is attempted first. As shown in Figure 24-18, each hand grasps one of the fetal poles, and the buttocks are elevated from the maternal pelvis and displaced laterally. The buttocks are then gently guided toward the fundus, while the head is directed toward the pelvis. If the forward roll is unsuccessful, then a *backward flip* is attempted. Version attempts are discontinued for excessive discomfort, persistently abnormal fetal heart rate, or after multiple failed attempts. The nonstress test is repeated after version until a normal test result is obtained.

Tocolysis

Although many clinicians recommend uterine relaxation with a tocolytic agent, their impact on success is controversial. For example, Robertson and associates (1987) used ritodrine, Tan and colleagues (1989) used salbutamol, and Yanny and associates (2000) used glyceryl trinitrate, but none observed apparent benefits. Indeed, Bujold and colleagues (2003) conducted a placebo-controlled trial of 99 women and reported that sublingual nitroglycerin was associated with a *lower* version success rate than placebo—48 versus 63 percent. In another randomized trial, however, Fernandez and co-workers (1996) reported that the success rate with subcutaneous terbutaline-52 percent-was significantly higher than without—27 percent. Our policies at the University of Alabama at Birmingham and at Parkland Hospital are to administer 250 μg of terbutaline subcutaneously to most women prior to attempted version. When maternal tachycardia—a known side effect of terbutaline—is noted, then the version attempt is begun.

Conduction Analgesia

Epidural analgesia has been reported to increase the success of version. In a randomized trial, Schorr and co-workers (1997) found that epidural analgesia given with terbutaline tocolysis resulted in a 60-percent success rate compared with 30 percent of women given only terbutaline. In another randomized trial of 108 women, Mancuso and associates (2000) reported a success rate of 59 percent with epidural analgesia versus 33 percent without.

Spinal analgesia has also been used for external version. Weiniger and associates (2007) reported in a small trial of 70 women that spinal analgesia increased the success rate of version. In the trials of Dugoff (2001) and Delisle (2001) and their colleagues, it was not of benefit. According to the American College of Obstetricians and Gynecologists (2000), there is not enough consistent evidence to recommend conduction analgesia routinely for external version.

Other Methods

There are some unconventional interventions that have been used to help effect version. Cardini and Weixen (1998) performed a randomized trial to evaluate *moxibustion*. This involves burning the herbal preparation *moxa* to generate heat to

stimulate acupuncture point BL67—to promote spontaneous breech version. Women in the intervention group experienced significantly increased fetal movements and more often had a cephalic presentation at delivery. These astounding results were not replicated in a follow-up study by Cardini and co-workers (2005). Mehl (1994) found *hypnosis* with suggestions for relaxation to be effective. Finally, Crawford (2005) described a case report of successful use of an old folk remedy—application of ice to the abdomen—to cause version.

Complications

Risks of external version include placental abruption, uterine rupture, fetomaternal hemorrhage, isoimmunization, preterm labor, fetal compromise, and even death. Most worrisome is the report by Stine and co-workers (1985) of a maternal death due to amnionic fluid embolism. That said, fetal deaths are rare (Zhang and colleagues, 1993).

With the exception of rare severe complications, based on a comprehensive review, Collaris and Oei (2004) concluded that external cephalic version is safe. One caveat was that complications were more common when conduction analgesia was used. Use of nitrous oxide or conduction analgesia was associated with twice as many abnormal fetal heart rate tracings. Moreover, vaginal bleeding and procedure-related emergency cesarean deliveries were increased tenfold. These reviewers concluded that diminished pain in these women likely encouraged overzealous application of force during the version attempts, which led to complications. More recently, Collins and associates (2007) report very low complication rates and an emergency cesarean rate of only 0.5 percent in 805 consecutive external cephalic version attempts at the John Radcliffe Hospital in Oxford, England.

Internal Podalic Version

This maneuver is used only for delivery of a second twin. It consists of the insertion of a hand into the uterine cavity to turn the fetus manually. The operator seizes one or both feet and draws them through the fully dilated cervix while using the other hand transabdominally to push the upper portion of the fetal body in the opposite direction as shown in Chapter 39 (p. 883). This is followed by breech extraction.

CHAPTER 25

Cesarean Delivery and Peripartum Hysterectomy

HISTORICAL BACKGROUND 544
CONTEMPORARY STATUS OF CESAREAN DELIVERY 544
TECHNIQUE FOR CESAREAN DELIVERY 549
PERIPARTUM HYSTERECTOMY 555
PERIPARTUM MANAGEMENT 560

Cesarean delivery is defined as the birth of a fetus through incisions in the abdominal wall (laparotomy) and the uterine wall (hysterotomy). This definition does not include removal of the fetus from the abdominal cavity in the case of rupture of the uterus or in the case of an abdominal pregnancy. In some cases, and most often because of emergent complications such as intractable hemorrhage, abdominal hysterectomy is indicated following delivery. When performed at the time of cesarean delivery, the operation is termed *cesarean hysterectomy.* If done within a short time after vaginal delivery, it is termed *postpartum hysterectomy.*

HISTORICAL BACKGROUND

The origin of the term *cesarean* is obscure, and three principal explanations have been suggested.

In the first, according to legend, Julius Caesar was born in this manner, with the result that the procedure became known as the Caesarean operation. Several circumstances weaken this explanation. First, the mother of Julius Caesar lived for many years after his birth in 100 BC, and as late as the 17th century, the operation was almost invariably fatal. Second, the operation, whether performed on the living or the dead, is not mentioned by any medical writer before the Middle Ages. Historical details of the origin of the family name Caesar are found in the monograph by Pickrell (1935).

The second explanation is that the name of the operation is derived from a Roman law, supposedly created in the 8th century BC by Numa Pompilius, ordering that the procedure be performed upon women dying in the last few weeks of pregnancy in the hope of saving the child. This *lex regia*—king's rule or law—later became the *lex caesarea* under the emperors, and the operation itself became known as the caesarean operation. The German term *Kaiserschnitt*—Kaiser cut—reflects this derivation.

The third explanation is that the word *caesarean* was derived sometime in the Middle Ages from the Latin verb *caedere, to cut.* This explanation seems most logical, but exactly when it was first applied to the operation is uncertain. Because *section* is derived from the Latin verb *seco,* which also means *cut,* the term *caesarean section* seems tautological—thus *cesarean delivery* is used. In the United States, the *ae* in the first syllable of *caesarean* is replaced with the letter *e.* In the United Kingdom, Australia, and most commonwealth nations, the *ae* is retained.

A more extensive review of the history of cesarean delivery can be found in the 22nd edition of *Williams Obstetrics* (Cunningham and colleagues, 2005), as well as in works by Boley (1991) and Sewell (1993).

CONTEMPORARY STATUS OF CESAREAN DELIVERY

Frequency

From 1970 to 2007, the cesarean delivery rate in the United States rose from 4.5 percent of all deliveries to 31.8 percent (Hamilton and colleagues, 2009; MacDorman and associates, 2008). This increase has been steady with the exception of the years between 1989 and 1996 when the annual rate of cesarean delivery actually decreased (Fig. 25-1). This decrease was largely due to a significantly increased rate of vaginal birth after cesarean (VBAC) and to a closely mirrored decrease in the primary rate

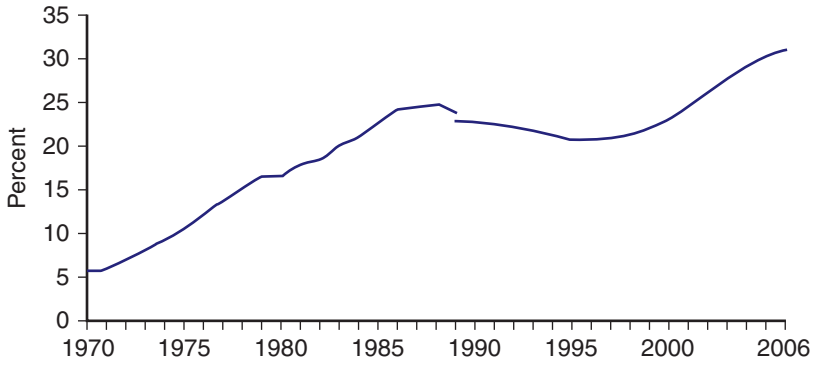

FIGURE 25-1 Total cesarean delivery rate: United States, 1970–2006. (Reprinted from *Clinics in Perinatology*, Vol. 35, No. 2, MF MacDorman, F Menacker, E Declercq, Cesarean birth in the United States: Epidemiology, trends, and outcomes, pp. 293–307, Copyright 2008, with permission from Elsevier.)

(Fig. 25-2). These trends were short lived, and in 2007, the primary cesarean delivery rate was above 30 percent, whereas VBAC rates dropped to 8.5 percent (Hamilton and associates, 2009).

In response to the increased use of cesarean delivery, the American College of Obstetricians and Gynecologists Task Force on Cesarean Delivery Rates (2000) recommended two benchmarks for the United States for the year 2010. Goals included a cesarean rate of 15.5 percent for nulliparous women at 37 weeks or more with a singleton cephalic presentation and secondly, a vaginal birth rate after a prior cesarean of 37 percent in women at 37 weeks or more with a singleton cephalic presentation who had a prior low transverse cesarean delivery. These goals are consistent with the 15-percent cesarean rate established by the U.S. Department of Health and Human Services *Healthy People 2010* program for primiparous, low-risk women. The department's mid-decade review of the program (2006), however, showed no progress on this goal.

The reasons for the continued increase in the cesarean rates are not completely understood, but some explanations include the following:

1. Women are having fewer children, thus, a greater percentage of births are among *nulliparas,* who are at increased risk for cesarean delivery.
2. The average *maternal age* is rising, and older women, especially nulliparas, are at increased risk of cesarean delivery (Fig. 25-3).
3. The use of *electronic fetal monitoring* is widespread. This technique is associated with an increased cesarean delivery rate compared with intermittent fetal heart rate auscultation (see Chap. 18, p. 436). Although cesarean delivery performed primarily for "fetal distress" comprises only a minority of all such procedures, in many more cases, concern for an abnormal or "nonreassuring" fetal heart rate tracing lowers the threshold for cesarean deliveries performed for abnormal progress of labor.
4. Most fetuses presenting as *breech* are now delivered by cesarean (see Chap. 24, p. 531).
5. The incidence of *forceps and vacuum deliveries* has decreased (see Chap. 23, p. 511).
6. Rates of *labor induction* continue to rise, and induced labor, especially among nulliparas, increases the risk of cesarean delivery (see Chap. 22, p. 500).
7. The prevalence of *obesity* has risen dramatically, and obesity increases the risk of cesarean delivery (see Chap. 43, p. 950).
8. Rates of cesarean delivery for women with preeclampsia have increased, whereas rates of labor induction in these patients has declined. In Norway, for example, cesarean delivery increased from 16.4 percent for nulliparous preeclamptics during 1967–1978, to 35.4 percent during 1979–1990, and to 37 percent during 1991–2003 (Basso and colleagues, 2006).
9. *Vaginal birth after cesarean*—*VBAC*—has decreased from a high of 26 percent in 1996 to a rate of 8.5 percent in 2007 (see Chap. 26, p. 565) (Hamilton and associates, 2009).
10. Elective cesarean deliveries are increasingly being performed for a variety of indications including concern for *pelvic floor injury* associated with vaginal birth, medically indicated *preterm birth*, to reduce the risk of *fetal injury*, and for *patient request* (Ananth and co-workers, 2005; Nygaard and Cruikshank, 2003).
11. *Malpractice litigation* continues to contribute significantly to the present cesarean rate. In a compilation of medical malpractice claim data for the years 1985 through 2003, obstetrics accounted for the largest number of claims paid (Texas Medical Liability Trust, 2004). A brain-damaged infant was one of the most prevalent patient conditions, and overall, the average indemnity paid on obstetrical claims was 28 percent greater than for the other 24 specialties included in the report. This data is especially troubling in view of the well-documented lack of association between cesarean delivery and any reduction in childhood neurological problems. According to Foley and colleagues (2002), the incidence of neither neonatal seizures nor cerebral palsy diminished as the rate of cesarean delivery increased (see Chap. 29, p. 611).

Indications

As shown in Table 25-1, repeat cesarean deliveries and those performed for dystocia have been the leading indications in both the United States and other western industrialized countries. Although it is not possible to catalog comprehensively all appropriate indications for cesarean delivery, more than 85 percent are performed because of prior cesarean delivery, dystocia, fetal distress, or breech presentation.

For women in whom scheduled cesarean delivery is selected, the risk of adverse neonatal respiratory outcome increases in those delivered before 39 weeks (Clark, 2009; Oshiro, 2009; Tita, 2009, and all their colleagues). The American College of Obstetricians and Gynecologists (2008) recommends that fetal pulmonary maturity should be confirmed before scheduled delivery at less than 39 weeks of gestation unless fetal maturity can be determined from historical criteria (see Table 26-4. p. 571).

TABLE 25-1. Indication for Cesarean Delivery from the Maternal-Fetal Medicine Units Network

	Cesarean Deliveries (%)[a]
Primary	**21,798**
Dystocia	8122 (37)
Nonreassuring fetal heart rate	5404 (25)
Abnormal presentation	4321 (20)
Other	3323 (15)
Unsuccessful trial of forceps or vacuum	628 (3)
Repeat	**15,312**
No VBAC attempt	12,565 (82)
Failed VBAC	2687 (17)
Unsuccessful trial of forceps or vacuum	60 (0.4)

Dystocia

Some form of dystocia is the most frequent indication for cesarean delivery in the United States. An analysis of dystocia as a contributing factor to the cesarean rate is difficult, however, because of the heterogeneity inherent in the condition (see Chap. 20, p. 464). Indeed, there are 28 different World Health Organization (2007) ICD-10 codes applicable to cesarean delivery performed for a labor abnormality! Descriptive terms vary from more precise definitions promulgated by Friedman (1978)—*secondary arrest of dilatation, arrest of descent*—to more ambiguous and commonly used terms such as *cephalopelvic disproportion* and *failure to progress.*

Fetal Distress

Electronic fetal monitoring was employed in 85 percent of labors in the United States in 2003 (Martin and colleagues, 2005). Its use increases the cesarean delivery rate, perhaps by as much as 40 percent (Thacker and associates, 2001). Unfortunately, despite initial optimism, it has become well established that management based on electronic monitoring is no better in reducing the risk of cerebral palsy or perinatal death than that based on intermittent heart rate auscultation. Indeed, the performance of cesarean delivery per se may have no bearing on the neurodevelopmental prognosis of the infant. Scheller and Nelson (1994), in a report from the National Institutes of Health, and Lien and associates (1995) presented data specifically refuting any association between cesarean delivery and either cerebral palsy or seizures.

Pertinent to the diagnosis of fetal distress are the recommendations of the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) that facilities giving obstetrical care have the capability of initiating a cesarean delivery within 30 minutes of the decision to operate. Misinterpretations of this guideline are common. Specifically, this recommendation addresses facilities and does not govern clinical decision-making. There is no nationally recognized standard of care that codifies an acceptable time interval for performance of cesarean delivery. In most instances, operative delivery is not necessary within this 30-minute time frame. Bloom and co-workers (2001) reported for Maternal-Fetal Medicine Units (MFMU) Network that 69 percent of 7450 cesareans performed in labor commenced more than 30 minutes after the decision to operate. In a second study, Bloom and colleagues (2006) evaluated cesarean deliveries performed for emergency indications. They reported that failure

to achieve a cesarean delivery decision-to-incision time of less than 30 minutes was not associated with a negative impact on neonatal outcome (Table 25-2). On the other hand, when faced with an acute, catastrophic deterioration in fetal condition, cesarean delivery usually is indicated as rapidly as possible, and purposeful delays of any time would be inappropriate.

Breech Presentation

Management of the breech-presenting fetus is discussed in Chapter 24. Concern for fetal injury, as well as the infrequency with which a breech presentation meets criteria for a trial of labor, make it likely that its contribution to the overall cesarean delivery rate will remain relatively static.

Prior Cesarean Delivery

Management of the woman with a prior cesarean delivery is discussed in Chapter 26.

Methods to Decrease Cesarean Delivery Rates

Several investigators have documented the feasibility of achieving significant reductions in institutional cesarean delivery rates without increased perinatal morbidity or mortality rates (DeMott, 1990; DeMuylder, 1990; Porreco, 1990; Pridijian, 1991; Sanchez-Ramos, 1990, and all their co-workers). Programs aimed at reducing the number of cesarean deliveries generally are focused on educating physicians, peer reviewing, encouraging a trial of labor after prior transverse cesarean delivery, and restricting cesarean deliveries for dystocia only to women who meet strictly defined criteria. In a randomized study from 34 Latin American hospitals, Althabe and colleagues (2004) reported that a mandatory second opinion was associated with a small, but significant, reduction in the cesarean delivery rate without an adverse effect on maternal or perinatal morbidity.

Maternal Mortality and Morbidity

In the United States, maternal death attributable solely to cesarean delivery is rare. Even so, large data sets attest to the mortality risks. Clark and colleagues (2008), in a review of nearly 1.5 million pregnancies, found maternal mortality rates of 2.2 per 100,000 cesarean deliveries. In another study, Hall and Bewley (1999) compiled data from more than 2 million births in the United Kingdom from 1994 through 1996. They showed that whereas emergency cesarean delivery was associated with an almost ninefold risk of maternal death compared with that of vaginal delivery, even elective cesarean delivery was associated with an almost threefold risk.

Rates of severe obstetrical complications increased in the U.S. from 1998–1999 to 2004–2005. Many of these increases were associated with the rising cesarean delivery rate (Kuklina and co-workers, 2009). The maternal morbidity rate is increased twofold with cesarean delivery compared with vaginal delivery (Villar and associates, 2007). Principal sources are puerperal infection, hemorrhage, and thromboembolism (Burrows and associates, 2004). Others are listed in Table 25-3, and not all morbidity is immediate. Declerq and colleagues (2007) reported that rehospitalization in the 30 days following cesarean delivery was more than twice as common as after vaginal delivery—75 versus 19 hospitalizations per 1000 deliveries. Rajasekar and Hall (1997) reported that the incidence of bladder laceration with cesarean operation was 1.4 per 1000 procedures, and the incidence of ureteral injury was 0.3 per 1000. Although bladder injury was immediately identified, the diagnosis of ureteral

injury often was delayed. Uterine infection is relatively common after cesarean delivery. The diagnosis and management of pelvic and wound infections following cesarean delivery are discussed in Chapter 31. Women with prior cesarean delivery have increased rates of uterine rupture in subsequent pregnancy compared with those with only prior vaginal deliveries. Fortunately, however, the risk of rupture is low, and the overall risk was found by Spong and colleagues (2007) to approximate 0.3 percent. As discussed in Chapter 43 (see p. 950), morbidity associated with cesarean delivery is increased dramatically in obese women. All of these morbidities, as well as the increased recovery time, result in a twofold increase in costs for cesarean versus vaginal delivery (Henderson and associates, 2001).

Patient Choice in Cesarean Delivery

As cesarean delivery has become safer and more commonly performed, and women have taken a more active role in their obstetrical care, it has been argued that women should be able to choose to undergo elective cesarean delivery (Harer, 2000). This has become one of the most important and controversial issues currently facing our specialty. Although the rate is difficult to determine with precision, elective cesarean delivery is on the rise and by one estimate, has increased 50 percent in the past decade (Meikle and colleagues, 2005). Gossman and associates (2005) estimated that 2.5 percent of all births in the United States in 2003 were defined as *cesarean delivery on maternal request (CDMR)*. Reasons for mothers to request cesarean delivery include avoidance of pelvic floor injury during vaginal birth, reduced risk of fetal injury, avoidance of the uncertainty and pain of labor, and convenience. Importantly, Worley and colleagues (2009) found that approximately one third of the pregnant women who delivered at their institution entered spontaneous labor at term, and 96 percent of these delivered vaginally without adverse neonatal outcomes. Thus, the debate surrounding CDMR includes its medical rationale from both a maternal and fetal-neonatal standpoint, the concept of informed free choice by the woman, and the autonomy of the physicians in offering this choice.

To address this, the National Institute of Health held a State-of-the-Science Conference on Cesarean Delivery on Maternal Request. A panel of experts critically reviewed available literature to form recommendations based on risks and benefits identified. It is noteworthy that most of the maternal and neonatal outcomes examined had insufficient data to permit such recommendations. Indeed, one of the main conclusions of the conference was that more high-quality research is needed to fully evaluate the issues. This was also the conclusion of the American College of Obstetricians and Gynecologists (2007a).

The panel was able to draw some conclusions from the existing data. Cesarean delivery on maternal request should not be performed prior to 39 weeks' gestation unless there is evidence of fetal lung maturity. It should be avoided in women desiring several children because of the risk of placenta accreta (see Chap. 35, p. 776). Finally, it should not be motivated by the unavailability of effective pain management.

Ethics

Cesarean delivery on maternal request has numerous ethical concepts that have been debated. Bewley and Cockburn (2002a, b) argue that the concept of elective cesarean delivery

lacks both ethical and medical merit. Others have concluded that currently available evidence does not support *routine* elective cesarean delivery. However, it does ethically support an obstetrical decision to accede to an *informed* patient's request for such a delivery (Kalish and associates, 2008; Minkoff, 2006; Minkoff and Chervenak, 2003). Clearly, and usually only with the benefit of hindsight, it can be said that some women and infants who have undergone difficult vaginal birth may have been better served by cesarean delivery. In most cases, however, clinically robust means of prospectively identifying otherwise uncomplicated pregnancies in which the woman or her fetus-infant would benefit from elective cesarean delivery are lacking. At this time, we conclude that it is difficult to justify a *laissez faire* approach to this major operation.

TECHNIQUE FOR CESAREAN DELIVERY

With minor variations, surgical performance of cesarean delivery is comparable worldwide. Most steps are founded on evidence-based data, and these have been reviewed by Berghella and associates (2005).

Abdominal Incision

Usually either a midline vertical or a suprapubic transverse incision is used. Only in special circumstances would a paramedian or midtransverse incision be employed.

Vertical Incision

An infraumbilical midline vertical incision is quickest to create. The incision should be of sufficient length to allow delivery of the infant without difficulty. Therefore, its length should correspond with the estimated fetal size. Sharp dissection is performed to the level of the anterior rectus sheath, which is freed of subcutaneous fat to expose a 2-cm-wide strip of fascia in the midline. Some surgeons prefer to incise the rectus sheath with the scalpel throughout the length of the fascial incision. Others prefer to make a small opening and then incise the fascial layer with scissors. The rectus and the pyramidalis muscles are separated in the midline by sharp and blunt dissection to expose transversalis fascia and peritoneum.

The transversalis fascia and preperitoneal fat are dissected carefully to reach the underlying peritoneum. The peritoneum near the upper end of the incision is opened carefully, either bluntly, or by elevating it with two hemostats placed about 2 cm apart. The tented fold of peritoneum between the clamps is then examined and palpated to be sure that omentum, bowel, or bladder is not adjacent. In women who have had previous intra-abdominal surgery, including cesarean delivery, omentum or bowel may be adherent to the undersurface of the peritoneum. *In women with obstructed labor, the bladder may be pushed cephalad almost to the level of the umbilicus* (see Chap. 20, p. 486). The peritoneum is incised superiorly to the upper pole of the incision and downward to just above the peritoneal reflection over the bladder.

Transverse Incisions

With the modified *Pfannenstiel incision,* the skin and subcutaneous tissue are incised using a lower, transverse, slightly curvilinear incision. The incision is made at the level of the pubic hairline and is extended somewhat beyond the lateral borders of the rectus muscles. Sharp dissection is continued through the subcutaneous layer to the level of the fascia. The superficial epigastric vessels can usually be identified halfway between the skin and fascia, several centimeters from the midline. If lacerated, these may be suture ligated or coagulated with an electrosurgical blade. After the subcutaneous tissue has been separated from the underlying fascia for 1 cm or so on each side, the fascia is incised. At this level, the anterior abdominal fascia is typically composed of two visible layers, the aponeuroses from the external oblique muscle and a fused layer containing aponeuroses of the internal oblique and transverse abdominis muscles. Ideally, the two layers are individually incised during lateral extension of the fascial incision. The inferior epigastric vessels typically lie outside the lateral border of the rectus abdominis muscle and beneath the fused aponeuroses of the internal oblique and transverse abdominis muscles. Thus, extension of the fascial incision further laterally may cut these vessels. Therefore, if lateral extension is required, these vessels should be identified and cauterized or ligated to prevent bleeding and vessel retraction if lacerated.

Sequentially, first the superior and then the inferior edge of the fascia is grasped with suitable clamps and elevated by the assistant as the operator separates the fascial sheath from the underlying rectus muscles either bluntly or sharply. Blood vessels coursing between the muscles and fascia are clamped, cut, and ligated, or they are fulgurated with electrocautery. Meticulous hemostasis is imperative to lower rates of infection and bleeding. The fascial separation is carried near enough to the umbilicus to permit an adequate midline longitudinal incision of the peritoneum. The rectus muscles are then separated in the midline to expose the underlying peritoneum. The peritoneum is opened as discussed earlier.

The Pfannenstiel incision follows Langer lines of skin tension, and thus, excellent cosmetic results can be achieved. It also offers decreased rates of postoperative pain, of fascial wound dehiscence, and of incisional hernia. Whether it is stronger and less likely to undergo dehiscence is debated (Hendrix and coworkers, 2000). The Pfannenstiel incision is often discouraged for cases in which a large operating space is essential or in which access to the upper abdomen may be required. With repeat cesarean delivery, reentry through a Pfannenstiel incision usually is more time consuming and difficult because of scarring.

When a transverse incision is desired and more room is needed, the *Maylard incision* provides a safe option (Ayers and Morley, 1987; Giacalone and colleagues, 2002). In this incision, the rectus muscles are divided sharply or with electrocautery. The incision also may be especially useful in women with significant scarring from previous transverse incisions.

Uterine Incisions

Most often, the lower uterine segment is incised transversely as described by Kerr in 1921. Occasionally, a low-segment vertical incision as described by Krönig in 1912 may be used. The so-called *classical incision* is a vertical incision into the body of the uterus above the lower uterine segment and reaches the uterine fundus. This incision is seldom used today, and indications are discussed on page 555. For most cesarean deliveries, the transverse incision is preferred. Compared with a

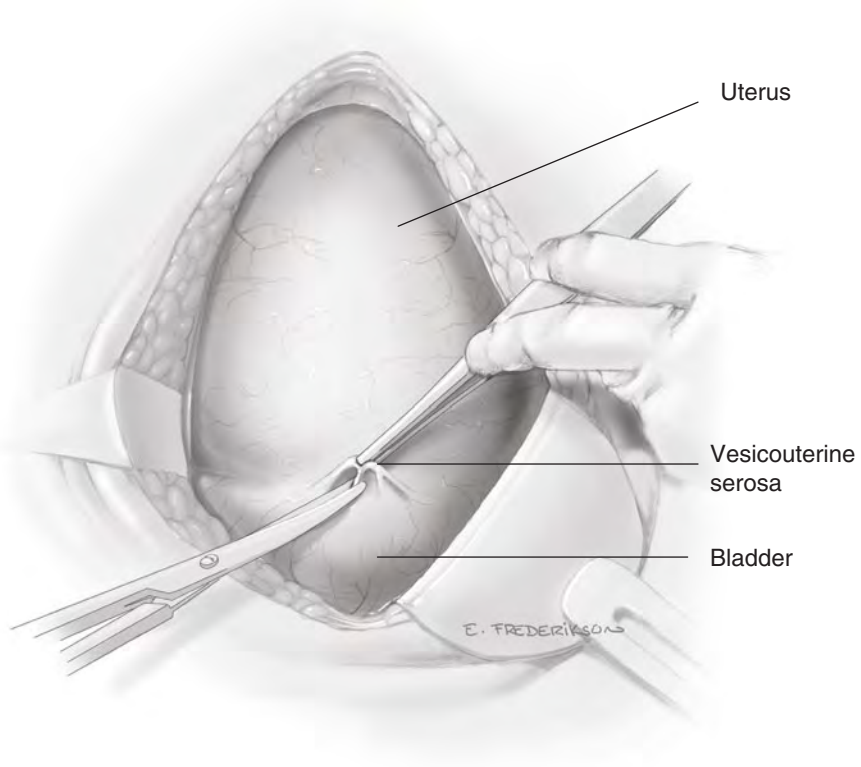

FIGURE 25-4 The loose vesicouterine serosa is grasped with forceps and incised with Metzenbaum scissors.

classical incision, it is easier to repair, is located at a site least likely to rupture during a subsequent pregnancy, and does not promote adherence of bowel or omentum to the incisional line.

Technique for Transverse Cesarean Incision

Commonly, the uterus is found to be dextrorotated so that the left round ligament is more anterior and closer to the midline than the right. With thick meconium or infected amnionic fluid, some surgeons prefer to put a moistened laparotomy pack in each lateral peritoneal gutter to absorb fluid and blood that escape from the opened uterus. The reflection of peritoneum above the upper margin of the bladder and overlying the anterior lower uterine segment—the *bladder flap*—is grasped in the midline with forceps and incised transversely with scissors (Fig. 25-4). Scissors are inserted between the vesicouterine serosa and myometrium of the lower uterine segment. The scissors are pushed laterally from the midline, and then withdrawn while partially opening the blades intermittently. This separates a 2-cm–wide strip of serosa, which is then incised. As the lateral margin on each side is approached, the scissors are directed somewhat more cephalad (Fig. 25-5). The lower flap of peritoneum is elevated, and the bladder is gently separated by blunt or sharp dissection from the underlying myometrium (Fig. 25-6). In general, the separation of bladder should not exceed 5 cm in depth and usually should be less. It is possible, especially with an effaced, dilated cervix, to dissect downward so deeply as inadvertently to expose and then enter the underlying vagina rather than the lower uterine segment.

The uterus is entered through the lower uterine segment approximately 1 cm below the upper margin of the peritoneal reflection. It is important to place the uterine incision relatively higher in women with advanced or complete cervical dilatation to minimize both lateral extension of the incision into the uterine arteries and unintended entry into the vagina. This is done by using the vesicouterine serosal reflection as a guide.

The uterus can be incised by a variety of techniques. Each is initiated by using a scalpel to transversely incise the exposed lower uterine segment for 1 to 2 cm in the midline (Fig. 25-7). This must be done carefully to avoid injury to the fetus. Skin laceration was the most common fetal injury seen with 37,110 cesarean deliveries in the Maternal Fetal Medicine Units Network study reported by Alexander and colleagues (2006). Careful blunt entry using hemostats or fingertip to split the muscle may be helpful. Once the uterus is opened, the incision can be extended by cutting laterally and then slightly upward with bandage scissors. Alternatively, when the lower uterine segment is thin, the incision can be extended by simply spreading the incision, using lateral and upward pressure applied with each index finger (Fig. 25-8). Although Rodriguez and associates (1994) reported that blunt and sharp extensions of the initial uterine incision are equivalent in terms of safety and postoperative complications, Magann and colleagues (2002) reported that sharp extension increased blood loss and the need for transfusion.

The uterine incision should be made large enough to allow delivery of the head and trunk of the fetus without either tearing into or having to cut into the uterine vessels

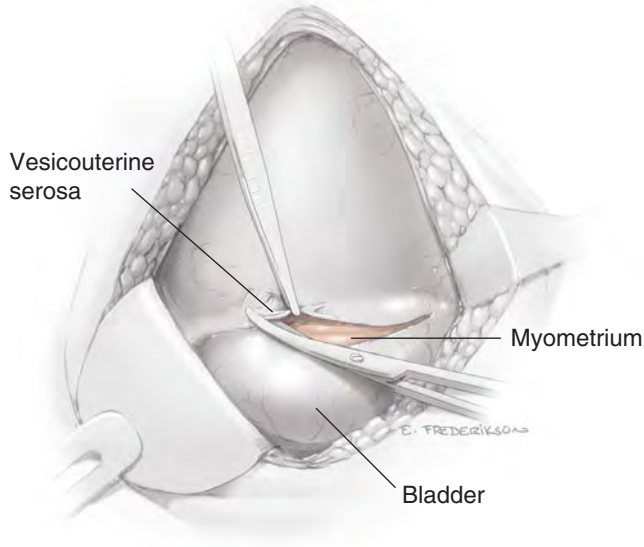

FIGURE 25-5 The loose serosa above the upper margin of the bladder is elevated and incised laterally.

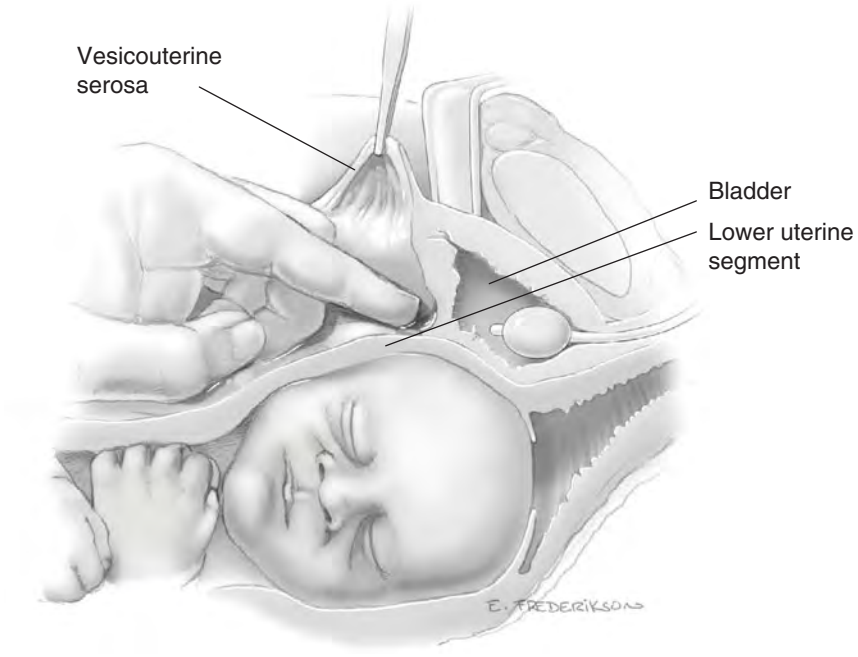

FIGURE 25-6 Cross section shows blunt dissection of the bladder off the uterus to expose the lower uterine segment.

that course through the lateral margins of the uterus. If the placenta is encountered in the line of incision, it must be either detached or incised. When the placenta is incised, fetal hemorrhage may be severe. Thus, delivery and cord clamping should be performed as soon as possible in such cases.

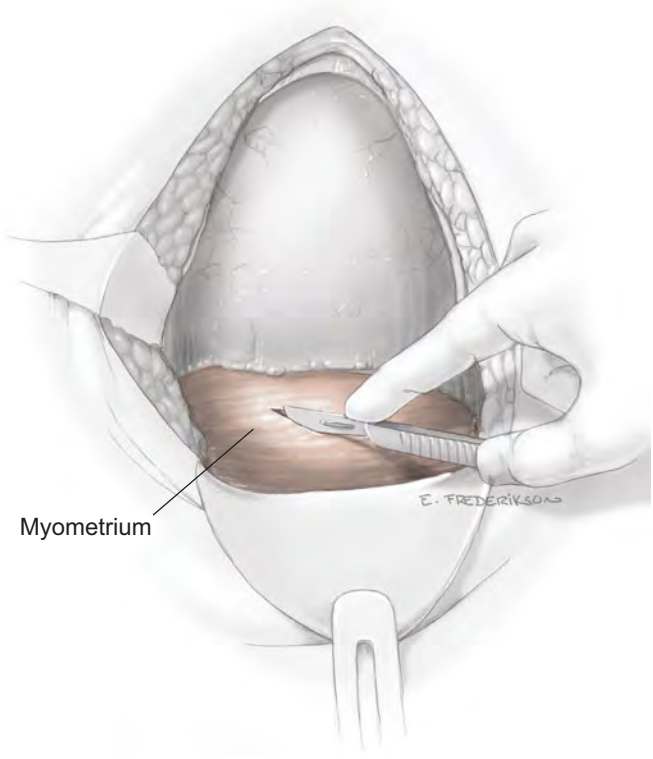

FIGURE 25-7 The myometrium is carefully incised to avoid cutting the fetal head.

Although the Pfannenstiel-Kerr technique for abdominal and uterine entry has been used for decades, newer methods have been suggested. The Joel-Cohen and Misgav-Ladach methods use an abdominal incision placed higher than the Pfannenstiel and use blunt dissection of all encountered layers following sharp skin incision (Joel-Cohen, 1977; Stark, 1995). These have been associated with lower rates of intraoperative blood loss, puerperal fever, and postoperative pain and with shorter operative times. Long-term outcomes with these techniques, such as subsequent rupture of the uterus, are unknown (Hofmeyr and co-workers, 2008).

Delivery of the Infant

In a cephalic presentation, a hand is slipped into the uterine cavity between the symphysis and fetal head. The head is elevated gently with the fingers and palm through the incision, aided by modest transabdominal fundal pressure (Fig. 25-9). After a long labor with cephalopelvic disproportion, the fetal head may be tightly wedged in the birth canal. Upward pressure exerted by a hand in the vagina by an assistant will help to dislodge the head and allow its delivery above the symphysis. Alternatively, in women without labor, the fetal head may be unmolded, and without a leading cephalic point, the round head may be difficult to lift through the uterine incision. In such instances, either forceps or a vacuum device may be used to deliver the fetal head (Fig. 25-10). The shoulders then are delivered using gentle traction plus fundal pressure (Fig. 25-11). The rest of the body readily follows. To minimize fetal aspiration of amnionic fluid, exposed nares and mouth are aspirated with a bulb syringe.

After the shoulders are delivered, an intravenous infusion containing two ampules or 20 units of oxytocin per liter of crystalloid is infused at 10 mL/min until the uterus contracts satisfactorily. After this, the rate can be reduced. Bolus doses of 5 to 10 units are avoided because of associated hypotension. Munn and colleagues (2001) studied a much higher initial concentration using a solution of 80 units of oxytocin in 500 mL of crystalloid, which was infused at about 17 mL/min. They reported that this approach significantly reduced the need for additional uterotonic agents.

The umbilical cord is clamped, and the newborn is given to the team member who will conduct resuscitative efforts as needed (see Chap. 28, p. 591). The uterine incision is observed for any vigorously bleeding sites. These should be promptly clamped with Pennington or ring forceps or similar instruments. The placenta is then delivered unless it has already done so spontaneously. Many surgeons prefer manual removal, but spontaneous delivery, as shown in Fig. 25-12, along with some cord traction has been shown to reduce the risk of operative blood loss and infection (Anorlu, 2008; Atkinson, 1996; Baksu, 2005, and all their colleagues). Fundal massage, begun as soon as the fetus is delivered, reduces bleeding and hastens placental delivery.

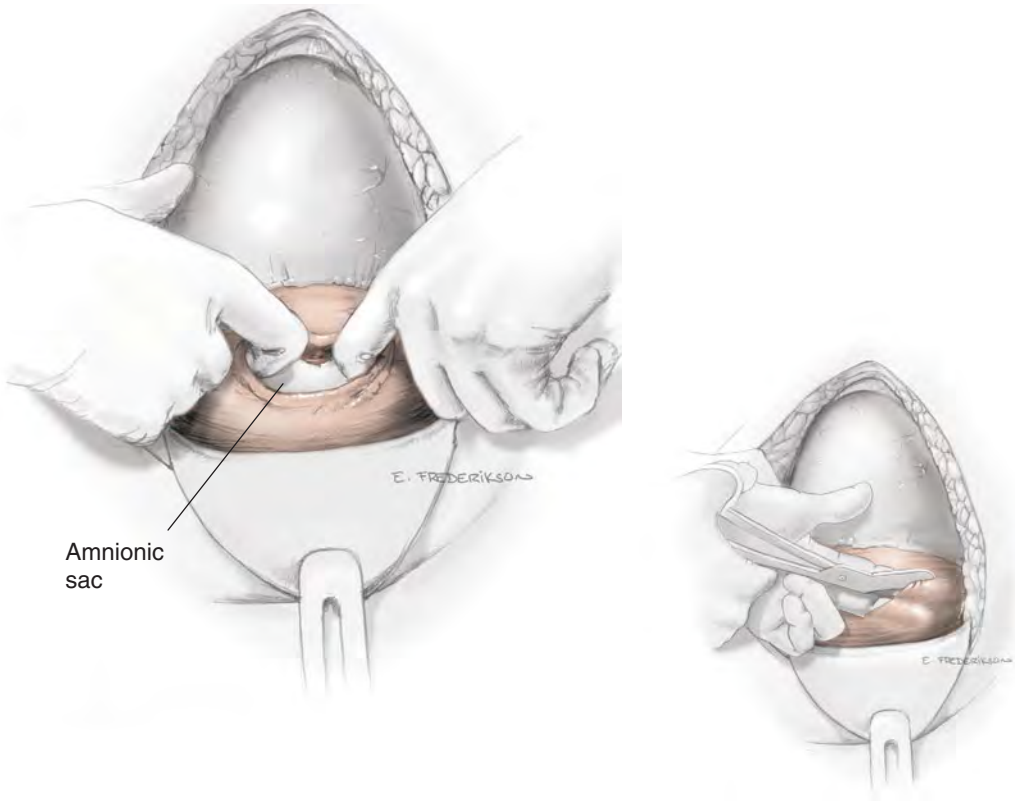

FIGURE 25-8 After entering the uterine cavity, the incision is extended laterally with fingers or with bandage scissors (*inset*).

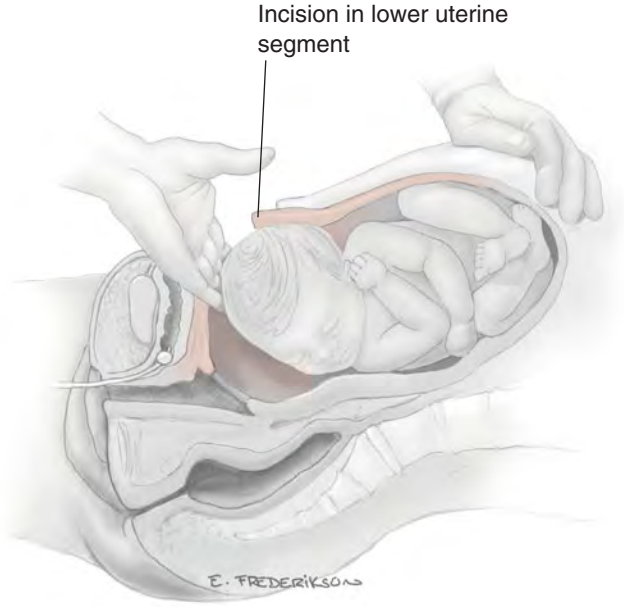

FIGURE 25-9 Immediately after incising the uterus and rupturing the fetal membranes, the fingers are insinuated between the symphysis pubis and the fetal head until the posterior surface of the head is reached. The head is lifted carefully anteriorly and as necessary, superiorly to bring it from beneath the symphysis forward through the uterine and abdominal incisions. As the fetal head is lifted through the incision, pressure usually is applied to the uterine fundus through the abdominal wall to help expel the fetus.

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) recommend that "a qualified person who is skilled in neonatal resuscitation should be in the operative delivery room, with all equipment needed for neonatal resuscitation, to care for the neonate." Jacob and Phenninger (1997) compared 834 cesarean deliveries with 834 low-risk vaginal deliveries. They found that, with regional analgesia, there is rarely a need for infant resuscitation after elective repeat cesarean delivery or cesarean delivery for dystocia without fetal heart rate abnormalities, and that a pediatrician may not be necessary at such deliveries. At Parkland Hospital, pediatric nurse practitioners attend uncomplicated, scheduled cesarean deliveries.

Uterine Repair

After delivery of the placenta, the uterus may be lifted through the incision onto the draped abdominal wall, and the fundus covered with a moistened laparotomy pack. Although some clinicians prefer to avoid it, uterine exteriorization often has advantages that outweigh its disadvantages. For example, the relaxed, atonic uterus can be recognized quickly and massage applied. The incision and bleeding points are more easily visualized and repaired, especially if there have been extensions laterally. Adnexal exposure is superior, and thus, tubal sterilization is easier. The principal disadvantage is from discomfort and vomiting caused by traction in cesarean deliveries performed

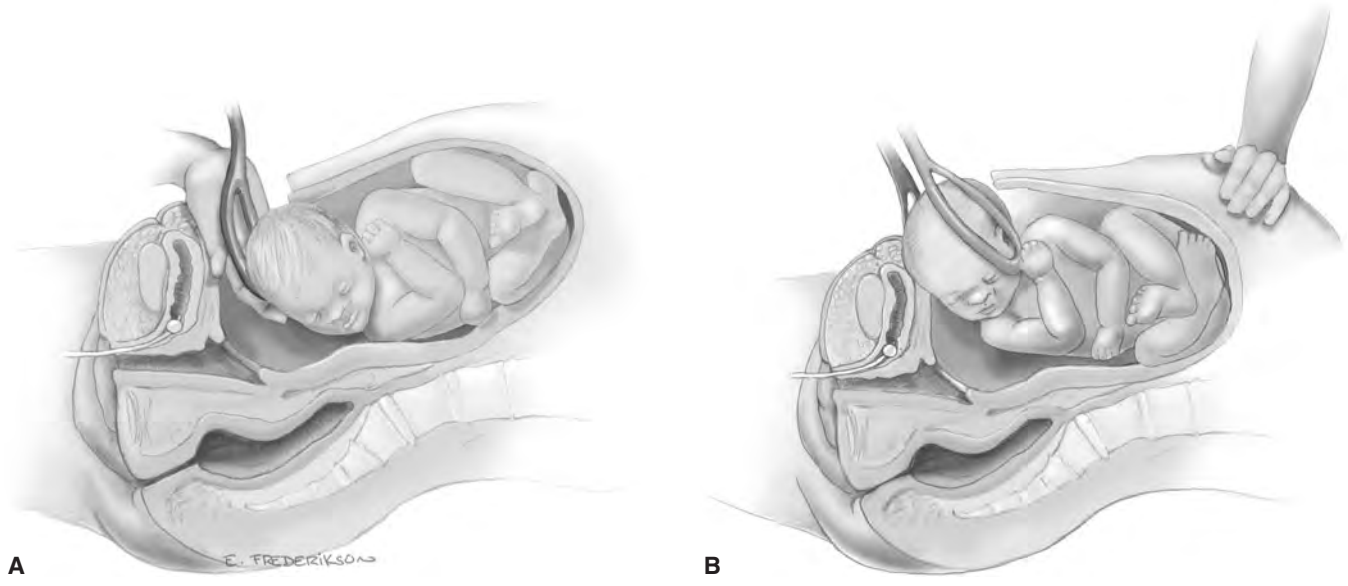

FIGURE 25-10 A. The first C-section forcep blade is placed. **B.** Slight upward and outward traction is used to lift the head through the incision.

under regional analgesia. Neither febrile morbidity nor blood loss appears to be increased with uterine exteriorization prior to repair (Coutinho and co-workers, 2008; Walsh and Walsh, 2009).

Immediately after delivery and examination of the placenta, the uterine cavity is inspected and either suctioned or wiped out with a gauze pack to remove avulsed membranes, vernix, clots, and other debris. The upper and lower cut edges and each lateral angle of the uterine incision are examined carefully for bleeding. Individually clamped large vessels are best ligated with a suture. Concern has been expressed by some clinicians that sutures through the decidua may lead to endometriosis in the hysterotomy scar, but this is rare.

The uterine incision is then closed with one or two layers of continuous 0- or #1 absorbable suture. Chromic suture is used by many, but some prefer synthetic delayed-absorbable sutures. Hauth and colleagues (1992) randomized 906 women to either one- or two-layer closure using 1-0 chromic gut. A continuous locking one-layer closure required less operative time and fewer additional hemostatic sutures. In a follow-up report of 164 women delivered subsequently, the type of uterine closure did not significantly affect several maternal and fetal complications in the next pregnancy (Chapman and associates, 1997). Similarly, Durnwald and Mercer (2003) reported no uterine ruptures in 182 women who underwent a trial of labor after single-layer closure compared with four ruptures in 340 women (1.2 percent) after double-layer closure. By contrast, Bujold and associates (2002) reported that single-layer closure was associated with a fourfold increased risk of uterine rupture during a subsequent trial of labor. Further study is needed to resolve this issue (see Chap. 26, p. 569).

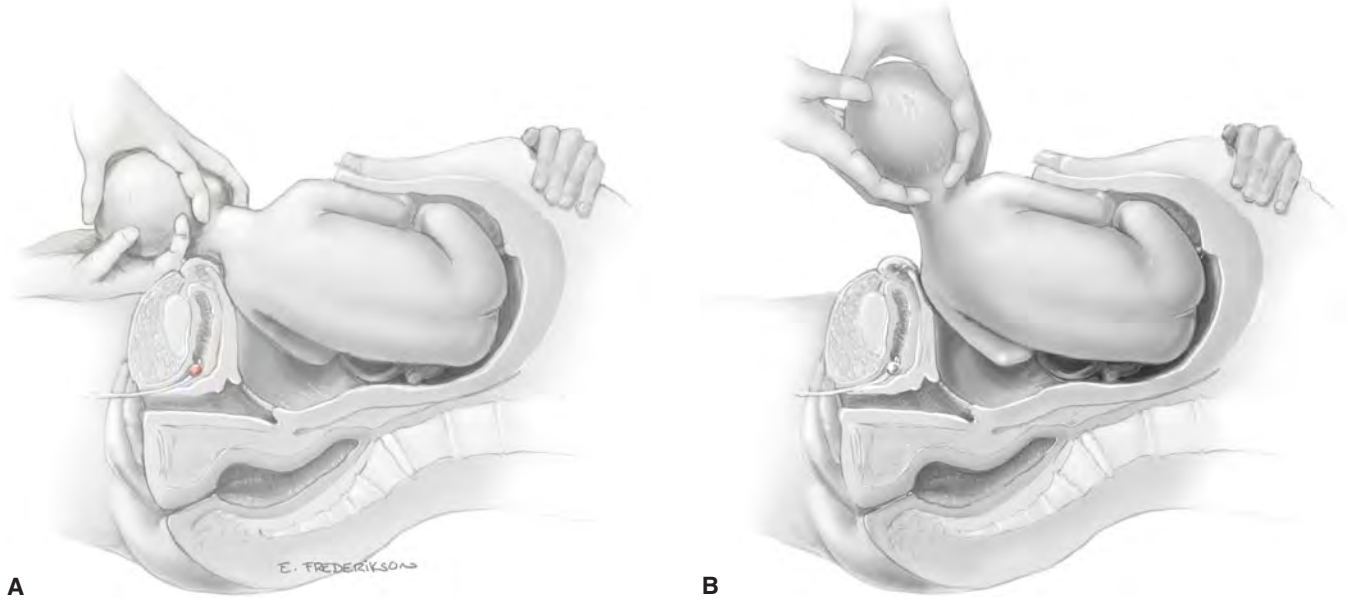

FIGURE 25-11 The anterior **(A)** and then the posterior shoulder **(B)** are delivered.

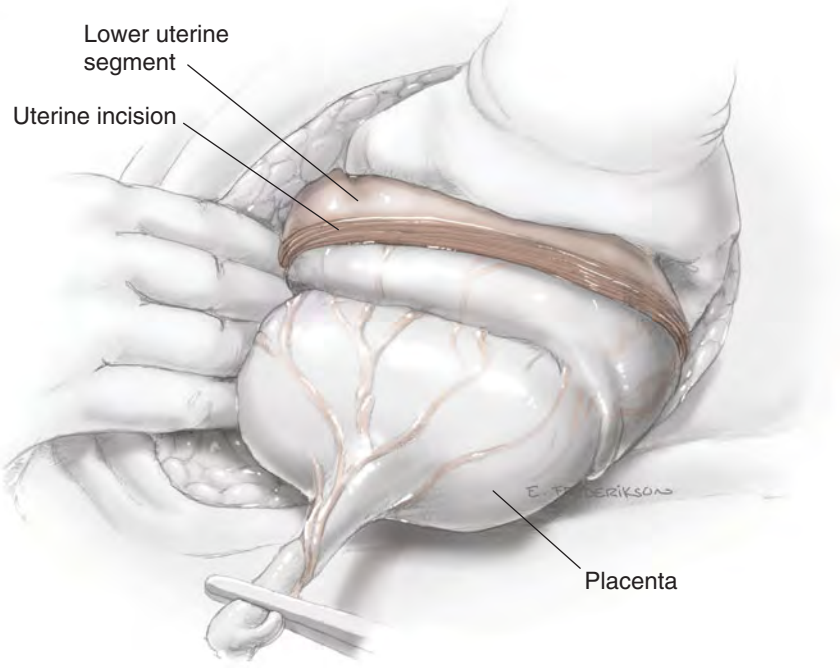

FIGURE 25-12 Placenta bulging through the uterine incision as the uterus contracts. A hand gently massages the fundus to help aid placental separation.

At both Parkland and the University of Alabama at Birmingham Hospitals, we favor the one-layer uterine closure. The initial suture is placed just beyond one angle of the uterine incision. A running-lock suture, which creates a more hemostatic closure, is then performed with each suture penetrating the full thickness of the myometrium (Fig. 25-13). It is important to carefully select the site of each stitch and to avoid withdrawing the needle once it penetrates the myometrium. This minimizes the perforation of unligated vessels and subsequent bleeding. The running-lock suture is continued just beyond the opposite incision angle. Especially when the lower segment is thin, satisfactory approximation of the cut edges usually can be obtained with one layer of suture. If approximation is not satisfactory after a single-layer continuous closure, or if bleeding sites persist, then more sutures are required. Either another layer of sutures may be placed to achieve approximation and hemostasis, or individual bleeding sites can be secured with figure-of-eight or mattress sutures.

Traditionally, serosal edges overlying the uterus and bladder have been approximated with a continuous 2-0 chromic catgut suture. Multiple randomized trials suggest that omission of this step causes no postoperative complications (Grundsell, 1998; Hull and Varner, 1991; Irion, 1996; Nagele, 1996; Pietrantoni, 1991, and all their associates). Specifically, not approximating the bladder flap is unlikely to increase adhesion formation or long-term morbidity (Roset and colleagues, 2003; Tulandi and Al-Jaroudi, 2003). Data are conflicting as to whether nonclosure of parietal peritoneum decreases postoperative discomfort and adhesions and need for analgesia (Chanrachakul, 2002; Lyell, 2005; Rafique, 2002; and all their colleagues).

If tubal sterilization is to be performed, it is now done as described in Chapter 33 (see p. 698).

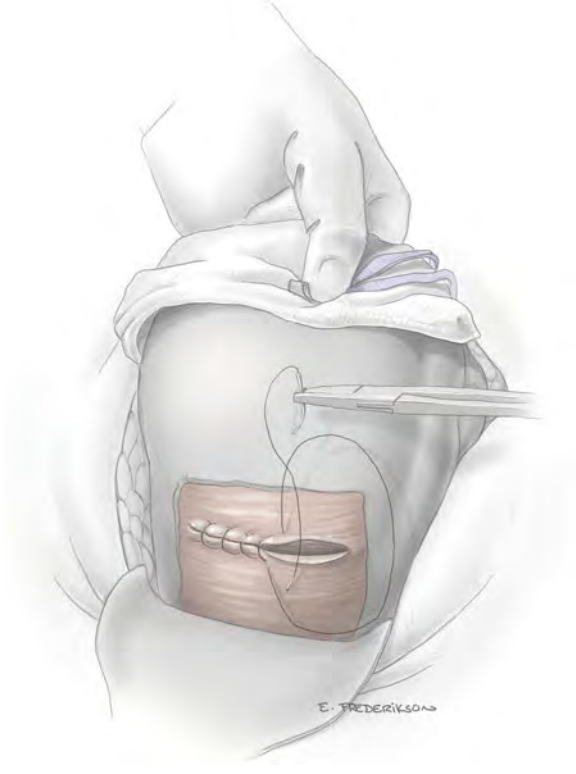

FIGURE 25-13 The cut edges of the uterine incision are approximated with a running-lock suture.

Abdominal Closure

All packs are removed, and the paracolic gutters and cul-de-sac are emptied of blood and amnionic fluid using gentle suction. Some surgeons irrigate the gutters and cul-de-sac, especially in the presence of infection or meconium. A small randomized trial by Harrigill and colleagues (2003) supports that this step is not necessary in low-risk women who undergo cesarean delivery in the absence of amnionitis. After the sponge and instrument counts are found to be correct, the abdominal incision is closed in layers. As previously discussed, many surgeons omit the parietal peritoneal closure because it serves little purpose. If there is distended bowel in the incision site, however, we find that peritoneal closure may help to protect the bowel when fascial sutures are placed. As each layer is closed, bleeding sites are located, clamped, and ligated or coagulated with an electrosurgical blade. The rectus muscles are allowed to fall into place, and the subfascial space is meticulously checked for hemostasis. With significant diastasis, the rectus muscles may be approximated with one or two figure-of-eight sutures of 0 or #1 chromic gut suture. The overlying rectus fascia is closed either with interrupted 0-gauge delayed-absorbable sutures that are placed lateral to the fascial edges and no more than 1 cm apart, or by a continuous, nonlocking technique with a delay-absorbable suture.

The subcutaneous tissue usually need not be closed if it is less than 2 cm thick, and the skin is closed with vertical mattress sutures of 3-0 or 4-0 silk or equivalent suture; with a running 4-0 subcuticular stitch using delayed-absorbable suture; or with skin clips. If the subcutaneous tissue is at least 2 cm thick, it should be closed. In a randomized prospective study of more than 1400 women undergoing cesarean delivery, Bohman and colleagues (1992) reported a significantly decreased frequency of superficial wound disruption when the subcutaneous layer was approximated. Based on their systematic review of six studies, Chelmow and colleagues (2004) concluded that suturing the subcutaneous tissue at cesarean delivery decreases the risk of wound disruption by 34 percent in women with fat thickness greater than 2 cm. Addition of a subcutaneous drain with closure, however, does not prevent significant wound complications (Hellums and colleagues, 2007; Ramsey and associates, 2005).

Technique for Classical Cesarean Incision

Occasionally it is necessary to use a classical incision for delivery. Some indications stem from difficulty in exposing or safely entering the lower uterine segment. For example, a *densely adhered bladder* from previous surgery is encountered; a *leiomyoma* occupies the lower uterine segment; the cervix has been *invaded by cancer*; *massive maternal obesity* precludes safe access to the lower uterine segment; and some cases of *placenta previa with anterior implantation*, especially in the case where the placenta has grown through a prior uterine incision—*placenta increta or percreta.*

In other instances, fetal indications dictate the need. *Transverse lie of a large fetus*, especially if the membranes are ruptured and the shoulder is impacted in the birth canal, usually necessitates a classical incision. A fetus presenting as a back-down transverse lie may be particularly difficult to deliver through a transverse uterine incision. Sometimes when the fetus is very small, especially if breech, and the lower uterine segment is not thinned out, a classical incision is the best choice. Finally, if there are multiple fetuses, a classical incision may be preferable.

Uterine Incision

A vertical uterine incision is initiated with a scalpel beginning as low as possible, depending on how well the lower segment is thinned out. If adhesions, insufficient exposure, a tumor, or placenta percreta preclude development of a bladder flap, then the incision is made above the level of the bladder. Once the uterus is entered with a scalpel, the incision is extended cephalad with bandage scissors until it is sufficiently long to permit delivery of the fetus. Numerous large vessels that bleed profusely are commonly encountered within the myometrium.

Uterine Repair

One method employs a layer of continuous 0- or #1 chromic catgut to approximate the deeper halves of the incision. The outer half of the uterine incision is then closed with similar suture, using either a continuous stitch or figure-of-eight sutures. No unnecessary needle tracts should be made lest myometrial vessels be perforated leading to subsequent hemorrhage or hematoma. To achieve good approximation and to prevent the suture from tearing through the myometrium, it is helpful to have an assistant compress the uterus on each side of the wound toward the midline as each suture is placed and tied. The edges of the uterine serosa, if not already so, are approximated with continuous 2-0 chromic catgut. The operation is then completed as described earlier.

Postmortem Cesarean Delivery

At times, cesarean delivery is performed in a woman who has just died, or who is expected to do so momentarily (Capobianco and colleagues, 2008). The issue of cesarean delivery to aid in cardiopulmonary resuscitation of the mother is further discussed in Chapter 42 (see p. 942).

PERIPARTUM HYSTERECTOMY

Hysterectomy performed at or following delivery may be lifesaving if there is severe obstetrical hemorrhage. It can be carried out in conjunction with cesarean delivery or following vaginal delivery. In a study of almost 29,000 cesarean deliveries, Shellhaas and colleagues (2001) reported that hysterectomy was performed in 1 in every 200 cesarean deliveries. If all deliveries are considered, the rate ranges from 0.4 to 0.8 percent (Briery, 2007; Forna, 2004; Glaze, 2008; Knight, 2008, and all their associates).

Indications

Most procedures are performed to arrest hemorrhage from intractable uterine atony, lower-segment bleeding associated with the uterine incision or placental implantation, uterine rupture, or uterine vessel laceration (Flood, 2009; Knight, 2008; Muench, 2008; Silver, 2006, and all their co-workers). These conditions are discussed in Chapter 35. Large leiomyomas may preclude satisfactory hysterotomy closure and thus necessitate hysterectomy. Elective indications for peripartum hysterectomy include large or symptomatic leiomyomas and severe cervical dysplasia or carcinoma in situ.

Major complications of peripartum hysterectomy compared with cesarean delivery are increased blood loss and greater risk of urinary tract damage. An important factor affecting the complication rate is whether the operation is performed electively or emergently. As shown in **Table 25-4**, the morbidity rate associated with emergency hysterectomy is substantively increased. Seago and associates (1999) reported that the rate of intraoperative and postoperative complications among 100 women who underwent planned cesarean hysterectomy was not increased compared with that of a control group of 37 women who underwent cesarean delivery followed by hysterectomy performed within the subsequent 6 months.

Although pelvic vessels are appreciably hypertrophied, hysterectomy usually is aided by the ease of tissue plane development in pregnant women. Blood loss is usually appreciable because hysterectomy performed for hemorrhage almost always is associated with torrential bleeding. Indeed, as shown in Table 25-4, 83 percent of women undergoing emergency peripartum hysterectomy required transfusions compared with only 28 percent of those undergoing a planned hysterectomy. Preoperative preparation such as intravascular balloon placement in cases of

TABLE 25-4. Comparison of Morbidity Rates with Elective Versus Emergency Peripartum Hysterectomy

	Complications in Percent[a]	
Complication	Elective (n = 345)	Emergency (n = 644)
Transfusions	28	83
Urinary tract injury	1.8	5.6
Surgical infection	21	25
Death	0	1.4

[a]All complications not reported by all studies. Averages calculated from reported data. Data from Briery (2007), Castaneda (2000), Glaze (2008), Kastner (2002), Kwee (2006), Plauche (1995), Sakse (2008), Zelop (1993), Zorlu (1998), and all their colleagues.

placenta percreta as described by Shrivastava and colleagues (2007) is discussed in Chapter 35 (p. 776).

Technique for Peripartum Hysterectomy

Supracervical or total hysterectomy is performed using standard operative techniques. Initially, placement of a self-retaining retractor such as a Balfour is not necessary. Satisfactory exposure is best obtained with cephalad traction on the uterus by an assistant, along with handheld retractors such as a Richardson or Deaver. The bladder flap is deflected downward to the level of the cervix if possible. After cesarean delivery and placental removal, if the hysterotomy incision is bleeding appreciably, either it can be sutured, or Pennington or sponge-forceps can be applied for hemostasis. If bleeding is minimal, neither maneuver is necessary.

The round ligaments close to the uterus are divided between Heaney or Kocher clamps and doubly ligated (Fig. 25-14). Either 0- or #1 suture can be used. The incision in the vesicouterine serosa that was made to mobilize the bladder is extended laterally and upward through the anterior leaf of the broad ligament to reach the incised round ligaments. The posterior leaf of the broad ligament adjacent to the uterus is perforated just beneath the fallopian tubes, utero-ovarian ligaments, and ovarian vessels (Fig. 25-15). These vessels then are doubly clamped close to the uterus and divided, and the lateral pedicle is doubly ligated (Fig. 25-16). The posterior leaf of the broad ligament is divided inferiorly toward the uterosacral ligaments (Fig. 25-17). Next, the bladder and attached peritoneal flap are again deflected and dissected from the lower uterine segment and retracted out of the operative field. If the bladder flap is unusually adherent, as it may be after previous hysterotomy incisions, careful sharp dissection may be necessary (Fig. 25-18).

Special care is required from this point on to avoid injury to the ureters, which pass beneath the uterine arteries. To help accomplish this, an assistant places constant traction on the uterus in the direction away from the side on which the uterine vessels are being ligated. The ascending uterine artery and veins on either side are identified near their origin. These pedicles are then doubly clamped immediately adjacent to the uterus, divided, and doubly suture ligated. As shown in Figure 25-19, we prefer to use three heavy clamps, incise the tissue between the most medial and two lateral clamps, and then ligate the two pedicles in the clamps lateral to the uterus.

In cases of profuse hemorrhage, it may be more advantageous to rapidly double clamp and divide all of the vascular pedicles between clamps to gain hemostasis and then return to suture ligate all of the pedicles.

Supracervical Hysterectomy

To perform a subtotal hysterectomy, it is necessary only to amputate the body of the uterus immediately below the level of

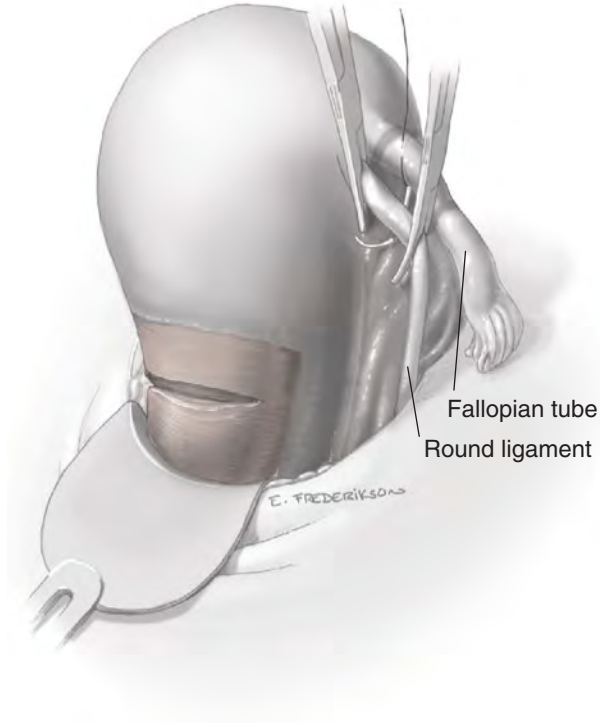

FIGURE 25-14 The round ligaments are clamped, ligated, and transected bilaterally.

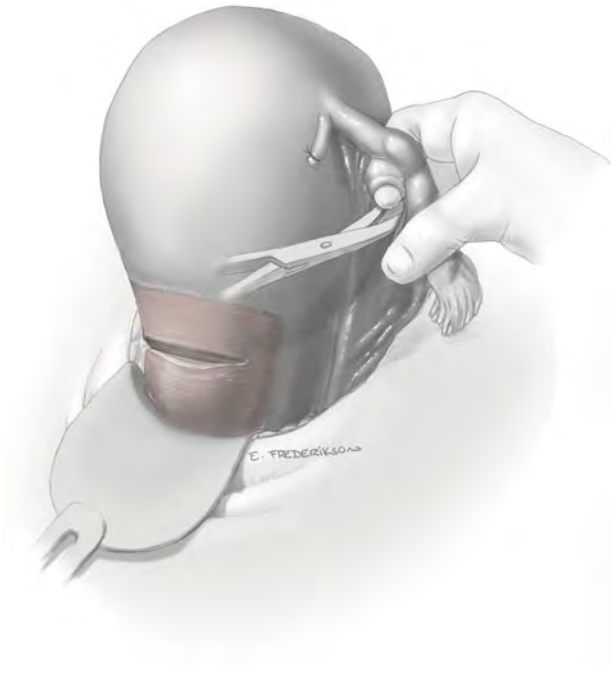

FIGURE 25-15 The posterior leaf of the broad ligament adjacent to the uterus is perforated just beneath the fallopian tube, utero-ovarian ligaments, and ovarian vessels.

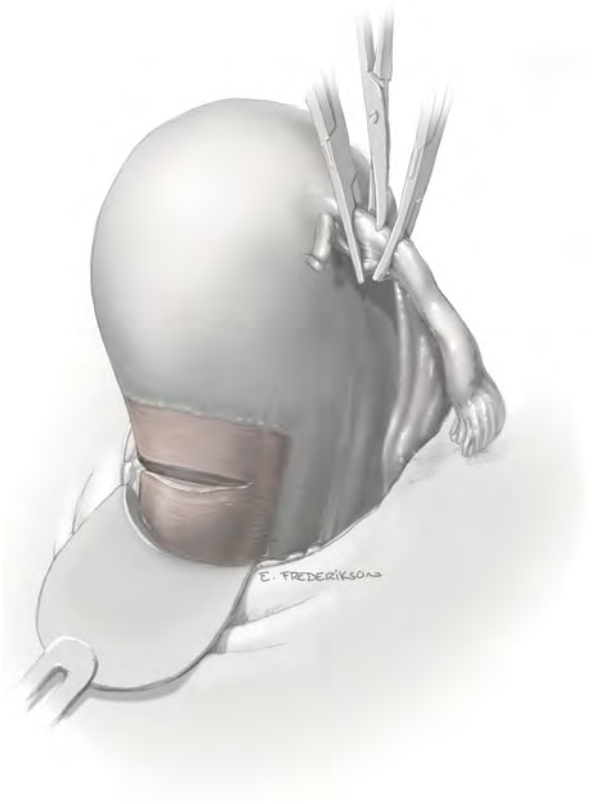

FIGURE 25-16 The utero-ovarian ligament and fallopian tube are clamped and cut bilaterally.

uterine artery ligation. The cervical stump may be closed with continuous or interrupted chromic catgut sutures. Subtotal hysterectomy is often all that is necessary to stop hemorrhage and may be the more prudent operation for selected women (Jones, 1999; Kastner, 2002; Learman, 2003; Munro, 1997, and all their associates).

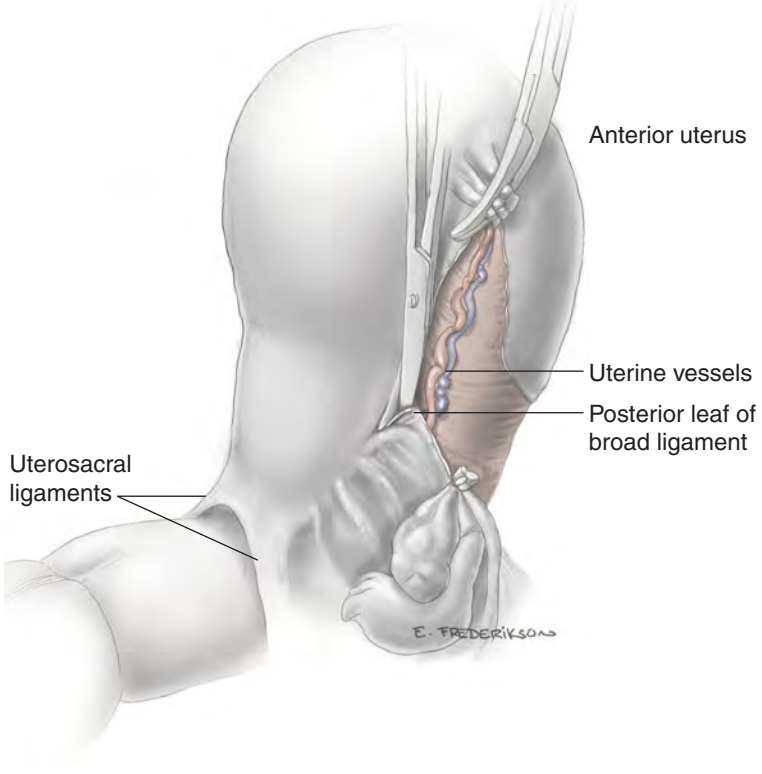

FIGURE 25-17 The posterior leaf of the broad ligament is divided inferiorly toward the uterosacral ligament.

Total Hysterectomy

Even if total hysterectomy is planned, we find it in many cases technically easier to finish the operation after amputating the uterine fundus and placing Ochsner or Kocher clamps on the stump for traction and hemostasis. Self-retaining retractors also may be placed at this time. To remove the cervix, it is necessary to extensively mobilize the bladder. This will help carry the ureters caudad as the bladder is retracted beneath the symphysis and will prevent laceration or suturing of the bladder during cervical excision and vaginal cuff closure. If the cervix is effaced and dilated appreciably, the cervicovaginal junction after delivery may be identified through a vertical uterine incision made anteriorly in the midline, either through the open hysterotomy incision or through an incision created at the level of the ligated uterine vessels. A finger is directed inferiorly through the incision to identify the free margin of the dilated, effaced cervix and the anterior vaginal fornix. The contaminated glove is replaced. Another useful method to identify the cervical margins is to transvaginally place four metal skin clips or brightly colored sutures at 12, 3, 6, and 9 o'clock positions on the cervical edges prior to hysterectomy.

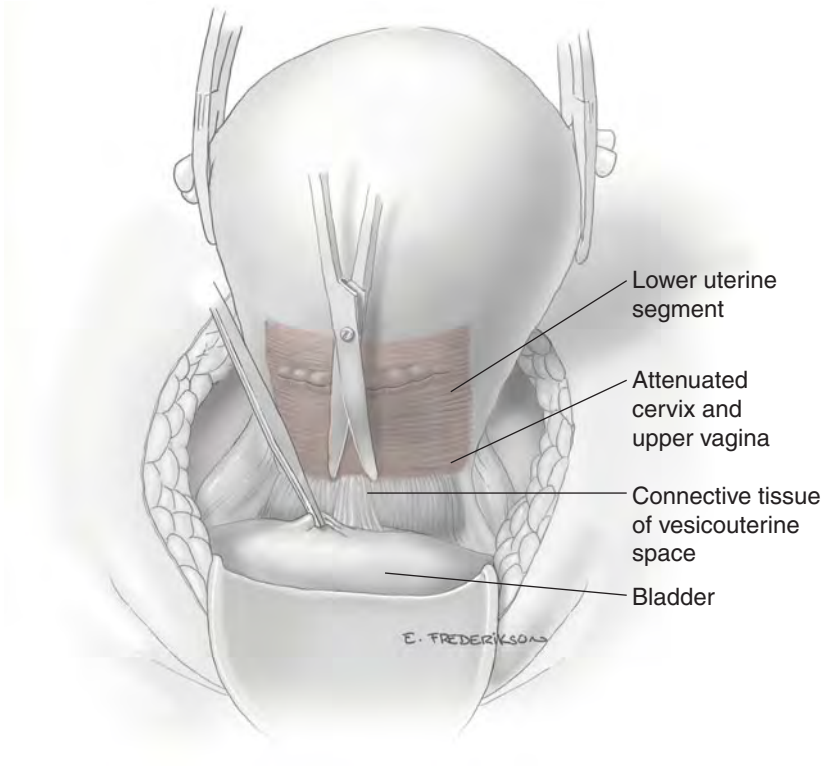

FIGURE 25-18 The bladder is dissected sharply from the lower uterine segment.

The cardinal ligaments, the uterosacral ligaments, and the many large vessels these ligaments contain are clamped systematically with Heaney-type curved clamps, Ochsner-type straight clamps, or similar instruments (**Fig. 25-20**). The clamps are placed as close to the cervix as possible, taking care not to include excessive tissue in each clamp. The tissue between the pair of clamps is incised and the distal pedicle suture ligated. These steps are repeated until the level of the lateral vaginal fornix is reached. In this way, the descending branches of the uterine vessels are clamped, cut, and ligated as the cervix is dissected from the cardinal ligaments.

Immediately below the level of the cervix, a curved clamp is placed across the lateral vaginal fornix, and the tissue is incised medially to the clamp (**Fig. 25-21**). The excised lateral vaginal fornix can be simultaneously doubly ligated and sutured to the stump of the cardinal ligament. The cervix is inspected to ensure that it has been completely removed, and the vagina is then repaired. Each of the angles of the lateral vaginal fornix is secured to the cardinal and uterosacral ligaments (**Fig. 25-22**). Following this step, some surgeons prefer to close the vagina using figure-of-eight chromic catgut sutures. Others achieve hemostasis by

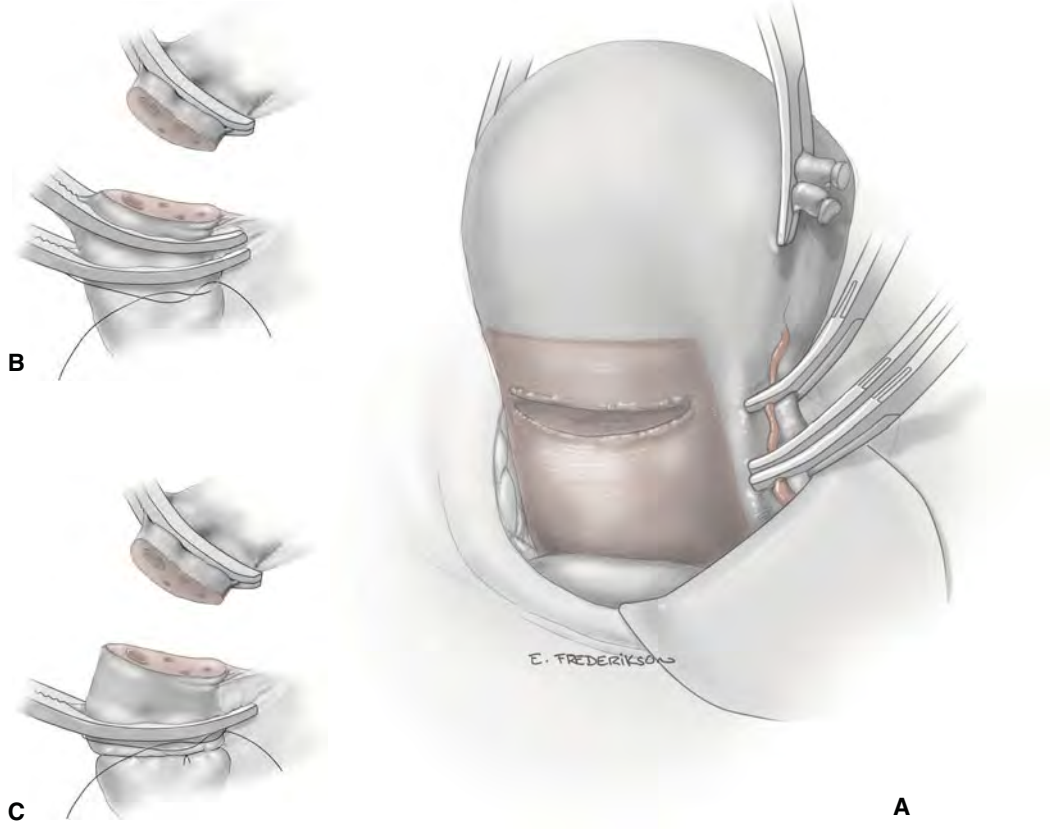

FIGURE 25-19 A. The uterine artery and veins on either side are doubly clamped immediately adjacent to the uterus and divided. **B, C.** The vascular pedicle is doubly suture ligated.

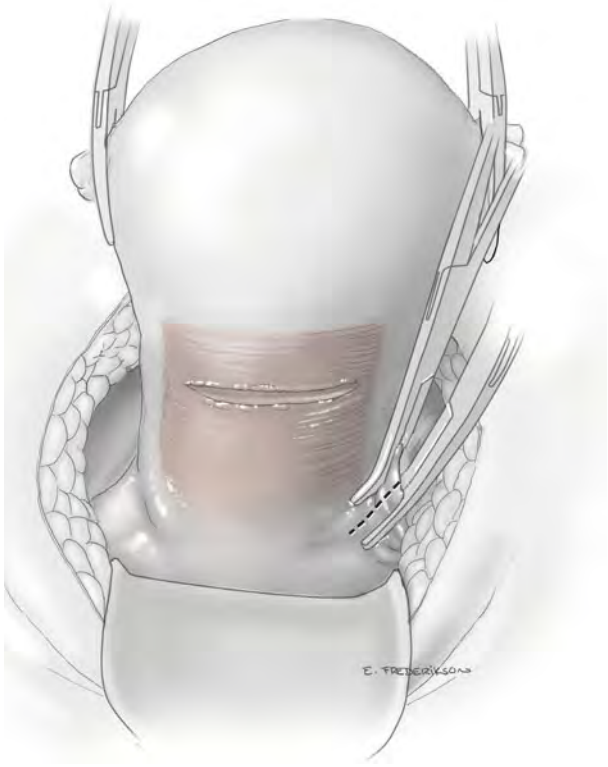

FIGURE 25-20 The cardinal ligaments are clamped, incised, and ligated.

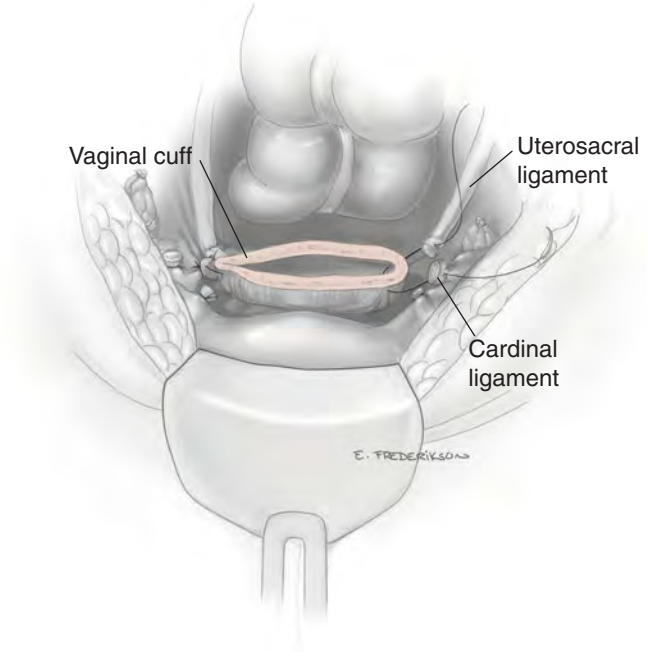

FIGURE 25-22 The lateral angles of the vaginal cuff are secured to the cardinal and uterosacral ligaments.

using a running-lock stitch of chromic catgut suture placed through the mucosa and adjacent endopelvic fascia around the circumference of the vaginal cuff (Fig. 25-23).

If a self-retaining retractor has not already been placed, some clinicians choose to insert the instrument at this point. The bowel is then packed out of the field, and all sites are examined carefully for bleeding. One technique is to perform a systematic bilateral survey from the fallopian tube and ovarian ligament pedicles to the vaginal vault and bladder flap. Bleeding sites are ligated with care to avoid the ureters. The abdominal wall normally is closed in layers, as previously described (p. 554).

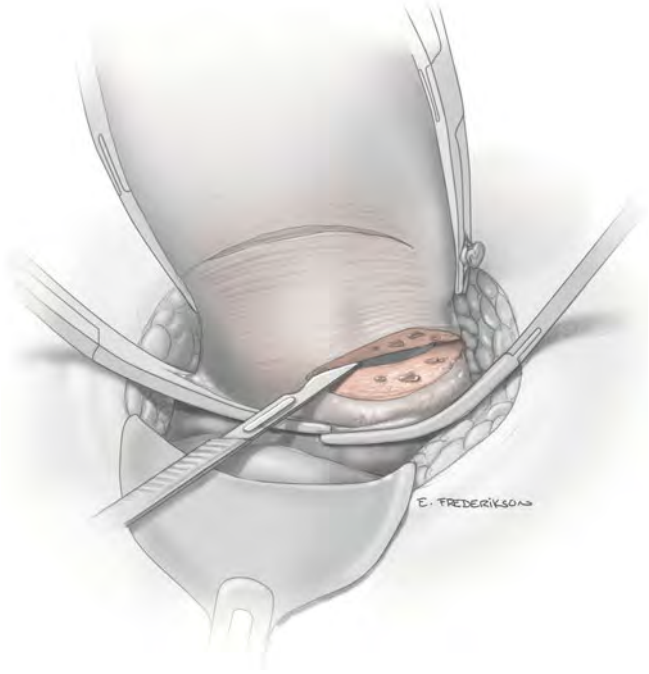

FIGURE 25-21 A curved clamp is placed across the lateral vaginal fornix below the level of the cervix, and the tissue incised medially to the point of the clamp.

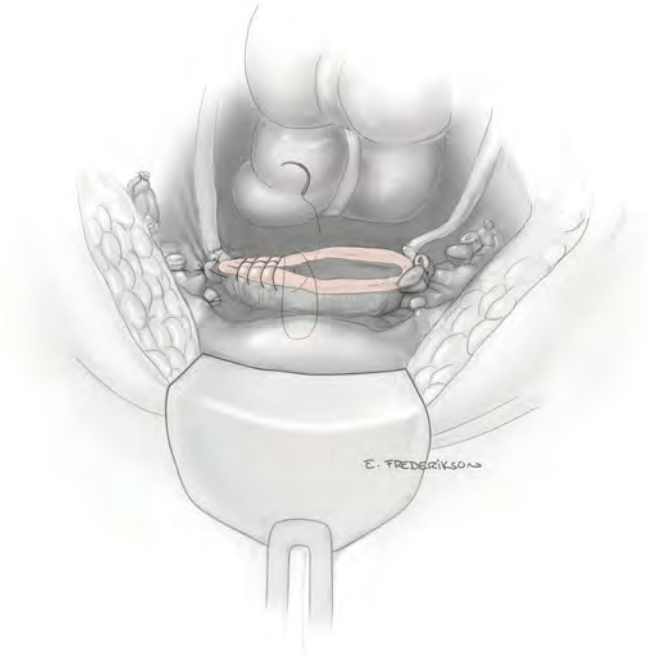

FIGURE 25-23 A running-lock suture approximates the vaginal wall edges.

Oophorectomy

Most studies indicate that in 5 percent of postpartum hysterectomies, one adnexum will have to be removed to stop bleeding (Plauche, 1995). In the recent report by Briery and colleagues (2007), a fourth of women had unilateral or bilateral oophorectomy. That said, during any hysterectomy, a decision as to the fate of the ovaries must be made. For women who are approaching menopause, the decision is not difficult, but few women who undergo cesarean hysterectomy are of this age.

Cystotomy

Rarely and usually in women who have had a previous cesarean delivery, injury to the bladder may occur, usually in the form of an incidental cystotomy. This complication is more common in women undergoing cesarean hysterectomy.

Bladder injury is typically identified at the time of surgery, and initially, a gush of clear fluid into the operating field may be seen. If laceration is suspected, it may be confirmed with instillation of sterile infant formula through a Foley catheter into the bladder. Leakage of opaque milk aids in identifying a laceration and delineating its borders. Additionally, cystoscopy may be indicated to further define bladder injury. Repair at the primary surgery is preferred and lowers the risk of postoperative vesicovaginal fistula formation. Once ureteral patency is confirmed, the bladder may be closed with a two- or three-layer running closure using a 3-0 absorbable or delayed-absorbable suture (Fig. 25-24). The first layer inverts the mucosa into the bladder, and subsequent layers reapproximate bladder muscularis. Postoperative care requires continuous bladder drainage for 7 to 10 days.

PERIPARTUM MANAGEMENT

Preoperative Care

If cesarean delivery is planned, a sedative may be given at bedtime the night before the operation. In general, no other sedatives, narcotics, or tranquilizers are administered until after the infant is born. Oral intake is stopped at least 8 hours before surgery. The woman scheduled for repeat cesarean delivery typically is admitted the day of surgery and evaluated by the obstetrician and the anesthesiologist. The hematocrit is rechecked, as is the indirect Coombs test. If the latter is positive, then availability of compatible blood must be ensured. An antacid, such as Bicitra, 30 mL, is given orally shortly before conduction analgesia or induction with general anesthesia to minimize the risk of lung injury from gastric acid aspiration (see Chap. 19, p. 460). An indwelling bladder catheter is placed. If hair obscures the operative field it should be removed the day of surgery by clipping or shaving. If shaving is performed the night before surgery, the risk of wound infection is increased. According to the American College of Obstetricians and Gynecologists (2007b), there are insufficient data to determine the value of fetal monitoring prior to *scheduled* cesarean delivery in women without risk factors. That said, fetal heart tones should be documented prior to surgery.

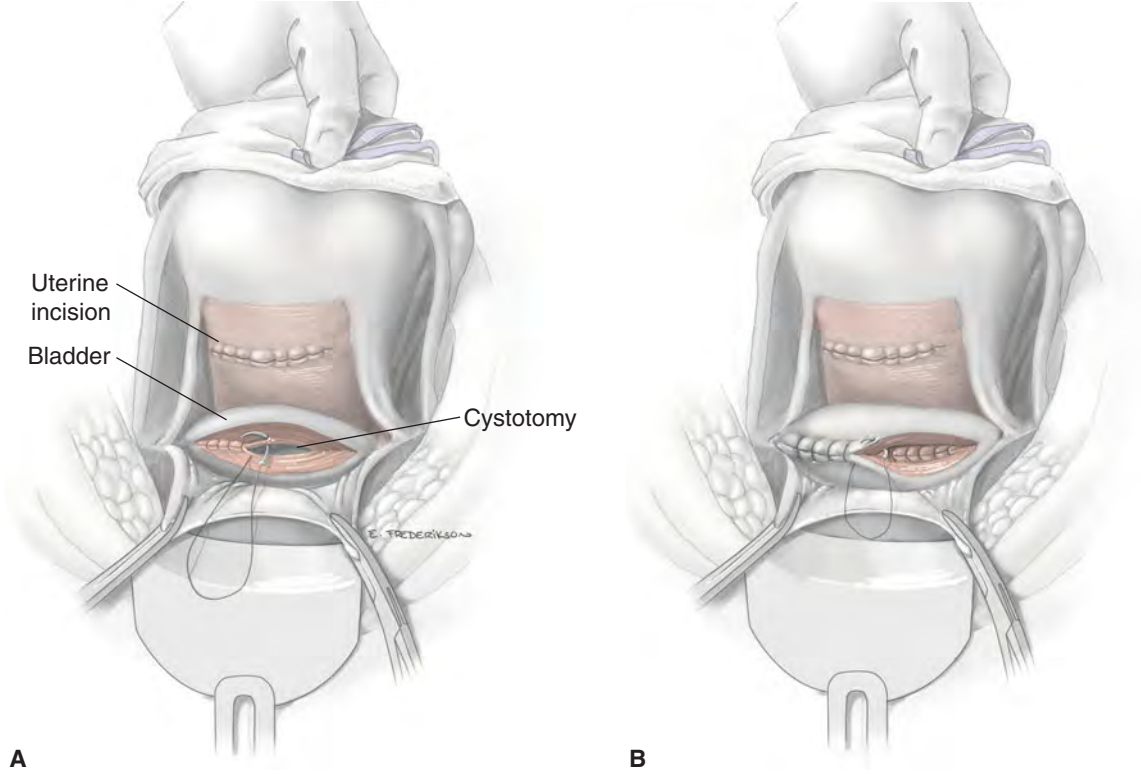

FIGURE 25-24 Cystotomy repair. **A.** The primary layer inverts the bladder mucosa with running or interrupted sutures of 3-0 delayed-absorbable or absorbable suture. **B.** Second and possibly a third layer approximate the bladder muscularis to reinforce the incision closure.

Intravenous Fluids

Requirements for intravenous fluids, including blood, during and after cesarean delivery can vary considerably. Intravenously administered fluids consist of either lactated Ringer solution or a similar crystalloid solution with 5-percent dextrose. Typically, at least 2 to 3 L are infused during surgery. Blood loss with uncomplicated cesarean delivery approximates 1000 mL. The woman of average size with a hematocrit of 30 percent or more and a normally expanded blood and extracellular fluid volume most often will tolerate blood loss up to 2000 mL without difficulty. Unappreciated bleeding through the vagina during the procedure, bleeding concealed in the uterus after its closure, or both commonly lead to underestimation.

Although blood loss averages about 1500 mL with elective cesarean hysterectomy, it is variable (Pritchard, 1965). Thus, throughout the procedure and subsequently, while in the recovery area, blood pressure and urine flow are monitored closely.

Prevention of Postoperative Infection

Febrile morbidity is frequent after cesarean delivery. A large number of randomized trials have demonstrated that a single dose of an antimicrobial agent given at the time of cesarean delivery will serve to decrease infectious morbidity significantly. This is true of high-risk laboring patients as well as those undergoing elective cesarean delivery (American College of Obstetricians and Gynecologists, 2003). For women in labor or with ruptured membranes, most clinicians recommend a single 2-g dose of a β-lactam drug—either a cephalosporin or extended-spectrum penicillin—after delivery of the newborn. The delay of prophylactic antibiotic administration after the delivery of the infant has been due to concerns surrounding neonatal exposure to antibiotics and the potential effect on neonatal sepsis evaluation. Some authors have found no effect on maternal infection rates whether prophylaxis is administered at the time of the skin incision or at cord clamping (Thigpen and coworkers, 2005). Others, however, reported decreased rates if given at the earlier time (Sullivan and associates, 2007; Tita and colleagues, 2009). Currently, the original concerns regarding effect on neonatal infections have not been adequately dispelled.

Postoperative pelvic infection is the most frequent cause of febrile morbidity and develops in up to 20 percent of these women despite peripartum prophylactic antimicrobials (Goepfert and associates, 2001). The addition of azithromycin to a standard first- or second-generation cephalosporin prophylactic dose was found to decrease the risk of postoperative endometritis compared with cephalosporin alone (Tita and colleagues, 2008, 2009). Treatment of uterine infection and its complications are discussed in Chapter 31 (p. 661).

Recovery Suite

Postoperatively, the amount of bleeding from the vagina must be monitored closely, and the uterine fundus must be identified frequently by palpation to ensure that the uterus is remaining firmly contracted. Unfortunately, as conduction analgesia fades or the woman awakens from general anesthesia, palpation of the abdomen is likely to produce considerable discomfort. This can be made tolerable by giving an effective analgesic intravenously, such as meperidine, 75 to 100 mg, or morphine, 10 to 15 mg. A thick dressing with an abundance of adhesive tape over the abdomen interferes with fundal palpation and massage and later causes discomfort as the tape is removed. Deep breathing and coughing are encouraged. Once the mother is fully awake, bleeding is minimal, blood pressure is satisfactory, and urine flow is at least 30 mL/hr, she may be transferred to her room.

Subsequent Care

Analgesia

For the woman of average size, meperidine, 50 to 75 mg, is given intramuscularly as often as every 3 hours as needed for discomfort (Table 25-5). Alternatively, morphine sulfate, 10 to 15 mg, is similarly administered. An antiemetic, such as promethazine, 25 mg, usually is given along with the narcotic. Intravenous meperidine or morphine via a patient-controlled pump is an even more effective alternative to bolus therapy in the immediate postoperative period (Table 25-5). The pump typically is programmed to deliver a continuous infusion of drug. The woman can supplement with intermittent boluses, the frequency of which are determined by the "lock-out" interval. In a trial at Parkland Hospital, morphine provided superior pain relief to meperidine and was associated with significantly

TABLE 25-5. Typical Settings for Administration of Intravenous Opioids via a Patient-Controlled Analgesia Pump

Recovery room:
IV meperidine, 25 mg every 5 min up to 100 mg
or
IV morphine, 2 mg every 5 min up to 10 mg
Postpartum ward (first 24 h after surgery):[a]
IM meperidine, 50–75 mg every 3–4 h as needed
or
PCA intravenous meperidine, 10 mg with a 6 min lockout interval and maximum dose of 200 mg in 4 h as needed. An additional 25-mg booster dose was permitted for a maximum of 2 doses
or
IM morphine, 10–15 mg every 3–4 h as needed
or
PCA intravenous morphine, 1 mg with a 6-min lockout interval and maximum dose of 30 mg in 4 h as needed. An additional 2-mg booster dose was permitted for a maximum of 2 doses

[a]Each postpartum ward regimen also included promethazine, 25 mg intravenously every 6 h as needed for nausea.

IM = intramuscular; IV = intravenous; PCA = patient-controlled analgesia.

higher rates of breast-feeding continuation and infant rooming-in (Yost and colleagues, 2004).

Vital Signs

After transfer to her room, the woman is assessed at least hourly for 4 hours and thereafter, at intervals of 4 hours. Blood pressure, pulse, temperature, uterine tone, urine output, and amount of bleeding are evaluated.

Fluid Therapy and Diet

The puerperium is characterized by excretion of fluid that was retained during pregnancy. Moreover, with the typical cesarean delivery, significant extracellular fluid sequestration in bowel wall and lumen does not occur, unless it was necessary to pack the bowel away from the operative field or peritonitis develops. Thus, the woman who undergoes cesarean delivery rarely develops fluid sequestration in the so-called third space. On the contrary, she normally begins surgery with a physiologically enlarged extravascular volume acquired during pregnancy that she mobilizes and excretes after delivery. Therefore, large volumes of intravenous fluids during and subsequent to surgery are not needed to replace sequestered extracellular fluid. As a generalization, 3 L of fluid should prove adequate during the first 24 hours after surgery. If urine output falls below 30 mL/hr, however, the woman should be reevaluated promptly. The cause of the oliguria may range from unrecognized blood loss to an antidiuretic effect from infused oxytocin.

Exception to this typical pattern of fluid mobilization include pathological constriction of the extracellular fluid compartment from severe preeclampsia, vomiting, fever, prolonged labor without adequate fluid intake, significant blood loss, or sepsis.

Bladder and Bowel Function

The bladder catheter most often can be removed by 12 hours postoperatively or more conveniently, the morning after surgery. The prevalence of urinary retention following cesarean delivery approximates 3 percent, and a failure to progress in labor following surgery is an identified risk (Chai and associates, 2008). Thus, surveillance for bladder overdistension should be implemented as with vaginal delivery.

In uncomplicated cases, solid food may be offered within 8 hours of surgery (Bar, 2008; Kramer, 1996; Orji, 2009, and all their co-workers). Although some degree of adynamic ileus follows virtually every abdominal operation, in most cases of cesarean delivery it is negligible. Symptoms include abdominal distension and gas pains, and an inability to pass flatus or stool. The pathophysiology of postoperative ileus is complex and involves hormonal, neural, and local factors that are incompletely understood (Livingston and Passaro, 1990). If associated with otherwise unexplained fever, an unrecognized bowel injury may be responsible. Treatment for ileus has changed little during the past several decades and involves intravenous fluid and electrolyte supplementation. If severe, nasogastric decompression is necessary. Frequently, a 10-mg bisacodyl rectal suppository provides appreciable relief.

Ambulation

Women undergoing cesarean have a two- to 20-fold increased of risk of pulmonary embolism compared with those delivering vaginally. Risks include age > 35; BMI > 30; parity >3; emergency cesarean; cesarean hysterectomy; concurrent infection, major illness, preeclampia, or gross varicosities; recent immobility; and prior deep-venous thrombosis or thrombophilia (Marik and Plante, 2008). Early ambulation lowers the risk of venous thrombosis and pulmonary embolism (see Chap. 47, p. 1013).

In most instances, by the day after surgery, a woman should get briefly out of bed with assistance at least twice to walk. Ambulation can be timed so that a recently administered analgesic will minimize the discomfort. By the second day, she may walk without assistance.

Wound Care

The incision is inspected each day, and the skin sutures or clips often can be removed on the fourth day after surgery. However, if there is concern for superficial wound separation, as in the obese patient, the suture or clips should remain in place for 7 to 10 days. By the third postpartum day, showering is not harmful to the incision.

Laboratory

The hematocrit is routinely measured the morning after surgery. It is checked sooner if there was unusual blood loss or if there is oliguria or other evidence to suggest hypovolemia. If the hematocrit is decreased significantly from the preoperative level, the measurement is repeated and a search is instituted to identify the cause of the decline. If the hematocrit stabilizes, the mother can be allowed to ambulate, and if there is little likelihood of further blood loss, iron therapy is preferred to transfusion.

Breast Care

Breast feeding can be initiated the day of surgery. If the mother elects not to breast feed, a binder that supports the breasts without marked compression usually will minimize discomfort (see Chap. 30, p. 651).

Hospital Discharge

Unless there are complications during the puerperium, the mother generally is discharged on the third or fourth postpartum day (see Chap. 30, p. 657). Strong and associates (1993) have presented data suggesting that discharge on day 2 may be appropriate for properly selected and motivated women. Activities during the first week should be restricted to self-care and care of her baby with assistance. Brooten and colleagues (1994) successfully combined early discharge with nurse-specialist transitional home care.

CHAPTER 26

Prior Cesarean Delivery

TRIAL OF LABOR VERSUS REPEAT CESAREAN DELIVERY 565
CANDIDATES FOR A TRIAL OF LABOR 567
LABOR AND DELIVERY CONSIDERATIONS 571
UTERINE RUPTURE 573
COMPLICATIONS WITH MULTIPLE REPEAT CESAREAN DELIVERIES 574
STATE OF VBAC IN 2009 575

Few issues in modern obstetrics have been as controversial as the management of the woman who has had a prior cesarean delivery. For many decades, a scarred uterus was believed by most to contraindicate labor out of fear of uterine rupture. In 1916 Cragin made his famous, oft-quoted, and now seemingly excessive pronouncement, "Once a cesarean, always a cesarean." Recall that when this statement was made, the classical vertical uterine incision was used almost universally. Even so, some of his contemporaries did not totally agree with his pronouncement. For example, J. Whitridge Williams (1917) termed the statement "an exaggeration" in the fourth edition of *Williams Obstetrics*.

In the 1920s the technique of low-transverse uterine incision was introduced by Kerr (1921). Leading obstetrical institutions subsequently reported that although catastrophic uterine rupture developed in at least 4 percent of prior classical incisions, only about 0.5 percent of transverse incisions ruptured. And while caution reigned, beginning in the 1950s comfort with the low-transverse incisions resulted in a number of reports that described the de facto policy of a trial of labor in some women without recurring indications for cesarean delivery. And even with repeat cesarean delivery being the stated norm, Hellman and Pritchard (1971) wrote in the 14th edition of *Williams Obstetrics* that "many reliable institutions, however, report a 30-to 40-percent rate of vaginal deliveries following cesarean section without difficulty." In 1978, Merrill and Gibbs reported that subsequent vaginal delivery was safely accomplished at the University of Texas at San Antonio in 83 percent of women with a prior cesarean delivery.

Thus, interest was rekindled in vaginal birth especially as the rates of primary cesarean delivery were increasing at an unprecedented pace. Between 1980 and 1988, for example, the cesarean rate jumped from 17 to 25 percent. Meanwhile, more evidence had accrued that uterine rupture was infrequent and rarely catastrophic. In an effort to address the rising cesarean delivery rate, the American College of Obstetricians and Gynecologists (1988) recommended that most women with one previous low-transverse cesarean delivery should be counseled to attempt labor in a subsequent pregnancy. Accordingly, the frequency of vaginal birth after cesarean—commonly referred to as *VBAC*—increased significantly. And as shown in **Figure 26-1**, by 1996 almost a third of women with a prior cesarean were being delivered vaginally. Pitkin (1991), who was editor of *Obstetrics & Gynecology* at that time, wrote that "without question, the most remarkable change in obstetric practice over the last decade was management of the woman with prior cesarean delivery."

TRIAL OF LABOR VERSUS REPEAT CESAREAN DELIVERY

Associated Risks

Beginning in 1989, as the number of women attempting vaginal delivery increased, there were a growing number of reports that described increased rates of uterine rupture and perinatal morbidity and mortality leading some to suggest that VBAC might be riskier than anticipated (Flamm, 1997; Leveno, 1999; Scott, 1991). In 1998 and 1999, the American College of Obstetricians and Gynecologists issued updated Practice Bulletins supporting VBAC, but also urging a more cautious approach. Subsequently,

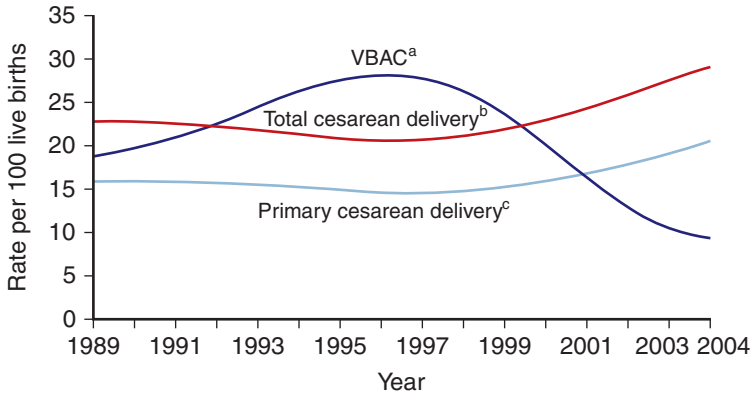

FIGURE 26-1 Total and primary cesarean delivery rates and vaginal birth after previous cesarean (VBAC) rate: United States, 1989–2004. [a]VBAC = number of vaginal births after previous cesarean delivery per 100 births. [b]Percentage of all live births by cesarean delivery. [c]Number of primary cesarean deliveries per 100 live births to women without a prior cesarean delivery. From National Institutes of Health State-of-the-Science Conference Statement, 2006.

fewer women attempted VBAC, and there was a corresponding increase in the overall cesarean delivery rate (see Fig. 26-1). In 2007, VBAC rates in the U.S. decreased to a rate of 8.5 percent (Hamilton and associates, 2009).

Fetal Risk

Uterine rupture and its associated complications clearly are increased with a trial of labor. But some have argued that these factors should weigh only minimally in the decision to attempt VBAC because their absolute risk is low. One of the largest and most comprehensive studies designed to examine risks associated with VBAC was conducted by the Maternal-Fetal Medicine Units (MFMU) Network and reported by Landon and colleagues (2004). In this prospective study conducted at 19 academic medical centers, the outcomes of nearly 18,000 women who attempted a trial of labor were compared with those of more than 15,000 women who underwent elective repeat cesarean delivery. As shown in Table 26-1, although the risk of uterine rupture was higher among women undergoing a trial of labor, the absolute risk was small—only 7 per 1000. To the contrary, however, there were no uterine ruptures in the elective cesarean delivery group. Of note, rates of stillbirth and hypoxic ischemic encephalopathy were significantly greater in the trial of labor arm. Others have reported similar results (Chauhan and colleagues, 2003; Mozurkewich and Hutton, 2000).

In another study, Smith and associates (2002) analyzed outcomes associated with a trial of labor compared with those of planned repeat cesarean delivery in nearly 25,000 women with a prior cesarean delivery. The risk of delivery-related perinatal death was 1.3 per 1000 among the 15,515 women who attempted VBAC. Although the absolute risk was again small, this rate was *11 times greater* than the risk of perinatal death in 9014 women who planned repeat cesarean delivery.

Collectively, these data suggest that the absolute risk of uterine rupture attributable to a trial of labor resulting in death or

injury to the fetus is approximately 1 per 1000. Thus, the major controversy surrounding the management of women with a prior cesarean delivery stems from the question: *Is a 1 per 1000 risk of having an otherwise healthy fetus die or be damaged as a result of a trial of labor acceptable?*

Maternal Risk

Another potential argument in support of VBAC has been that a trial of labor is associated with reduced risks for the mother compared with those of a repeat cesarean delivery. Most studies suggest that the maternal *mortality* rate does not differ significantly between women undergoing a trial of labor compared with those undergoing an elective repeat cesarean (Landon and collaborators, 2004; Mozurkewich and Hutton, 2000). In a retrospective cohort study of more than 300,000 Canadian women with a prior cesarean delivery, Wen and associates (2005) found an increased—albeit statistically nonsignificant—maternal mortality rate with elective repeat cesarean delivery. Specifically, the maternal death rate for women undergoing an elective repeat cesarean delivery was 5.6 per 100,000 compared with 1.6 per 100,000 for those having a trial of labor.

Estimates of maternal *morbidity* have produced conflicting results. In the meta-analysis by Mozurkewich and Hutton (2000), women undergoing a trial of labor were approximately half as likely to require a blood transfusion or hysterectomy compared with those undergoing repeat cesarean delivery. Conversely, in the MFMU Network study cited earlier, Landon and co-workers (2004) observed that the risks of transfusion and infection were significantly greater for women attempting a trial of labor (see Table 26-1). Rossi and D'Addario (2008) reported similar findings in their meta-analysis. McMahon and associates (1996), in a population-based study of 6138 women, found that major complications—hysterectomy, uterine rupture, or operative injury—were almost twice as common in women undergoing a trial of labor compared with those undergoing an elective second cesarean delivery. Moreover, compared with a successful trial of labor, the risk of these major complications was fivefold greater in women whose attempt at a vaginal delivery failed. Similarly, El-Sayed and associates (2007) found a fivefold higher rate of chorioamnionitis and a twofold higher rate of hemorrhage among women with a failed trial of labor compared with those having a successful attempt. Finally, after their meta-analysis, Rossi and D'Addario (2008) also reported an increased incidence of overall maternal complications when women with a failed VBAC were compared with those undergoing successful VBAC—17 versus 3 percent, respectively.

Patient Preference

As described in Chapter 25 (p. 547), compared with vaginal delivery, cesarean birth is associated with increased risks. Some of these are anesthesia complications, hemorrhage, damage to the bladder and other organs, pelvic infection, and adhesion formation. Moreover, many of these risks escalate progressively with increasing numbers of cesarean deliveries (Silver and associates, 2006).

Despite these potential concerns, an elective repeat cesarean delivery is considered by many women to be preferable to a trial of labor. Frequent reasons include the convenience of a scheduled delivery and the fear of a prolonged and potentially dangerous labor. Abitbol and associates (1993) found that these preferences persisted despite extensive antepartum counseling. They interviewed women at discharge and of those who selected repeat cesarean delivery, 93 percent reported satisfaction. This compared with only 53 percent of women overall who elected a trial of labor and 80 percent of those who had an uncomplicated trial of labor.

CANDIDATES FOR A TRIAL OF LABOR

Selection of women best suited for a trial of labor is particularly challenging. Indeed, reviews by Hashima (2004) and Guise (2004) and their associates led them to conclude that there are few high-quality data available to guide this clinical decision. Clearly, however, the fewer the number of complicating risk factors, the greater is the likelihood of success (Gregory and co-workers, 2008).

In a recent secondary analysis of the MFMU Network study cited earlier, Grobman and colleagues (2007b) developed a nomogram to help predict a successful trial of labor (**Fig. 26-2**). These investigators also used this tool to predict risk of associated maternal morbidity with VBAC (Grobman and colleagues, 2009). The model is applicable only to women with one prior cesarean delivery who are at term. In a comparable effort, Srinivas and associates (2007) concluded that the use of only six variables—maternal age and race, gestational age, type of labor, prior cesarean indication, and history of vaginal delivery—could not be reliably used to predict successful VBAC. And in a third study, Macones and associates (2006) attempted to develop a clinical model to predict uterine rupture. They incorporated many antepartum and intrapartum factors and concluded that rupture was not predictable with either individual or multiple clinical characteristics. The investigators from the MFMU Network reached a similar conclusion (Grobman and colleagues, 2008).

Despite these limitations for precision, a number of points are pertinent to the evaluation of women for a trial of labor. Current recommendations of the American College of Obstetricians and Gynecologists (2004) for selecting appropriate candidates are listed in **Table 26-2**.

TABLE 26-2. Some Factors for Consideration in Selection of Candidates for Vaginal Birth after Cesarean Delivery (VBAC)

- One previous prior low-transverse cesarean delivery
- Clinically adequate pelvis
- No other uterine scars or previous rupture
- Physician immediately available throughout active labor capable of monitoring labor and performing an emergency cesarean delivery
- Availability of anesthesia and personnel for emergency cesarean delivery

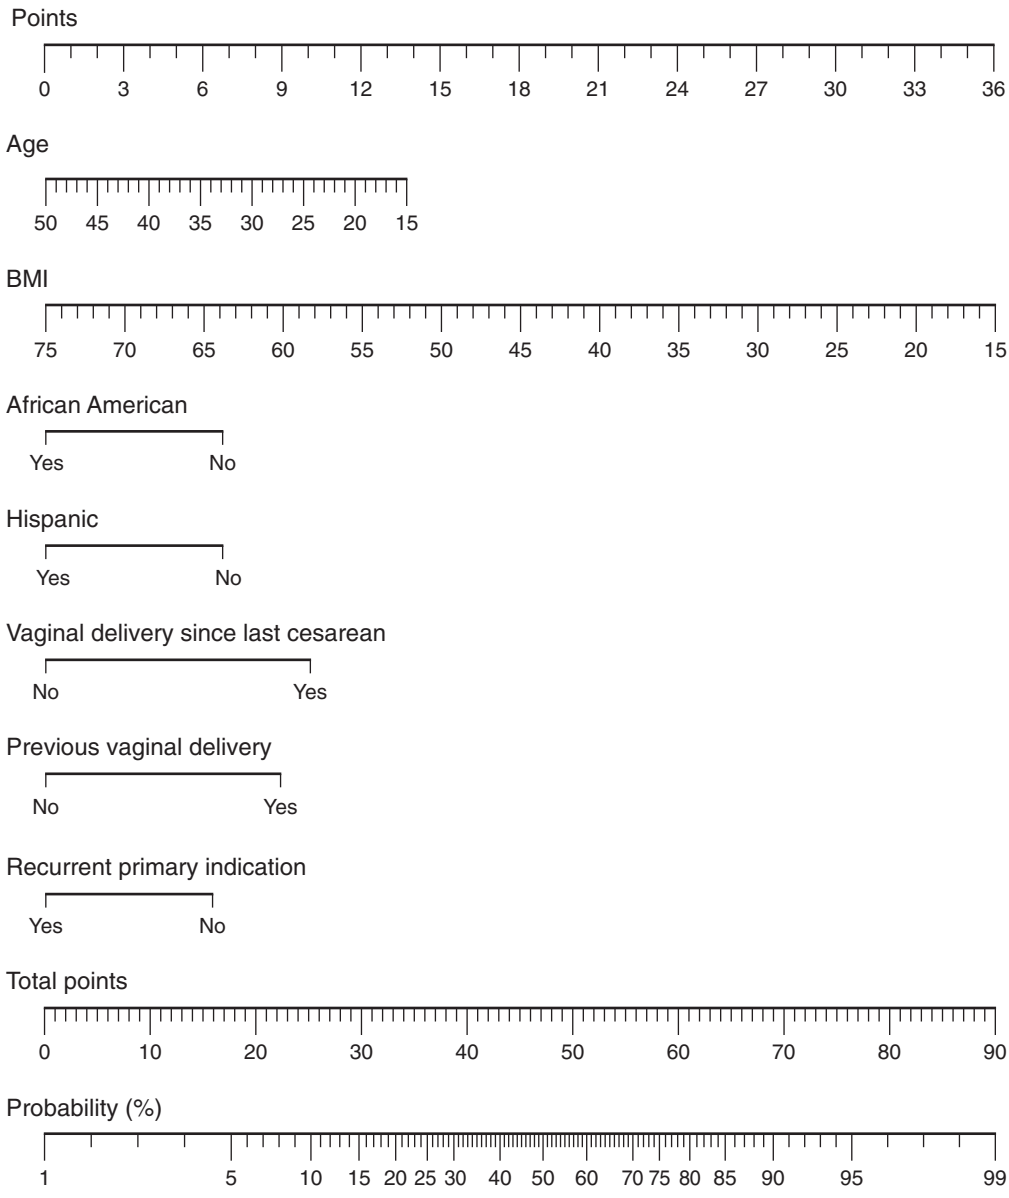

FIGURE 26-2 Predictive nomogram for probability of vaginal birth after cesarean delivery (VBAC). This nomogram is used by locating each patient characteristic and finding the number of points on the uppermost scale to which that characteristic corresponds. For example, a maternal age of 26 years corresponds to approximately 10 points. The sum of points generated from each of these characteristics is compared with the "total points" scale, and the predicted probability of VBAC is determined from the corresponding point on the lowermost scale. As an example, the woman with 60 total points has a 75- to 80-percent chance of a successful VBAC. (Reproduced from Grobman and colleagues, 2007b, with permission.)

Type of Prior Uterine Incision

Women with a transverse scar confined to the lower uterine segment have the lowest risk of symptomatic scar separation during a subsequent pregnancy (Table 26-3). The highest risks are with prior vertical incisions extending into the fundus such as the classical incision shown in Figure 26-3. Importantly, in some women, the classical scar will rupture before the onset of labor, and this can happen several weeks before term. In a review of 157 women with a prior classical cesarean delivery, Chauhan and colleagues (2002) reported that one woman had a complete uterine rupture prior to the onset of labor, whereas 9 percent had a uterine dehiscence.

The risk of uterine rupture in women with a prior vertical incision that did not extend into the fundus is unclear. Martin (1997) and Shipp (1999) and their co-workers reported that these low vertical uterine incisions did not have an increased risk for rupture compared with that of low transverse incisions. The American College of Obstetricians and Gynecologists (2004) concluded that, although there is limited evidence, women with a prior vertical incision in the lower uterine segment without fundal extension may be candidates for VBAC. This is in contrast to prior classical or T-shaped uterine incisions, which are considered contraindications to labor.

TABLE 26-3. Types of Prior Uterine Incisions and Estimated Risks for Uterine Rupture

Prior Incision	Estimated Rupture Rate (Percent)
Classical	4–9
T-shaped	4–9
Low-vertical[a]	1–7
Low-transverse	0.2–1.5
Prior uterine rupture	
Lower segment	6
Upper uterus	32

Data from the American College of Obstetricians and Gynecologists (1999, 2004), Chauhan (2002), Martin (1997), Reyes-Ceja (1969), Ritchie (1971), Shipp (1999), and all their colleagues.

Nowadays, there are very few indications for a primary vertical incision, and in those instances—for example, preterm breech fetus with an undeveloped lower segment—the "low vertical" incision almost invariably extends into the active segment. It is not known, however, how far upward the incision has to extend before risks become those of a true classical incision. It is helpful in the operative report to document its exact extent.

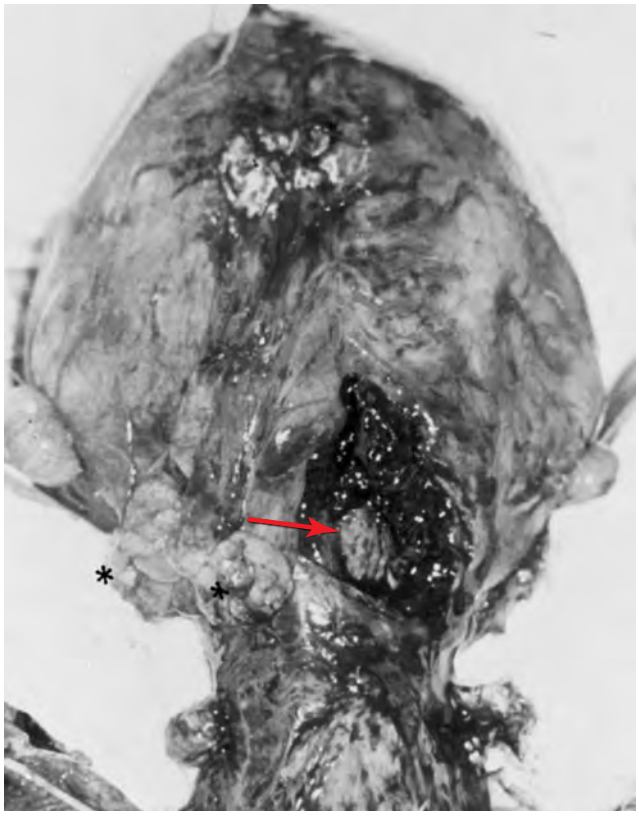

FIGURE 26-3 Ruptured vertical cesarean section scar (*arrow*) identified at time of repeat cesarean delivery early in labor. The asterisk to the left indicates some of the sites of densely adherent omentum.

And although the type of prior incision was not known, Sciscione and associates (2008) reported that women who had a prior preterm cesarean delivery were approximately twice as likely to suffer a uterine rupture compared with those with a prior term cesarean delivery. This may be in part explained by the increased likelihood of extension of the uterine incision into the contractile portion. Harper and co-workers (2009), however, did not find a significantly increased rate of rupture during subsequent VBAC in those with a prior cesarean delivery performed at ≤ 34 weeks.

There are special considerations for women with uterine malformations who have undergone cesarean delivery. Earlier reports suggested that the risks for uterine rupture in a subsequent pregnancy may be as high as with a classical incision. Specifically, Ravasia and associates (1999) in a study of 25 women with müllerian duct anomalies and a prior low transverse cesarean delivery reported that subsequent uterine rupture occurred in 2 women—8 percent. Importantly, and as discussed later (see p. 572), both of these women had labor induced with prostaglandin E_2 gel. In a more recent study, Erez and co-workers (2007) described the outcomes of 165 women with müllerian duct anomalies who had one prior cesarean delivery. In this retrospective study, 103 of the women attempted a trial of labor, and 61 percent of these delivered vaginally. There were no cases of uterine rupture—and in only 10 women was labor induced—and maternal morbidity rates were comparable with similar women without müllerian anomalies (Chap. 40, p. 891).

Given the wide range of risk for uterine rupture associated with various types of prior uterine incisions, it is not surprising that most fellows of the American College of Obstetricians and Gynecologists consider the type of prior incision to be the most important factor when considering a trial of labor (Coleman and co-workers, 2005).

Prior Uterine Rupture

Women who have previously sustained a uterine rupture are at increased risk for recurrence during a subsequent attempted VBAC. As shown in Table 26-3, those with a previous low-segment rupture have a 6-percent recurrence risk, whereas prior upper uterine rupture confers a 32-percent risk (Reyes-Ceja and associates, 1969; Ritchie, 1971). We believe that women with prior uterine ruptures or classical or T-shaped incisions ideally should undergo repeat cesarean delivery when fetal pulmonary maturity is assured, and preferably prior to the onset of labor. They should also be counseled regarding the hazards of unattended labor and signs of possible uterine rupture.

Closure of Prior Incision

As discussed in Chapter 25 (see p. 552), the low-transverse uterine incision can be sutured in either one or two layers. Whether the risk of subsequent uterine rupture is affected by these is unclear. Chapman (1997) and Tucker (1993) and their associates found no relationship between a one- and two-layer closure and the risk of subsequent uterine rupture. And although Durnwald and Mercer (2003) also found no increased risk of rupture, they reported that uterine dehiscence was more common after single-layer closure. In contrast, Bujold and co-workers (2002) found that a single-layer closure was associated with

nearly a fourfold increased risk of rupture compared with a double-layer closure. In response, Vidaeff and Lucas (2003) argued that experimental models of wound healing have not demonstrated advantages of a double-layer closure. Because of potentially confounding variables inherent in this type of retrospective study, they concluded that the evidence is insufficient to routinely recommend a double-layer closure. At our institutions we routinely suture the low-segment incision with one running locking suture (see Chap. 25, p. 552).

Interdelivery Interval

It seems logical to assume that the risk of uterine rupture would be increased if a hysterotomy scar did not have sufficient time to heal. Magnetic resonance imaging studies of myometrial healing suggest that complete uterine involution and restoration of anatomy may require at least 6 months (Dicle and colleagues, 1997). To explore this issue further, Shipp and associates (2001) examined the relationship between interdelivery interval and uterine rupture in 2409 women who had one prior cesarean delivery. Uterine rupture developed in 29 women—1.4 percent. Interdelivery intervals of 18 months or less were associated with a threefold increased risk of symptomatic rupture during a subsequent trial of labor compared with intervals greater than 18 months. Similarly, Stamilio and co-workers (2007) noted a threefold increased risk of uterine rupture in women with an interpregnancy interval of less than 6 months compared with one of 6 months or longer. However, interpregnancy intervals of 6 to 18 months did not significantly increase the risk of uterine rupture or maternal morbidity.

Number of Prior Cesarean Incisions

It also seems logical that the risk of uterine rupture would increase with the number of previous cesarean deliveries. Miller and colleagues (1994) studied 12,707 such women undergoing a trial of labor. They reported rupture rates of 0.6 percent following one cesarean delivery and 1.8 percent for women with two prior cesarean deliveries. Similarly, Macones and associates (2005a) reported a twofold increase in the rate of uterine rupture among women attempting trial of labor after two prior cesarean deliveries—1.8 percent—compared with those with one—0.9 percent. In contrast, analysis of the MFMU Network database by Landon and co-workers (2006) did not confirm this. Instead, they reported an insignificant difference in the uterine rupture rate in 975 women with multiple prior cesarean deliveries compared with 16,915 women with a single prior operation—0.9 versus 0.7 percent, respectively.

Prior Vaginal Delivery

Any previous vaginal delivery, either before or following a cesarean birth, significantly improves the prognosis for a subsequent vaginal delivery with either spontaneous or induced labor (Grinstead and Grobman, 2004; Hendler and co-workers, 2004; Mercer and colleagues, 2008). Prior vaginal delivery also lowers the risk of subsequent uterine rupture and other morbidities (Cahill and co-workers, 2006; Zelop and associates, 2000). Indeed, the most favorable prognostic factor is prior vaginal delivery. The American College of Obstetricians and Gynecologists (2004) has taken the position that for women with two prior low transverse cesarean deliveries, only those with a prior vaginal delivery should be considered candidates for a spontaneous trial of labor.

Indication for Prior Cesarean Delivery

The success rate for a trial of labor depends to some extent on the indication for the previous cesarean delivery. Generally, 60 to 80 percent of labor trials after prior cesarean birth result in vaginal delivery (American College of Obstetricians and Gynecologists, 2004). In a large series reported by Wing and Paul (1999), 91 percent of women whose first cesarean delivery was for breech presentation subsequently delivered vaginally. If fetal distress was the original indication, the success rate was 84 percent. Importantly, only 38 percent delivered vaginally if the fetus born during a trial of labor birth had a birthweight exceeding the initial pregnancy birthweight by more than 500 g.

Prior dystocia is an important predictor of vaginal delivery after prior cesarean. In more than 1900 women, Peaceman and associates (2006) found that those with dystocia as the original indication had a significantly lower success rate compared with those with other indications—54 versus 67 percent, respectively. Bujold and Gauthier (2001) reported a 75-percent vaginal delivery rate in women whose prior cesarean delivery was for second-stage dystocia.

Fetal Size

It has not been conclusively proven that increasing fetal size increases the risk for uterine rupture with VBAC. Zelop and associates (2001) compared the outcomes of almost 2750 women undergoing a trial of labor of whom 1.1 percent had a uterine rupture. The rate increased—albeit not significantly—with increasing fetal weight—1.0 percent for <4000 g, 1.6 percent for >4000 g, and 2.4 percent for >4250 g. Similarly, Elkousy and colleagues (2003) reported that for women attempting VBAC who had no previous vaginal deliveries, the relative risk of rupture doubled if birthweight was >4000 g. Finally, women who attempt a trial of labor with a preterm fetus have lower rupture rates with successful vaginal delivery rates that are the same or higher as for other conditions discussed (Durnwald and associates, 2006; Quiñones and colleagues, 2005).

Multifetal Gestation

Perhaps surprisingly, twin pregnancy does not appear to increase the risk of uterine rupture with VBAC. Ford and associates (2006) analyzed the outcomes of 1850 such women with a prior cesarean delivery who attempted a trial of labor. The uterine rupture rate was 0.9 percent, and the rate of successful vaginal delivery was 45 percent. Similar studies by Cahill (2005) and Varner (2007) and their colleagues reported rupture rates of 0.7 to 1.1 percent and vaginal delivery rates of 75 to 85 percent.

TABLE 26-4. Timing of Elective Repeat Cesarean Delivery at Term and Neonatal Outcomes

Outcome	Wk 37 (n = 834) (%)	Wk 38 (n = 3909) (%)	Wk 39 (n = 6512) (%)	Wk 40 (n = 1385) (%)	*p* for trend[a]
Any adverse outcome or death	15.3	11.0	8.0	7.3	<0.001
Admission to the NICU	12.8	8.1	5.9	4.8	<0.001
Adverse respiratory outcome					
RDS	3.7	1.9	0.9	0.9	<0.001
RDS or TTN	8.2	5.5	3.4	3.0	<0.001
Ventilation in 1st 24 hr	1.9	0.9	0.4	0.4	<0.001
Newborn sepsis[b]	7.0	4.0	2.5	2.7	<0.001
Proven case	0.4	0.1	0.1	0.1	0.260

Maternal Obesity

Obesity decreases the success of VBAC. Hibbard and colleagues (2006) reported the following vaginal delivery rates: 85 percent with a normal body mass index (BMI), 78 percent with a BMI between 25 and 30, 70 percent with a BMI between 30 and 40, and 61 percent with a BMI of 40 or more. Similar findings were reported by Juhasz and associates (2005).

LABOR AND DELIVERY CONSIDERATIONS

If elective repeat cesarean delivery is planned, it is essential that the fetus be mature. Significant and appreciable adverse neonatal morbidity has been reported with elective delivery prior to 39 completed weeks (Table 26-4) (Clark and colleagues, 2009; Tita and co-workers, 2009). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) have established guidelines shown in Table 26-5 for timing an elective operation. If none of the four is met, then fetal pulmonary maturity should be documented by amnionic fluid analysis before elective repeat cesarean delivery. Techniques for amnionic fluid assessment are outlined by the American College of Obstetricians and Gynecologists (2008) and described in Chapter 29 (p. 606). Alternatively, spontaneous labor is awaited.

Informed Consent

No woman with a prior uterine incision should be forced to undergo a trial of labor. Instead, the risks and benefits of a trial of labor versus a repeat cesarean delivery should be discussed. The ultimate decision to attempt VBAC should be made by the informed woman in conjunction with her physician. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) recommend that the issues listed in Table 26-6 be addressed in arriving at that decision.

Intrapartum Care

The guidelines listed in Table 26-2 are used in the care of women who have chosen a trial of labor. Lavin and co-workers (2002) surveyed all hospitals in Ohio to determine the number that actually

TABLE 26-5. Criteria for Establishment of Fetal Maturity

Fetal maturity may be assumed if one of the following criteria is met:

1. Fetal heart sounds have been documented for 20 weeks by nonelectronic fetoscope or for 30 weeks by Doppler ultrasound.
2. It has been 36 weeks since a positive serum or urine hCG pregnancy test was performed by a reliable laboratory.
3. A sonographic measurement of the crown-rump length, obtained at 6 to 11 weeks, supports a current gestational age of 39 weeks or more.
4. Clinical history and physical and sonographic examination performed at 12 to 20 weeks support current gestational age of 39 weeks or more.

TABLE 26-6. Recommended Counseling Points for Women With a Prior Cesarean Delivery

- Advantages of a successful vaginal delivery, for example, shorter postpartum hospital stay; less painful, more rapid recovery; and others.
- Contraindications to a trial of labor, for example, prior classical cesarean, previous uterine rupture, lack of resources to perform emergency cesarean delivery during labor, and others.
- Relative contraindications, for example, two prior uterine surgeries with no previous vaginal delivery.
- Risk of uterine rupture—generally less than 1 percent.
- Increased risk of uterine rupture with multiple uterine surgeries, uterine tachysystole, attempts at cervical ripening or labor induction with oxytocin.
- Uterine rupture has been associated with fetal death as well as severe neonatal neurological injury and may occur no matter what resources are available to manage it.

From the American College of Obstetricians and Gynecologists and American Academy of Pediatrics (2007), with permission.

had an obstetrician, anesthesia personnel, and a surgical team immediately available—present in the hospital—when a woman attempted a VBAC. A complete complement was available in 15 percent of Level I, 63 percent of Level II, and 100 percent of Level III institutions. Because VBAC attempts were equally distributed among the institutions, it is obvious that many women are undergoing a trial of labor under less than optimal conditions.

Similar concerns were raised by Bucklin and associates (2005) after their 2001 obstetrical anesthesia workforce survey. They reported that hospital by-laws require an anesthesiologist to be in-hospital for women attempting a VBAC without epidural analgesia in 86 percent of hospitals that have at least 1500 annual deliveries, 45 percent of hospitals with 500 to 1499 deliveries, and 33 percent of those with 100 to 500 deliveries.

Cervical Ripening and Labor Stimulation

Most evidence suggests that any attempt to stimulate cervical ripening or to induce or augment labor increases the uterine rupture risk in women undergoing a trial of labor.

Oxytocin

Induction or augmentation of labor with oxytocin has been implicated in increased rates of uterine rupture in women attempting VBAC. In the MFMU Network study reported by Landon and colleagues (2004), uterine rupture was more frequent in those women induced with oxytocin alone—1.1 percent—compared with those in spontaneous labor—0.4 percent. Among women in this trial who had never had a prior vaginal delivery, the uterine rupture risk associated with an oxytocin induction was 1.8 percent—a fourfold increased risk compared with spontaneous labor (Grobman and co-workers, 2007a). These observations are similar to those of Zelop and associates (1999), who reported a 2.3-percent uterine rupture rate with labor induction compared with 1 percent of women whose labor was augmented or 0.4 percent with spontaneous labor.

Cahill and colleagues (2008) found that as the infusion dose of oxytocin increased, so did the risk of uterine rupture. At their maximum infusion dose of 21 to 30 mU/min, the risk of uterine rupture was fourfold greater than that in women not given oxytocin. Goetzl and associates (2001) described similar findings. They concluded that differences in the dose or patterns of oxytocin use associated with uterine rupture were not substantive enough to develop safer induction protocols.

Experiences at Parkland Hospital. Our experiences with uterine ruptures led us to discontinue oxytocin use for labor induction or augmentation in women with a prior cesarean delivery. Specifically, between 1986 and 1990, a trial of labor was undertaken by 2044 of 7049 women—29 percent—with a prior cesarean. Of these, 1482 or 73 percent delivered vaginally. In women who labored spontaneously, uterine rupture with part of the fetus extruded outside of the uterus was identified in three women—a rate of 1.5 per 1000. But in another 307 women who were given oxytocin during their trial of labor, there were three uterine ruptures—a significantly increased rate of 10 per 1000. Because of this sixfold increase with oxytocin use, we adopted the conservative approach.

Prostaglandins

A number of prostaglandin preparations that are commonly employed for cervical ripening or labor induction are discussed in Chapter 22 (p. 502). Their use in women with a prior cesarean delivery is less clear. The studies that have been published, however, urge caution with prostaglandin use in these women.

Wing and colleagues (1998) described a comparative study of prostaglandin E_1—*misoprostol*—versus oxytocin for labor induction in women with a prior cesarean delivery. They terminated their trial after two of the first 17 women assigned to misoprostol developed a uterine rupture. There are several studies that evaluated other prostaglandins for labor induction. In general, they also demonstrated an increased risk of uterine rupture, albeit with variable rates. Ravasia and colleagues (2000) compared uterine rupture in 172 women given prostaglandin E_2 gel with 1544 women in spontaneous labor. The rate of rupture was significantly greater in women treated with prostaglandin E_2 gel—2.9 percent—compared with 0.9 percent in those with spontaneous labor. Lydon-Rochelle and associates (2001) performed a retrospective population-based study. They found that induction of labor with prostaglandins for VBAC increased the uterine rupture risk more than 15-fold compared with elective repeat cesarean delivery. Based in large part on the results of this latter study, the American College of Obstetricians and Gynecologists (2002, 2004) discouraged the use of prostaglandin analogs for cervical ripening or labor induction in women attempting a VBAC.

It is important to note, however, that subsequent studies repeated over the intervening years have been less ominous. For example, in the MFMU Network study cited previously, Landon and colleagues (2004) reported a uterine rupture rate of 1.4 percent when any prostaglandin was used in combination with oxytocin.

But in the subgroup of 227 women in whom labor was induced with a prostaglandin only, there were no ruptures. Macones and co-workers (2005b) reported similar findings. They found that intravaginal prostaglandins alone, *excluding misoprostol*, were not associated with an increased risk of uterine rupture. Importantly, they found that sequential use of a prostaglandin followed by oxytocin was associated with a threefold-increased risk of rupture compared with spontaneous labor. Kayani and Alfirevic (2005) reported two ruptures in 52 women with such sequential use.

In an interesting report, Buhimschi and colleagues (2005) found that women given prostaglandins were more likely to rupture at the site of their old scar. In contrast, women given oxytocin were more likely to rupture at a site *remote* from the old scar. They hypothesized that prostaglandins might induce biochemical modifications in the lower uterine segment scar that predispose it to rupture during labor.

After again reviewing contemporaneous reports, the American College of Obstetricians and Gynecologists (2006) concluded that labor induction in women who attempt a VBAC is a reasonable option. The College advises that potentially increased risk of uterine rupture associated with any induction should be discussed with the woman and documented. Finally, selection of women most likely to have a successful VBAC, as well as avoiding misoprostol and sequential use of prostaglandins and oxytocin, appear to offer the lowest risk of uterine rupture.

Epidural Analgesia

Concerns that epidural analgesia for labor might mask the pain of uterine rupture have not been verified (Farmer and colleagues, 1991; Flamm and associates, 1994). Less than 10 percent of women with scar separation experience pain and bleeding, and fetal heart rate decelerations are the most likely sign of rupture (Flamm and associates, 1990; Kieser and Baskett, 2002). Successful VBAC rates are similar, and in some cases higher, among women with labor epidural analgesia compared with those using other forms of analgesia (Landon and co-workers, 2005; Stovall and colleagues, 1987). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) have concluded that epidural analgesia may safely be used during a trial of labor. Importantly, they also recommend that the anesthesia service be available whenever a woman with a prior cesarean delivery is admitted in active labor.

Uterine Scar Exploration

Most clinicians routinely document the integrity of a prior scar by palpation following successful vaginal delivery. Alternatively, uterine exploration is considered by others to be unnecessary. Currently, the benefits of scar evaluation in the asymptomatic women are unclear. There is general agreement, however, that surgical correction of a scar dehiscence is necessary only if significant bleeding is encountered. Asymptomatic separations do not generally require exploratory laparotomy and repair. Our practice is to routinely examine these prior incision sites. Any decision for laparotomy and repair takes into consideration the extent of the tear as well as whether the peritoneal cavity is entered.

External Cephalic Version

Limited data suggest that external cephalic version for breech presentation may be as successful in women with a prior cesarean delivery who are contemplating a trial of labor (American College of Obstetricians and Gynecologists, 2004). This procedure is addressed in Chapter 24 (p. 539).

UTERINE RUPTURE

Classification

Uterine rupture typically is classified as either: (1) *complete* when all layers of the uterine wall are separated, or (2) *incomplete* when the uterine muscle is separated but the visceral peritoneum is intact. Incomplete rupture is also commonly referred to as *uterine dehiscence*. As expected, morbidity and mortality rates are appreciably greater when rupture is complete. The greatest risk factor for either form of rupture is prior cesarean delivery (see Fig. 26-3). In a review of all cases of uterine rupture in Nova Scotia between 1988 and 1997, Kieser and Baskett (2002) reported that 92 percent were in women with a prior cesarean birth. Other causes of uterine rupture are discussed in Chapter 35 (see p. 784).

Diagnosis

Prior to developing hypovolemic shock, symptoms and physical findings in women with uterine rupture may appear bizarre unless the possibility is kept in mind. For example, hemoperitoneum from a ruptured uterus may result in diaphragmatic irritation with pain referred to the chest—directing one to a diagnosis of pulmonary or amnionic fluid embolism instead of uterine rupture. The most common sign of uterine rupture is a nonreassuring fetal heart rate pattern with variable heart rate decelerations that may evolve into late decelerations, bradycardia, and death (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2007). Contrary to older teachings, few women experience cessation of contractions following uterine rupture, and the use of intrauterine pressure catheters has not been shown to assist reliably in the diagnosis (Rodriguez and associates, 1989).

In some women, the appearance of uterine rupture is identical to that of placental abruption. In most, however, there is remarkably little appreciable pain or tenderness. Also, because most women in labor are treated for discomfort with either narcotics or epidural analgesia, pain and tenderness may not be readily apparent. The condition usually becomes evident because of signs of fetal distress and occasionally because of maternal hypovolemia from concealed hemorrhage.

If the fetal presenting part has entered the pelvis with labor, loss of station may be detected by pelvic examination. If the fetus is partly or totally extruded from the site of uterine rupture, abdominal palpation or vaginal examination may be helpful to identify the presenting part, which will have moved away from the pelvic inlet. A firm contracted uterus may at times be felt alongside the fetus.

Prognosis

With rupture and expulsion of the fetus into the peritoneal cavity, the chances for intact fetal survival are dismal, and reported

mortality rates range from 50 to 75 percent. Fetal condition depends on the degree to which the placental implantation remains intact, although this can change within minutes. With rupture, the only chance of fetal survival is afforded by immediate delivery, most often by laparotomy. Otherwise, hypoxia from both placental separation and maternal hypovolemia is inevitable. If rupture is followed by immediate total placental separation, then very few intact fetuses will be salvaged. For example, in the August 2008 issue of *acog Today*, the emergency team at Sharp Mary Birch Hospital for Women is described. After training, the "decision-to-incision" time was decreased to 14 ± 5.6 minutes. Thus, even in the best of circumstances, fetal salvage will be impaired.

In a study using the Swedish Birth Registry, Kaczmarczyk and colleagues (2007) found that the risk of neonatal death following uterine rupture was 5 percent—a 60-fold increase in the risk compared with pregnancies not complicated by uterine rupture. In the MFMU Network study, 7 of the 114 uterine ruptures—6 percent—associated with a trial of labor were complicated by the development of hypoxic ischemic encephalopathy (Spong and associates, 2007).

Maternal deaths from rupture are uncommon. For example, of 2.5 million women who gave birth in Canada between 1991 and 2001, there were 1898 cases of uterine rupture, and four of these—0.2 percent—resulted in maternal death (Wen and associates, 2005). In other regions of the world, however, maternal mortality rates associated with uterine rupture are much higher. In a report from rural India, for example, the maternal mortality rate associated with uterine rupture was 30 percent (Chatterjee and Bhaduri, 2007).

Hysterectomy versus Repair

With complete rupture during a trial of labor, hysterectomy may be required. In the reports by McMahon (1996) and Miller (1997) and their colleagues, 10 to 20 percent of such women required hysterectomy for hemostasis. In selected cases, however, suture repair with uterine preservation may be performed. Sheth (1968) described outcomes from a series of 66 women in whom repair of a uterine rupture was elected rather than hysterectomy. In 25 instances, the repair was accompanied by tubal sterilization. Thirteen of the 41 mothers who did not have tubal sterilization had a total of 21 subsequent pregnancies, and uterine rupture recurred in four of these—approximately 25 percent. More recently, Usta and associates (2007) identified 37 women with a prior complete uterine rupture delivered over a 25-year period in Lebanon. Hysterectomy was performed in 11, and in the remaining 26 women, the rupture was repaired. Twelve of these women had 24 subsequent pregnancies, of which one third were complicated by recurrent uterine rupture. Hysterectomy is described in Chapter 25 (see p. 556), and management of obstetrical hemorrhage is detailed in Chapter 35 (p. 791).

COMPLICATIONS WITH MULTIPLE REPEAT CESAREAN DELIVERIES

Because of the concerns with attempting a trial of labor—even in the woman with excellent criteria that forecast successful VBAC—most women in the United States chose elective repeat cesarean delivery (see Fig. 26-1). This choice is not without a number of significant maternal complications that increase in women who have multiple repeat operations. The incidences of some common complications for women with one prior transverse cesarean delivery who undergo an elective repeat cesarean delivery were shown in Table 26-1.

The MFMU Network addressed issues of increased morbidity in a cohort of 30,132 women who had from one to six repeat cesarean deliveries (Silver and associates, 2006). This report addressed a list of morbidities, most of which increased as a trend with increasing number of repeat operations. The rates of some of the more common or serious complications are depicted in **Figure 26-4**. In addition to ones shown, injuries to the bowel or bladder, admissions to an intensive care unit or ventilator therapy, operative time and hospitalization, and maternal mortality showed significantly increasing trends. Similar results have been reported by Nisenblat (2006) and Usta (2005) and their colleagues.

One particular complication that is especially worrisome is the significantly increased risks for placenta previa with growth into the prior cesarean delivery scar. In some cases a percreta may invade the bladder or other adjacent structures. Difficult resection carries an inordinately high risk of hysterectomy, massive hemorrhage with transfusions, and maternal mortality. Management is described in detail in Chapter 35 (p. 776).

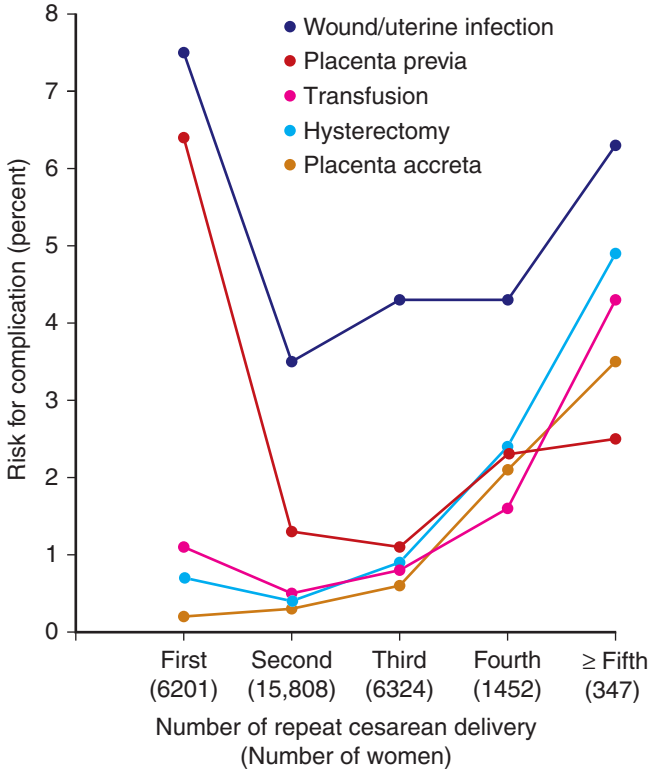

FIGURE 26-4 Maternal-Fetal Medicine Units Network: Rates of some complications with increasing number of repeat cesarean deliveries. (Data from Silver and colleagues, 2006.)

STATE OF VBAC IN 2009

In the United States, VBAC rates have ebbed and flowed from virtually none, to a significant increase, and then to a current decreasing trend. Reasons for this pendulum swing are multifaceted. The most prominent driving force in the repeat cesarean delivery rate is the slow but steady increase in the primary cesarean delivery rate shown in Figure 26-1. Also shown is the effect that decreasing VBAC rates have on the total cesarean delivery rate. The risks versus benefits, along with the pros and cons of a woman electing a trial of labor for VBAC versus elective repeat cesarean delivery, can be complex. The "best answer" for a given woman with a prior cesarean delivery is unknown. Thus, she and her partner are encouraged to actively participate with her healthcare provider in the final decision after appropriate counseling. To minimize some of the confusion in arriving at the decision, the National Institutes of Health is planning a Consensus Development Conference to elucidate the current knowledge on VBAC and its various scenarios. At this time, these deliberations are scheduled to be presented in the spring of 2010.

CHAPTER 27

Abnormalities of the Placenta, Umbilical Cord, and Membranes

ABNORMALITIES OF THE PLACENTA 577
ABNORMALITIES OF THE MEMBRANES 581
ABNORMALITIES OF THE UMBILICAL CORD 581
PATHOLOGICAL EXAMINATION 584

With basic knowledge of placental implantation, development, and anatomy presented in Chapter 3, clinicians can more easily understand the genesis of abnormal placental types. Much of the ever-growing knowledge of placental pathology was stimulated by a nucleus of placental pathologists that includes, among others, Benirschke, Driscoll, Fox, Naeye, Salafia, and Faye-Petersen. For a detailed account of these disorders, the reader is referred to the 5th edition of *Pathology of the Human Placenta* by Benirschke and colleagues (2006) and the 2nd edition of the *Handbook of Placental Pathology* by Faye-Petersen and associates (2006).

ABNORMALITIES OF THE PLACENTA

Abnormal Shape or Implantation

Most placentas are either round or oval, but variations are common. As discussed in this chapter, many of these have clinical importance.

Multiple Placentas with a Single Fetus

Uncommonly, the placenta forms as separate, near equally sized disks. The cord inserts between the two placental lobes—either into a connecting chorionic bridge or into intervening membranes. This condition is termed *bilobate placenta,* but is also known as *bipartite placenta* or *placenta duplex* (Fig. 27-1). Fox and Sebire (2007) reported its incidence to be approximately 1 in 350 deliveries. A placenta containing three or more lobes is rare and termed *multilobate*.

Succenturiate Lobe

These placentas are a smaller version of the bilobate placenta. One or more small accessory lobes develop in the membranes at a distance from the main placenta, to which they usually have vascular connections of fetal origin. Although its incidence has been cited by Benirschke and associates (2006) to be as high as 5 percent, we have encountered these much less frequently. Suzuki and co-workers (2009) noted a twofold higher incidence of succenturiate lobes in twin placentas. The accessory lobe may sometimes be retained in the uterus after delivery and may cause serious hemorrhage. In some cases, an accompanying vasa previa may cause dangerous fetal hemorrhage at delivery.

Placenta Membranacea

Rarely, all or a large part of the fetal membranes are covered by functioning villi. Placenta membranacea may occasionally give rise to serious hemorrhage because of associated placenta previa or accreta (Greenberg and colleagues, 1991).

Ring-Shaped Placenta

In fewer than 1 in 6000 deliveries, the placenta is annular in shape, and sometimes a complete ring of placental tissue is present. This development may be a variant of placenta membranacea. Because of tissue atrophy in a portion of the ring, a horseshoe shape is more common. These abnormalities appear to be associated with a greater likelihood of antepartum and postpartum bleeding and fetal-growth restriction (Faye-Petersen and colleagues, 2006).

Placenta Fenestrata

In this rare anomaly, the central portion of a discoidal placenta is missing. In some instances, there is an actual hole in the placenta, but more often, the defect involves only villous tissue,

FIGURE 27-1 Bilobate placenta with marginal insertion of the umbilical cord. There also is partial velamentous insertion of the cord with the fetal vessels traversing the membranes to reach the smaller lobe on the right.

and the chorionic plate remains intact. Clinically, it may erroneously prompt a search for a retained placental lobule.

Extrachorial Placentation

When the chorionic plate, which is on the fetal side of the placenta, is smaller than the placental basal plate, which is located on the maternal side, the periphery is uncovered, and the term *extrachorial placenta* is used (**Fig. 27-2**). If the fetal surface of such a placenta presents a central depression surrounded by a thickened, gray-white ring, it is called a *circumvallate placenta.* The ring is composed of a double fold of chorion and amnion, with degenerated decidua and fibrin in between. Within the ring, the fetal surface presents the usual appearance, except that the large vessels terminate abruptly at the ring edge. When the ring does not have the central depression, the placenta is described as *circummarginate* (see Fig. 27-2).

With circumvallate placentas, there is an increased risk of antepartum hemorrhage—from both placental abruption and fetal hemorrhage—as well as of preterm delivery, perinatal mortality, and congenital malformations (Lademacher and co-workers, 1981; Suzuki, 2008). Adverse clinical outcomes with circummarginate placentas are less well defined.

Placenta Accreta, Increta, and Percreta

These abnormalities are serious variations in which trophoblastic tissues invade the myometrium to varying depths. They are much more likely with placenta previa or with implantation over a prior uterine incision or perforation. Torrential hemorrhage is a frequent complication (see Chap. 35, p. 776).

Circulatory Disturbances

Conceptually, placental perfusion disorders may be grouped into: (1) those that disrupted maternal blood flow to or within the placenta and (2) those that disturb fetal blood flow through

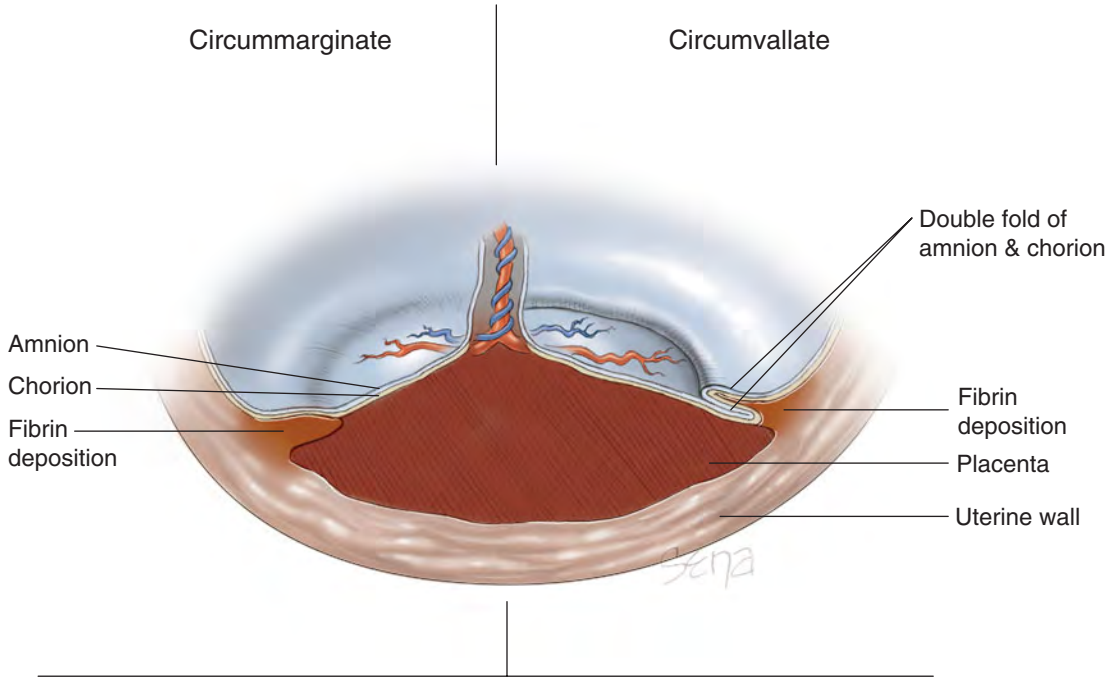

FIGURE 27-2 Circumvallate *(right)* and circummarginate *(left)* varieties of extrachorial placentas. With circumvallate placenta, the double fold of amnion and chorion creates the broad white ring seen on the fetal surface of these placentas. Circummarginate placentas lack this double fold and white ring.

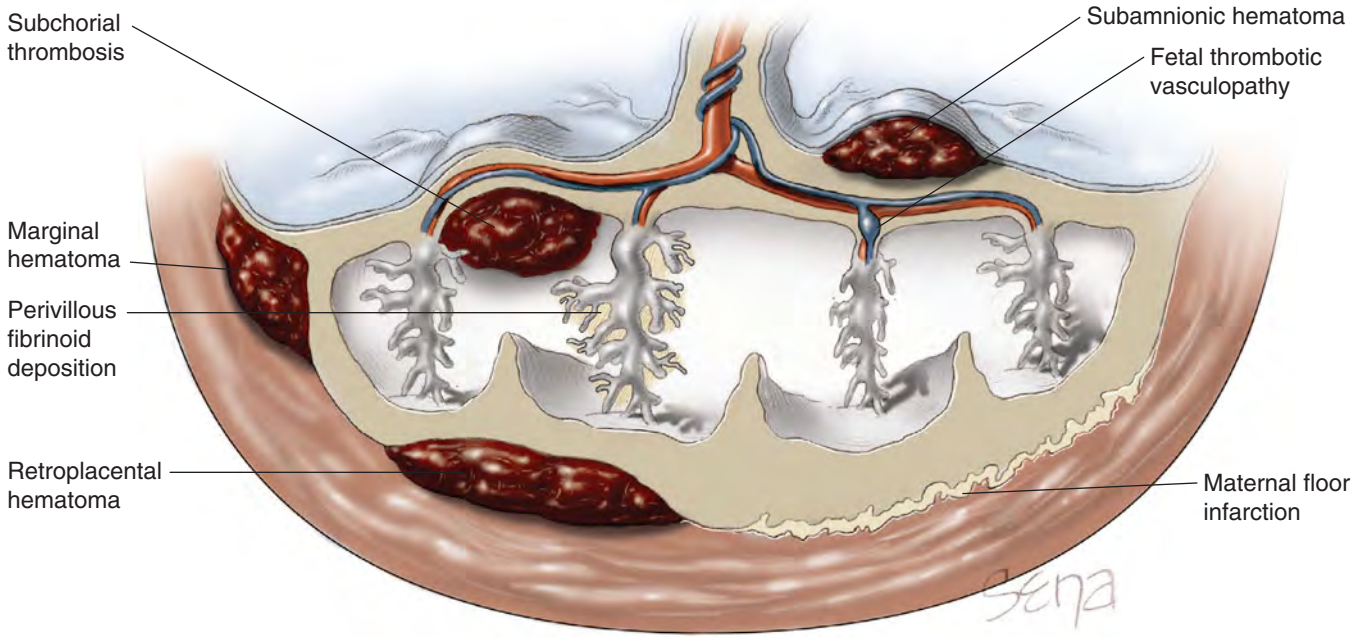

FIGURE 27-3 Potential sites of placental circulatory disturbances. (Adapted from Faye-Peterson and colleagues, 2006.)

the villi. Many of these lesions are common and are found in normal mature placentas. Although they limit maximal placental blood flow, the placenta's functional reserve is great. Some estimate that the placenta can lose up to 30 percent of its villi without untoward fetal effect (Fox and Sebire, 2007). If lesions are extensive, however, they have the potential to profoundly limit fetal growth.

Maternal Blood Flow Disruption

A number of lesions can restrict or abate intervillous blood flow.

Maternal Floor Infarction. Erroneously termed *infarction*, this condition deposits a dense fibrinoid layer on the placental basal plate (**Fig. 27-3**). This thick, white, firm, corrugated surface acts as a blockade to normal maternal blood flow. These infarctions are associated with fetal growth restriction, abortion, preterm delivery, and stillbirths (Andres and coworkers, 1990; Mandsager and colleagues, 1994). It occasionally recurs in subsequent pregnancies. Their etiopathogenesis is not well defined, although it may be associated with maternal thrombophilia (Gogia and Machin, 2008; Katz and associates, 2002; Sebire and colleagues, 2002, 2003). These lesions are considered in further detail in Chapter 47 p. 1014).

Perivillous Fibrinoid Deposition. These small yellow-white nodules within the placenta are considered a normal part of placental aging. They form when normal maternal blood flow currents around an individual villus are slowed, which leads to blood stasis and fibrin deposition. This layer of fibrin diminishes oxygenation to the villus and results in syncytiotrophoblast necrosis (Faye-Petersen and colleagues, 2006). When extreme, this lesion can cause fetal growth restriction or fetal demise.

Hematoma. Placental hematomas are described in a number of ways depicted in Figure 27-3. These include: (1) *retroplacental hematoma*—between the placenta and its adjacent decidua; (2) *marginal hematoma*—between the chorion and decidua and also clinically called subchorionic hemorrhage; (3) *subchorial thrombosis*, also known as *Breus mole*—along the roof of the intervillous space and beneath the chorionic plate; and (4) *subamnionic hematoma*—between the placenta and amnion.

Large retroplacental, marginal, and subchorial collections have been associated with higher rates of miscarriage, abruption, fetal-growth restriction, preterm delivery, and adherent placenta (Ball, 1996; Madu, 2006; Nagy, 2003; Nyberg, 1987, and all their colleagues). Subamnionic hematomas are of fetal vessel origin and discussed later.

Infarction. Chorionic villi receive oxygen solely from maternal circulation through the uteroplacental vessels, which jet blood into the intervillous space. Uteroplacental diseases that diminish or obstruct this connection can lead to villous infarction. Although these are common lesions in mature placentas, if they are numerous, placental insufficiency may develop. When they are thick, centrally located, and randomly distributed, they may be associated with preeclampsia or lupus anticoagulant.

Fetal Blood Flow Disruption

There are a number of lesions that may restrict fetoplacental blood flow.

Fetal Thrombotic Vasculopathy. Fetal blood flows from the two umbilical arteries into the placenta. These arteries divide and send branches out across the placental surface. Eventually, these supply individual stem villi, which may thrombose and

obstruct fetal blood flow (see Fig. 27-3). Distal to the point of obstruction, affected portions of the villus are rendered nonfunctional. Thrombi are normally found in mature placentas but may become clinically significant if a large portion of villi is lost.

Hematoma. As indicated, subamnionic hematomas lie between the placenta and amnion (see Fig. 27-3). These hematomas most often are acute events during third-stage labor when cord traction ruptures a vessel near the cord insertion. With chronic lesions, fetomaternal hemorrhage or fetal-growth restriction have been reported (Deans and Jauniaux, 1998). In addition, these may be confused with other potentially dangerous placental masses such as chorioangioma, which is discussed subsequently (Sepulveda, 2000; Van Den Bosch, 2000; Volpe, 2008, and all their associates).

Placental Calcification

Calcium salts may be deposited throughout the placenta, but are most common on maternal surface in the basal plate. Calcification is associated with nulliparity, higher socioeconomic status, and greater maternal serum calcium levels (Fox and Sebire, 2007). Calcifications can be seen with sonography, however, criteria to grade its degree have not been found useful to predict neonatal outcome (Hill, 1983; McKenna, 2005; Montan, 1986; Sau, 2004 and all their colleagues).

Hypertrophic Villous Lesions

Striking enlargement of the chorionic villi is commonly seen in association with severe erythroblastosis and fetal hydrops. It also has been described in maternal diabetes, fetal congestive heart failure, and maternal-fetal syphilis (Sheffield and colleagues, 2002). Many of these conditions are discussed in Chapter 29.

Placental Tumors

Gestational Trophoblastic Disease

These pregnancy-related trophoblastic proliferative abnormalities are discussed in Chapter 11.

Chorioangioma

Because of the resemblance of their components to the blood vessels and stroma of the chorionic villus, the term *chorioangioma—or chorangioma*—is considered the most appropriate designation. These are the only benign tumors of the placenta and have an incidence of approximately 1 percent (Guschmann and associates, 2003).

Levels of maternal serum alpha-fetoprotein (MSAFP) may be elevated with these and may prompt sonographic evaluation (see Chap. 13, p. 290). A well-circumscribed, rounded, predominantly hypoechoic lesion near the chorionic surface and protruding into the amnionic cavity is a common characteristic (Fig. 27-4). Documenting increased blood flow by color Doppler can assist in distinguishing these lesions from other placental masses (Prapas, 2000).

Small growths are usually asymptomatic. Large tumors, typically those measuring greater than 5 cm, however, may be associated with significant arteriovenous shunting within the placenta, leading to fetal anemia and hydrops (see Chap. 29, p. 626). Antepartum hemorrhage, preterm delivery, amnionic fluid abnormalities, and fetal growth restriction may also complicate large tumors (Sepulveda and associates, 2003a; Zalel and co-workers, 2002). Because of severe fetal sequelae with large tumors, treatment may include an attempt to reduce blood flow to the tumor by means of vessel occlusion or ablation (Lau, 2003; Nicolini, 1999; Quintero, 1996; Sepulveda, 2009, and all their colleagues).

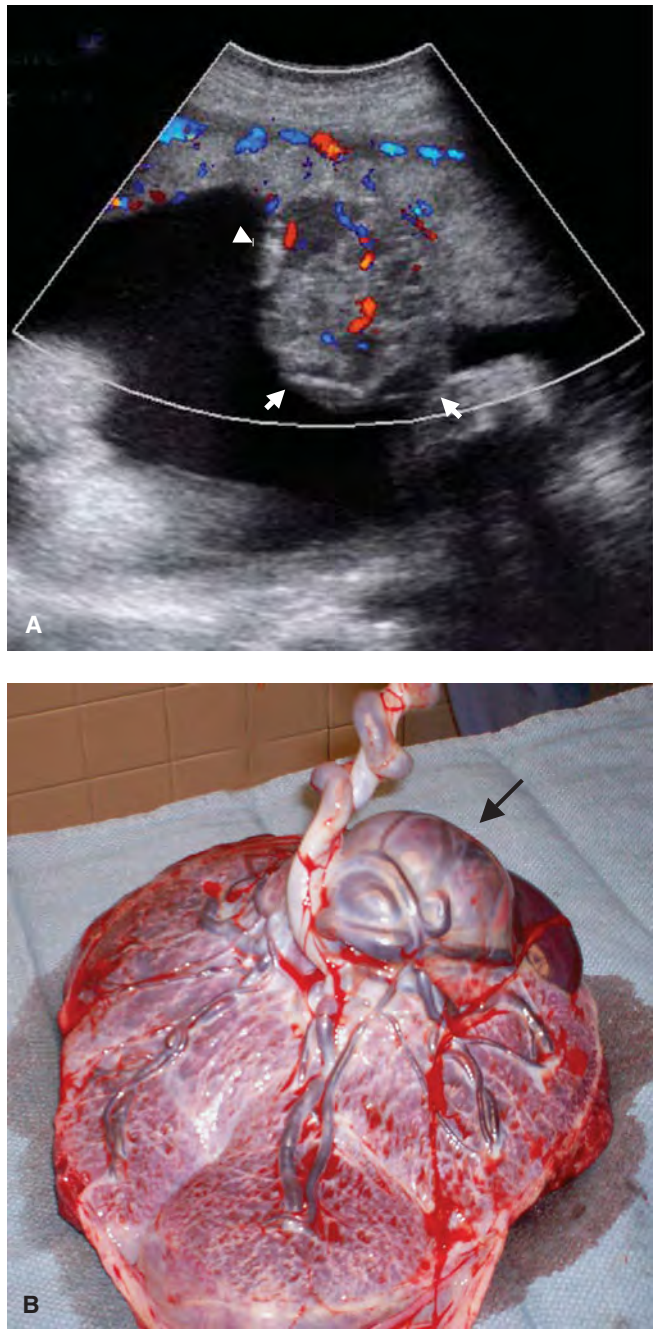

FIGURE 27-4 Placental chorioangioma. **A.** Color Doppler imaging displays blood flow through a large chorioangioma. The tumor border is outlined by white arrows. **B.** After delivery, the chorioangioma is seen as a round, well-circumcised mass (*black arrow*) protruding from the fetal surface.

Tumors Metastatic to the Placenta

Malignant tumors rarely metastasize to the placenta. Of those that do, melanomas, leukemias and lymphomas, and breast cancer are the most common (Al-Adnani and co-workers, 2007). Tumor cells usually are confined within the intervillous space. As a result, metastasis to the fetus is uncommon, but is most often seen with melanoma (Alexander and colleagues, 2003; Altman and associates, 2003).

ABNORMALITIES OF THE MEMBRANES

Meconium Staining

The presence of meconium in amniotic fluid is relatively common, and incidences range from 12 to 20 percent (Ghidini and Spong, 2001; Oyelese and co-workers, 2006; Tran and associates, 2004). Staining of the amnion can be obvious within 1 to 3 hours after meconium passage (Miller and colleagues, 1985). More-prolonged exposure results in staining of the chorion, umbilical cord, and decidua. According to Benirschke and colleagues (2006), meconium passage cannot be timed or dated accurately.

Meconium may be passed in a variety of clinical settings. First, in most fetuses, meconium passage is prevented by tonic anal sphincter contraction and by lack of intestinal peristalsis. Thus, preterm fetuses, with immature gastrointestinal mechanisms, infrequently pass meconium. In contrast, for postterm fetuses, whose intestinal tracts are mature, meconium passage may be normal, and stained fluid is seen in approximately 30 percent of these deliveries (Katz and Bowes, 1992; Tybulewicz and co-workers, 2004; Walsh and Fanaroff, 2007). Secondly, vagal stimulation produced by cord or head compression may be associated with meconium passage in the absence of fetal distress. Lastly, meconium passage is also associated with fetal acidosis, nonreassuring fetal heart rate patterns, and low Apgar scores (Krebs and co-workers, 1980; Nathan and colleagues, 1994). In these cases, theories suggest that fetal hypoxia produces relaxation of the anal sphincter and gasping of the fetus with subsequent in utero aspiration of meconium. If aspirated by the fetus before or during birth, meconium can obstruct the airways, leading to severe hypoxia, inflammation, and infection—*meconium aspiration syndrome.*

Neonatal effects of meconium aspiration syndrome are found in Chapter 29 (p. 628). One serious maternal risk is that meconium-laden amniotic fluid embolism greatly increases maternal mortality rates from cardiorespiratory failure and consumptive coagulopathy (see Chap. 35, p. 788). In addition, the risk of puerperal metritis with meconium-stained amniotic fluid is increased two- to fourfold (Jazayeri and colleagues, 2002; Tran and co-workers, 2004).

Chorioamnionitis

A variety of organisms may infect the membranes, umbilical cord, and eventually the fetus. Routes of infection include ascending infection from the lower genital tract, hematogenous spread from maternal blood, direct spread from the endometrium or fallopian tube, and iatrogenic contamination during invasive procedures (see Fig. 36-10, p. 813). Of these, ascending infection is most common and frequently is associated with prolonged membrane rupture and long labor.

In general, vaginal bacteria are excluded from the upper reproductive tract by a closed internal cervical os and intracervical mucus plug. Entry of organisms can create initial infection of the chorion and adjacent decidua in the area overlying the internal os. Subsequently, progression leads to full-thickness involvement of the membranes—*chorioamnionitis.* Organisms may then spread along the chorioamnionic surface and infect the amniotic fluid. There can be subsequent inflammation of the chorionic plate and of the umbilical cord—*funisitis* (Al-Adnani and Sebire, 2007; Goldenberg and co-workers, 2000; Redline, 2006). Fetal infection may result from hematogenous routes, aspiration, swallowing, or other direct contact with infected amniotic fluid and is discussed in Chapter 36 (p. 812).

Grossly, infection is characterized by clouding of the membranes. There also may be a foul odor, depending on bacterial species and concentration. Occult chorioamnionitis, caused by a wide variety of microorganisms, frequently is cited as a possible explanation for many otherwise unexplained cases of ruptured membranes, preterm labor, or both (see Chap. 6, p. 163).

Other Abnormalities

Amnion nodosum is a placental lesion consisting of numerous small, light-tan nodules on the amnion that overlies the placenta. It is considered a hallmark of prolonged and severe oligohydramnios (Adeniran and Stanek, 2007). *Amnionic bands* are caused when disruption of the amnion leads to formation of bands or strings that entrap the fetus and impair growth and development of the involved structure (see Chap. 29, p. 637).

ABNORMALITIES OF THE UMBILICAL CORD

The cord develops in close association with the amnion, as described in Chapter 3 (p. 61). It serves a vital function, but it unfortunately is susceptible to entanglement, compression, and occlusion.

Cord Measurements

Length

Most cords are 50 to 60 cm long, and very few are abnormally short or long. Short cords may be associated with adverse perinatal outcomes such as fetal-growth restriction, congenital malformations, intrapartum distress, and a twofold risk of death (Berg and Rayburn, 1995; Krakowiak and associates, 2004). Excessively long cords are more likely to be associated with cord prolapse or entanglement and with fetal anomalies, distress, and demise.

Cord length is influenced positively by both the volume of amniotic fluid and fetal mobility. Miller and associates (1981) identified higher rates of appreciably shortened cords if there was chronic fetal constraint from oligohydramnios or decreased fetal movement, such as that seen with Down syndrome or limb dysfunction.

Diameter

Antenatal determination of cord length has technical limitations. For this reason, investigators have evaluated cord diameter as a predictive fetal marker. Although lean umbilical cords have been associated with poor fetal growth and large-diameter cords with macrosomia, the clinical utility of this parameter is still unclear (Barbieri, 2008; Cromi, 2007; Raio 1999b, 2003, and all their colleagues).

Cord Coiling

In most cases, the umbilical vessels spiral through the cord, and a predictable number of coils per unit length can be determined. This *umbilical coiling index (UCI)* is defined as the number of complete coils divided by the length of the cord in centimeters (Strong and colleagues, 1994). Antenatally, coiling can be determined sonographically, although with lower sensitivity than measurement postpartum (Predanic and associates, 2005a). Clinically, hypocoiling has been linked with fetal demise, whereas hypercoiling is related to fetal-growth restriction and intrapartum fetal acidosis and asphyxia. Both have been linked to trisomies and single umbilical artery (de Laat and co-workers, 2005, 2006, 2007; Predanic and colleagues, 2005c).

Vessel Number

Single Umbilical Artery

In a review of nearly 350,000 deliveries, Heifetz (1984) found an incidence of a single artery to be 0.63 percent in liveborns, 1.92 percent in perinatal deaths, and 3 percent in twins. The incidence is increased considerably in women with diabetes, epilepsy, preeclampsia, antepartum hemorrhage, oligohydramnios or hydramnios, and chromosomal abnormalities (Byrne and Blanc, 1985; Leung and Robson, 1989). Although several theories exist, secondary atrophy of a previously normal umbilical artery is most commonly accepted as the etiology.

In many cases, a single umbilical artery is detected by routine sonographic screening. Hill and co-workers (2001) reported that the number of cord vessels could be quantified sonographically in almost 98 percent of cases studied between 17 and 36 weeks.

For most fetuses, a two-vessel cord is an isolated finding and not associated with other anomalies. But up to a third of all infants with only one umbilical artery have associated anomalies (Gornall, 2003; Pierce, 2001; Prucka, 2004, and all their colleagues) Perinatal prognosis is better if a two-vessel umbilical cord is an *isolated sonographic finding*. Moreover, many investigators have found no increased risk of aneuploidy if no other structural abnormalities accompany a two-vessel cord (Budorick and co-workers 2001; Lubusky and associates, 2007). Conversely, Catanzarite (1995) described 46 fetuses with this isolated sonographic finding, and two had lethal chromosomal abnormalities and a third had a tracheoesophageal fistula. Data from studies evaluating the risk of growth restriction in otherwise normal fetuses with a single umbilical artery are contradictory (Goldkrand, 2001; Predanic, 2005b; Wiegand, 2008, and all their colleagues).

If a two-vessel cord is a *nonisolated finding,* the risk of aneuploidy is increased (Granese and associates, 2007). There are a number of associated anomalies, and Martinez-Frias (2008) reported associated increased frequency of renal agenesis, imperforate anus, and vertebral defects.

Hyrtl Anastomosis. This connection between the two umbilical arteries is found within approximately 3 cm of the placental insertion of the cord. Found in most placentas, this anastomosis acts as a pressure-equalizing system between umbilical arteries (Gordon and associates, 2007). As a result, redistribution of pressure gradients and blood flow improves placental perfusion, especially during uterine contractions or during compression of one umbilical artery. Fetuses with a single umbilical artery, lack this safety valve. This may partially explain the increased rate of otherwise unexplained fetal demise in late pregnancy or during labor in these fetuses (Raio and co-workers, 1999a, 2001).

Four-Vessel Cord

Careful inspection may disclose a venous remnant. These are uncommon, and their association with an increased risk of congenital anomalies is unclear (Meyer and colleagues, 1969; Jeanty, 1990).

Fused Umbilical Artery

During embryological development, the umbilical artery rarely may fail to split, and as a result, creates a fused shared lumen. This may extend through the entire cord, but if partial, it is typically found toward the cord's placental insertion (Yamada and colleagues, 2005). Fujikura (2003) noted higher rates of marginal or velamentous cord insertion, but not congenital fetal anomalies.

Cord Insertion

Marginal Insertion

The cord usually is inserted at or near the center of the fetal surface of the placenta. Cord insertion at the placental margin is sometimes referred to as a *Battledore placenta* (Fig. 27-5). It is

FIGURE 27-5 Battledore placenta—there is marginal insertion of the cord.

found in about 7 percent of term placentas (Benirschke and associates, 2006). With the exception of the cord being pulled off during delivery of the placenta, it is of little clinical significance (Liu and co-workers, 2002).

Furcate Insertion

In this uncommon anomaly, the insertion site is normal, but umbilical vessels lose their protective Wharton jelly shortly before insertion. As a result, they are covered only by amnion and prone to compression, twisting, and thrombosis.

Velamentous Insertion

This type of insertion is of considerable clinical importance. The umbilical vessels spread within the membranes at a distance from the placental margin, which they reach surrounded only by a fold of amnion (Fig. 27-6). As a result, vessels are vulnerable to compression, which may lead to fetal anoxia. Although their incidence is approximately 1 percent, velamentous insertion develops in more commonly with placenta previa and multifetal gestations (Feldman and associates, 2002; Fox and Sebire, 2007; Papinniemi and co-workers, 2007).

Vasa Previa. In some cases of velamentous insertion, placental vessels overlie the cervix, lie between the cervix and the presenting fetal part, and are supported only by membranes. As a result, vessels are vulnerable not only to compression, which may lead to fetal anoxia, but also to laceration, which can lead to fetal exsanguination. Fortunately, vasa previa is uncommon, and Lee and co-workers (2000) identified it in 1 in 5200 pregnancies. Risk factors include bilobate or succenturiate placentas and second-trimester placenta previa, with or without later migration (Baulies and associates, 2007; Suzuki and Igarashi, 2008). It is also increased in pregnancies conceived by in vitro fertilization (IVF), and this is believed to stem from greater rates of abnormal cord insertion with pregnancies so conceived (Schachter and associates, 2003).

FIGURE 27-6 Velamentous insertion of the cord. The placenta and membranes have been inverted to expose the amnion. Part of the fetal surface of the placenta appears at the bottom of the photograph. The large fetal vessels extend from the cord insertion and within the membranes. From the proximity of the vessels to the site of membrane rupture, it can be seen how a vessel could easily be torn by digital manipulation or descent of the fetal head during labor.

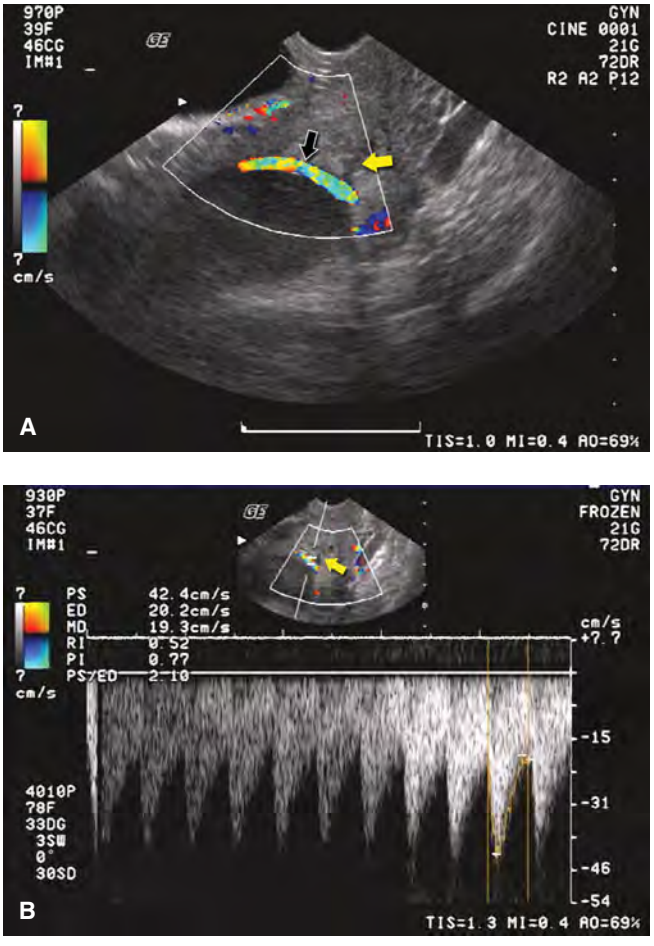

FIGURE 27-7 Vasa previa. **A.** Transvaginal sonogram with color mapping shows the large vessel (*black arrow*) covering the internal os of the cervix (*yellow arrow*). **B.** Doppler waveform of the vessel shows the typical appearance of the umbilical artery with a rate of 150 beats per minute.

Antepartum diagnosis results in improved rates of fetal survival compared with intrapartum diagnosis (Oyelese and associates, 2004). Thus, vasa previa would ideally be identified early, and scheduled cesarean delivery planned. Clinically, an examiner is occasionally able to palpate or directly see a tubular fetal vessel in the membranes overlying the presenting part. With endovaginal sonography, a vessel may be identified as echogenic, parallel or circular line near the cervix (Fig. 27-7). Because of a low sensitivity for imaging vasa previa with sonography, color Doppler examination is recommended when vasa previa is suspected. Canterino and colleagues (2005) have also described use of 3D-sonography with power Doppler angiography.

Whenever there is hemorrhage antepartum or intrapartum, the possibility of vasa previa and a ruptured fetal vessel should be considered. Determination of bleeding as fetal or maternal is possible, and a variety of tests may be used. Each relies on the increased resistance of fetal hemoglobin compared with maternal to denaturing by alkaline reagents (Lindqvist and Gren,

2007; Oyelese and co-workers, 1999). Unfortunately, the amount of fetal blood that can be shed without killing the fetus is relatively small. Thus, in many cases, fetal death is virtually instantaneous.

Cord Abnormalities Capable of Impeding Blood Flow

Several mechanical and vascular abnormalities of the umbilical cord are capable of impairing fetal–placental blood flow.

Knots

False knots appear as knobs protruding from the cord surface and are focal redundancies of a vessel or Wharton jelly, with no clinical significance. With *true knots,* active fetal movements create cord knotting. The incidence of true knots is approximately 1 percent, and these are more common in monoamnionic twins. The risk of stillbirth is increased five- to tenfold in those with true knots (Airas and Heinonen, 2002; Sørnes, 2000). In live fetuses, although heart rate abnormalities are increased during labor with this complication, cord blood acid-base values are usually normal (Airas and Heinonen, 2002; Maher and Conti, 1996).

Loops

The cord frequently becomes coiled around portions of the fetus, and this is more likely with longer cords. Those looped around the neck are termed a *nuchal cord*, and several large studies have reported one loop of nuchal cord in 20 to 34 percent of deliveries; two loops in 2.5 to 5 percent; and three loops in 0.2 to 0.5 percent (Kan and Eastman, 1957; Sørnes, 1995; Spellacy and associates, 1966). As labor progresses, contractions may compress the cord vessels and create fetal heart rate decelerations that persist until the contraction ceases. In labor, 20 percent of fetuses with a nuchal cord have moderate or severe variable heart rate decelerations, and they are also more likely to have a lower umbilical artery pH (Hankins and colleagues, 1987). Fortunately, coiling of the cord around the neck is an uncommon cause of adverse perinatal outcome (Mastrobattista and co-workers; 2005; Sheiner and associates, 2006).

Funic Presentation

Uncommonly, the umbilical cord may be the presenting part in labor and most often is associated with fetal malpresentation. Cord prolapse or fetal heart rate abnormalities is an associated labor finding, although funic presentation may be identified antenatally with sonography and with color flow Doppler (Ezra and co-workers, 2003; Raga and associates, 1996). If present during labor, cesarean delivery is typically indicated.

Umbilical Cord Stricture

This is a focal narrowing of the cord diameter that typically develops in the area of fetal umbilical insertion (Peng and co-workers, 2006). Absence of Wharton jelly and stenosis or obliteration of cord vessels at the narrow segment are characteristic pathological features (Sun and associates, 1995). Most fetuses are stillborn (French and colleagues, 2005).

Hematoma

These accumulations of blood are associated with short cords, trauma, and entanglement. They may result from a varix rupture, usually of the umbilical vein, with effusion of blood into the cord. Hematomas also may be caused by umbilical vessel venipuncture.

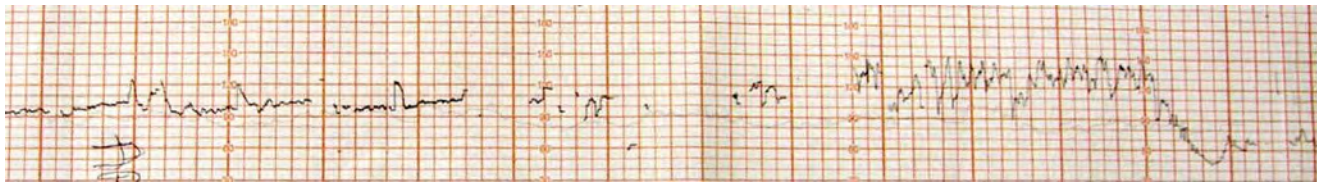
Cysts

Cord cysts occasionally may be found along the course of the cord and are designated true cysts or pseudocysts, according to their origin. *True cysts* are epithelium-lined remnants of the allantois and may co-exist with a persistently patent urachus. In contrast, the more common *pseudocysts* form from local degeneration of Wharton jelly. Both have a similar sonographic appearance.

Single umbilical cord cysts found in the first trimester tend to resolve completely, whereas multiple cysts may portend miscarriage or aneuploidy (Ghezzi and co-workers, 2003; Sepulveda and colleagues, 1999b). Moreover, pseudocysts persisting beyond this can be associated with structural and chromosomal anomalies defects, especially trisomy 18 and 13 (Sepulveda and associates, 1999a; Smith and colleagues, 1996).

Thrombosis

Intrauterine thrombosis of umbilical cord vessels is a rare event (**Fig. 27-8**). Approximately 70 percent are venous, 20 percent are venous and arterial, and 10 percent are arterial thromboses (Heifetz, 1988). Venous thromboses have lower perinatal morbidity and mortality rates than those in the artery. The latter is associated with fetal-growth restriction and fetal demise (Klaritsch and associates, 2008; Sato and Benirschke, 2006; Singh and co-workers, 2003).



Vessel Dilatation

An *umbilical vein varix* is a marked focal dilatation that may develop within the intra-amnionic part of the umbilical vein or within its fetal intra-abdominal portion. Those found intra-abdominally have increased rates of fetal demise, structural anomalies, and aneuploidy (Fung and co-workers, 2005). The most common complications are varix rupture, varix thrombosis, compression of the umbilical artery, and fetal cardiac failure due to increased preload (Mulch and associates, 2006).

An *umbilical artery aneurysm* is a rare congenital thinning of the vessel wall with diminished support from Wharton jelly. Indeed, most form at or near the cord insertion into the placenta, where this support is absent. There is an association with single umbilical artery, trisomy 18, fetal-growth restriction, and stillbirth (Sepulveda and colleagues, 2003b; Weber and associates, 2007). It has been suggested that these aneurysms lead to fetal hypoxia and death by umbilical vein compression.

PATHOLOGICAL EXAMINATION

Most authorities agree that routine placental examination by a pathologist is not indicated, although there still is debate as to which placentas should be submitted. The College of American

A

B

FIGURE 27-8 A. Fetal heart rate tracing shows an initially reassuring and reactive pattern. The fetal heart rate becomes erratic and is followed by persistent fetal bradycardia, which prompts emergent cesarean delivery. **B.** A segment of the umbilical cord following delivery. A neonatal endotracheal tube is seen in the umbilical vein, which is held by forceps. One of the umbilical arteries has been dissected from the surrounding Wharton jelly *(black arrows)*. Two distinct thrombi are seen within this vessel *(white arrows)*. (Used with permission from Dr. J. Seth Hawkins.)

Pathologists recommends routine examination for an extensive list of indications (Langston and colleagues, 1997). Using these guidelines, Curtin and co-workers (2007) computed that 37 percent of all placentas would be submitted. The American College of Obstetricians and Gynecologists (1993) concluded that there are insufficient data to support all of these recommendations.

TABLE 27-1. Some Indications for Placental Examination by a Pathologist

Maternal fever
Chorioamnionitis
Placental abruption
Hypertension
Thyroid disease
Autoimmune disease, thrombosis, or other disorder associated with vasculitis
Meconium
Cord abnormalities
Gross placental abnormalities
Stillbirth/early neonatal death
Neonatal neurological problems
Multifetal gestation
Fetal-growth restriction
Acidotic newborn
Low Apgar scores
Very-low-birthweight infant
Unexpectedly "flat" term or near-term infant[a]

[a]An infant in whom the obstetrical surveillance has been reassuring but who has low Apgar scores or other evidence of poor performance in the delivery room. Infection is a classic cause.

From Gibbs and colleagues (2004), with permission.

Certainly, all agree that the placenta and cord should be examined in the delivery room. The decision to request pathological examination will depend on clinical and placental findings. At this time, some correlation of specific placental findings with both short- and long-term neonatal outcomes is possible. Gibbs and co-workers (2004), based largely on conclusions reached in the 2003 American College of Obstetricians and Gynecologists/American Academy of Pediatrics publication, *Neonatal Encephalopathy and Cerebral Palsy*, provide the indications shown in Table 27-1.

SECTION 5

FETUS AND NEWBORN

CHAPTER 28

The Newborn Infant

INITIATION OF AIR BREATHING 590
MANAGEMENT OF DELIVERY 590
METHODS USED TO EVALUATE NEWBORN CONDITION 594
PREVENTIVE CARE 598
ROUTINE NEWBORN CARE 598

Immediately following birth, infant survival depends on a prompt and orderly conversion to air breathing. Fluid-filled alveoli expand with air, perfusion must be established, and oxygen and carbon dioxide exchanged.

INITIATION OF AIR BREATHING

Stimuli to Breathe Air

The newborn begins to breathe and cry almost immediately after birth, indicating the establishment of active respiration. Factors that appear to influence the first breath of air include:

1. Physical *stimulation,* such as handling the neonate during delivery
2. *Deprivation of oxygen and accumulation of carbon dioxide,* which serve to increase the frequency and magnitude of breathing movements both before and after birth (Dawes, 1974)
3. *Compression of the thorax,* which during pelvic descent and vaginal birth forces an amount of fluid from the respiratory tract equivalent to about a fourth of the ultimate functional residual capacity (Saunders and Milner, 1978).

Aeration of the newborn lung does not involve the inflation of a collapsed structure, but instead, the rapid replacement of bronchial and alveolar fluid by air. After delivery, the residual alveolar fluid is cleared through the pulmonary circulation and to a lesser degree, through the pulmonary lymphatics (Chernick, 1978). Delay in removal of fluid from the alveoli probably contributes to the syndrome of *transient tachypnea of the newborn (TTN)* (Guglani and co-workers, 2008). As fluid is replaced by air, the compression of the pulmonary vasculature is reduced considerably and in turn, resistance to blood flow is lowered. With the fall in pulmonary arterial blood pressure, the ductus arteriosus normally closes (see Fig. 4-12, p. 90).

High negative intrathoracic pressures are required to bring about the initial entry of air into the fluid-filled alveoli. Normally, from the first breath after birth, progressively more residual air accumulates in the lung, and with each successive breath, lower pulmonary opening pressure is required. In the normal mature newborn, by approximately the fifth breath, pressure-volume changes achieved with each respiration are very similar to those of the adult. Thus, the breathing pattern shifts from the shallow episodic inspirations characteristic of the fetus to regular, deeper inhalations (see Chap. 15, p. 336). Surfactant—synthesized by type II pneumocytes and already present—lowers alveolar surface tension and thereby prevents collapse of the lung with each expiration. Lack of sufficient surfactant, common in preterm infants, leads to the prompt development of *respiratory distress syndrome* (see Chap. 29, p. 605).

MANAGEMENT OF DELIVERY

Immediate Care

Before and during delivery, careful consideration must be given to several determinants of neonatal well-being including: (1) health status of the mother; (2) prenatal complications, including

any suspected fetal malformations; (3) gestational age; (4) labor complications; (5) duration of labor and ruptured membranes; (6) type and duration of anesthesia; (7) difficulty with delivery; and (8) medications given during labor and their amounts, times given, and routes of administration.

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) recommend attendance at delivery of at least one person whose primary responsibility is the neonate and who is capable of initiating resuscitation. Either that person or someone else who is immediately available should have the skills required to perform complete resuscitation.

Newborn Resuscitation

Approximately 10 percent of newborns require some degree of active resuscitation to stimulate breathing, and 1 percent require extensive resuscitation (International Liaison Committee on Resuscitation, 2006). It is perhaps not coincidental that the risk of death for newborns delivered at home in Washington State between 1989 and 1996 was nearly twice that of those delivered in hospitals (Pang and co-workers, 2002). When deprived of oxygen, either before or after birth, neonates demonstrate a well-defined sequence of events leading to apnea. As shown in **Figure 28-1**, oxygen deprivation results initially in a transient period of rapid breathing. If such deprivation persists, however, breathing stops and the infant enters a stage of *primary apnea.* This stage is accompanied by a fall in heart rate and loss of neuromuscular tone. Simple stimulation and exposure to oxygen will usually reverse primary apnea. If oxygen deprivation and asphyxia persist, however, the newborn will develop deep gasping respirations, followed by *secondary apnea.* This latter stage is associated with a further decline in heart rate, falling blood pressure, and loss of neuromuscular tone. Neonates in secondary apnea will not respond to stimulation and will not spontaneously resume respiratory efforts. Unless ventilation is assisted, death follows. Clinically, primary and secondary apnea are indistinguishable. Thus, secondary apnea must be assumed and resuscitation of the apneic newborn must be started immediately.

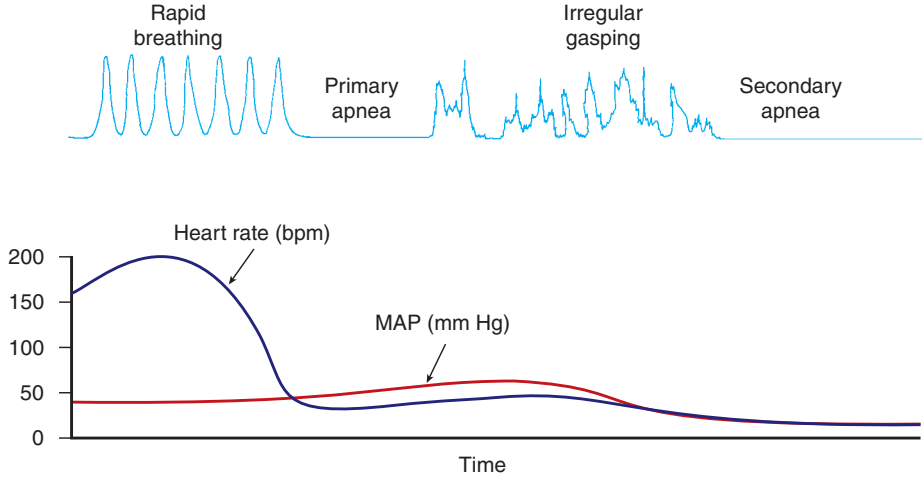

FIGURE 28-1 Physiological changes associated with primary and secondary apnea in the newborn. (Adapted from Kattwinkel, 2000.)

Resuscitation Protocol

The following is a summary of the guidelines for neonatal resuscitation recommended by the International Liaison Committee on Resuscitation (2006).

Basic Steps. As shown in **Figure 28-2**, the newborn is first placed in a warm environment to minimize heat loss. Next, the airway is cleared as necessary. If the delivery is complicated by meconium and the infant is not vigorous, tracheal intubation is recommended as subsequently discussed to allow suctioning before further resuscitative efforts are performed. The infant is then dried and stimulated after which respiratory effort, heart rate, and color are assessed. In most instances, the newborn will take a breath within a few seconds of birth and cry within half a minute. If the infant is breathing, the heart rate is greater than 100 bpm, and the skin of the central portion of the body and mucous membranes are pink, then routine supportive care is provided.

Ventilation. Apnea, gasping respirations, or bradycardia beyond 30 seconds after delivery should prompt administration of *positive-pressure ventilation* (**Fig. 28-3**). Assisted ventilation rates of 30 to 60 breaths per minute are commonly employed. Adequate ventilation is indicated by bilateral rise of the chest, ability to auscultate breath sounds, and improvement of heart rate and color. If ventilation is inadequate, the head position should be checked as shown in Figure 28-3, secretions cleared, and if necessary, inflation pressure increased.

Failure by the newborn to establish effective respirations may result from a variety of complications, including the following:

- Hypoxemia or acidosis from any cause
- Drugs administered to the mother prior to delivery
- Immaturity
- Upper airway obstruction
- Pneumothorax
- Lung abnormalities, either intrinsic—for example, hypoplasia, or extrinsic—for example, diaphragmatic hernia
- Aspiration of meconium-laden amniotic fluid
- Central nervous system developmental abnormality
- Septicemia.

Endotracheal Intubation. If bag-and-mask ventilation is ineffective or prolonged, tracheal intubation should be performed. Other indications include the need for chest compressions or tracheal administration of medications, or special circumstances such as extremely low birthweight or congenital diaphragmatic hernia. A laryngoscope with a straight blade—size 0 for a preterm infant and size 1 for a term neonate—is introduced at the side of the mouth and then directed posteriorly toward the oropharynx (**Fig. 28-4**). The laryngoscope is next moved gently into the space, termed the vallecula, between the base of the

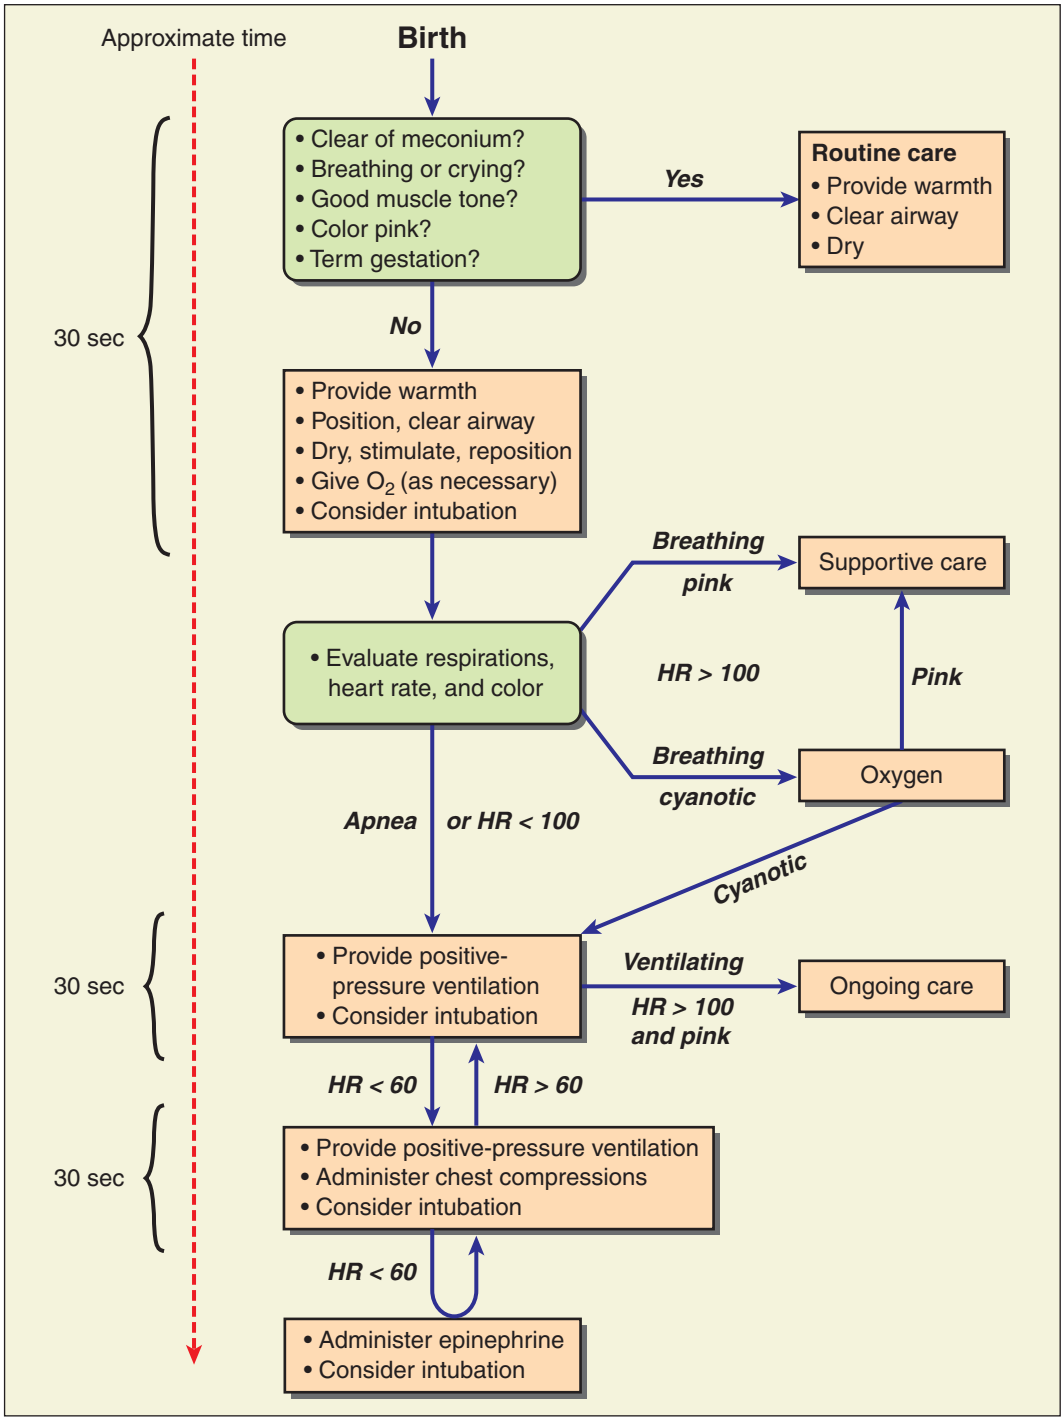

FIGURE 28-2 Algorithm for resuscitation of the newborn infant. HR = heart rate.

tongue and the epiglottis. Gentle elevation of the tip of the laryngoscope will raise the epiglottis and expose the glottis and the vocal cords. The tube is then introduced through the vocal cords. Gentle cricoid pressure may be useful. Suggested tube sizes and depth of insertion are shown in Table 28-1.

Several steps are taken to ensure that the tube is positioned in the trachea and not the esophagus: observation for symmetrical chest wall motion; auscultation for equal breath sounds, especially in the axillae; and auscultation for the absence of breath sounds or gurgling over the stomach. Given that meconium, blood, mucus, and particulate debris in amnionic fluid or in the birth canal may have been inhaled prior to delivery, any foreign material encountered in the tracheal tube is suctioned immediately. During suctioning a negative pressure of 80 to 100 mm Hg is applied as the cannula is slowly withdrawn. The endotracheal tube is then replaced. Kaiser and colleagues (2008) caution that suctioning in very-low-birth-weight infants causes potentially deleterious increases of up to 30 percent in cerebral blood flow velocity.

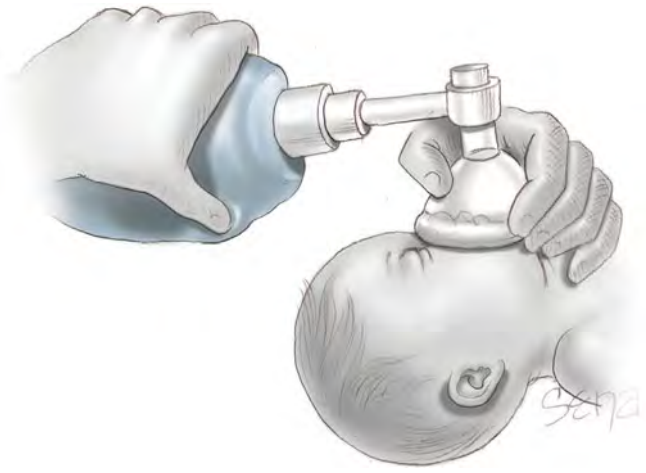

FIGURE 28-3 Correct use of bag-and-mask ventilation. The head should be in a sniffing position with the tip of the nose pointing to the ceiling, and care should be taken to avoid hyperextension of the neck.

Using an appropriate ventilation bag attached to the tracheal tube, puffs of air are delivered into the tube at 1- to 2-second intervals with a force adequate to gently lift the chest wall. Pressures of 25 to 35 cm H_2O typically will expand the alveoli without causing pneumothorax, pneumomediastinum, or other barotrauma. If ventilatory pressure is not being monitored, an increase in heart rate should be used to indicate adequate inflation pressure. If there is central cyanosis, the air should be oxygen-enriched.

Chest Compressions. If the heart rate remains below 60 bpm despite adequate ventilation with 100-percent oxygen for 30 seconds, chest compressions are initiated. Compressions are delivered on the lower third of the sternum at a depth sufficient to generate a palpable pulse. A 3:1 ratio of compressions to ventilations is recommended, with 90 compressions and 30 breaths to achieve approximately 120 events each minute. The heart rate is reassessed every 30 seconds, and chest compressions are continued until the spontaneous heart rate is at least 60 bpm.

Medications and Volume Expansion. Epinephrine is indicated when the heart rate remains below 60 bpm after a minimum of 30 seconds of adequate ventilation and chest compressions. Epinephrine is particularly indicated if there is asystole. The recommended intravenous dose is 0.01 to 0.03 mg/kg, that is, 0.1 to 0.3 mL/kg of a 1:10,000 solution. If given through the tracheal tube, higher doses are employed, up to 0.1 mg/kg, that is, 1 mL/kg. Epinephrine is repeated every 3 to 5 minutes as indicated.

Volume expansion should be considered when blood loss is suspected, the infant appears to be in shock, or the response to resuscitative measures is inadequate. An isotonic crystalloid solution, such as normal saline or Ringer lactate, is recommended. Symptomatic anemia may require transfusion of red blood cells. The initial dose of either type of volume expander is 10 mL/kg given by slow intravenous push over 5 to 10 minutes. This is delivered via a catheter placed into the umbilical vein.

Routine use of *sodium bicarbonate* during neonatal resuscitation is controversial and usually not done. The hyperosmolarity and CO_2-generating properties of bicarbonate may be detrimental to myocardial and cerebral function (Kette and associates, 1991). If sodium bicarbonate is used during prolonged arrests unresponsive to other therapy, it should be administered only after establishment of adequate ventilation and circulation.

Naloxone is a narcotic antagonist indicated for reversal of respiratory depression in a newborn whose mother received narcotics within 4 hours of delivery. It is not recommended as part of initial resuscitation, and heart rate and color should be restored by adequate ventilation prior to naloxone administration. The standard dose of naloxone is 0.1 mg/kg, although this has been poorly studied. Because the narcotic duration of action may exceed that of naloxone, continued monitoring of respiratory function is essential, and repeated doses may be necessary. Based on their systematic review of nine studies, McGuire and Fowlie (2003) concluded that *prophylactic* naloxone administration has not been shown to have any clinical benefits. Gill and Colvin (2007) question its use at all.

Discontinuation of Resuscitation. As expected, newborns with cardiopulmonary arrest who do not respond promptly to resuscitation are at great risk for mortality and if they survive, severe morbidity. Haddad and associates (2000) described 33 infants born without cardiac or respiratory effort that persisted for at least the first 5 minutes of life, and in whom resuscitation was attempted. Of 11 survivors, five had clinical or radiological signs of neurological injury, four were lost to follow-up, and the

TABLE 28-1. Suggested Endotracheal Tube Size and Depth of Insertion

Weight (g)	Gestational Age (wk)	Tube Size (mm) (Inside diameter)	Depth of Insertion from Upper Lip (cm)
<1000	<28	2.5	6–7
1000–2000	28–34	3.0	7–8
2000–3000	34–38	3.5	8–9
>3000	>38	3.5–4.0	>9

other two had normal neurological development. The International Liaison Committee on Resuscitation (2006) concluded that discontinuation of resuscitative efforts may be appropriate if there are no signs of life after 10 minutes of continuous and adequate resuscitative efforts. This is because continued resuscitation is associated with a very high mortality rate or severe neurodevelopmental disability.

METHODS USED TO EVALUATE NEWBORN CONDITION

Apgar Score

This scoring system is a useful clinical tool to identify those neonates who require resuscitation as well as to assess the effectiveness of any resuscitative measures (Apgar, 1953). As shown in Table 28-2, each of the five easily identifiable characteristics—heart rate, respiratory effort, muscle tone, reflex irritability, and color—is assessed and assigned a value of 0 to 2. The total score, based on the sum of the five components, is determined 1 and 5 minutes after delivery.

The 1-minute Apgar score reflects the need for immediate resuscitation. The 5-minute score, and particularly the change in score between 1 and 5 minutes, is a useful index of the effectiveness of resuscitative efforts. The 5-minute Apgar score also has prognostic significance for neonatal survival, because survival is related closely to the condition of the neonate in the delivery room (Apgar and associates, 1958). In an analysis of more than 150,000 infants delivered at Parkland Hospital, Casey and associates (2001b) assessed

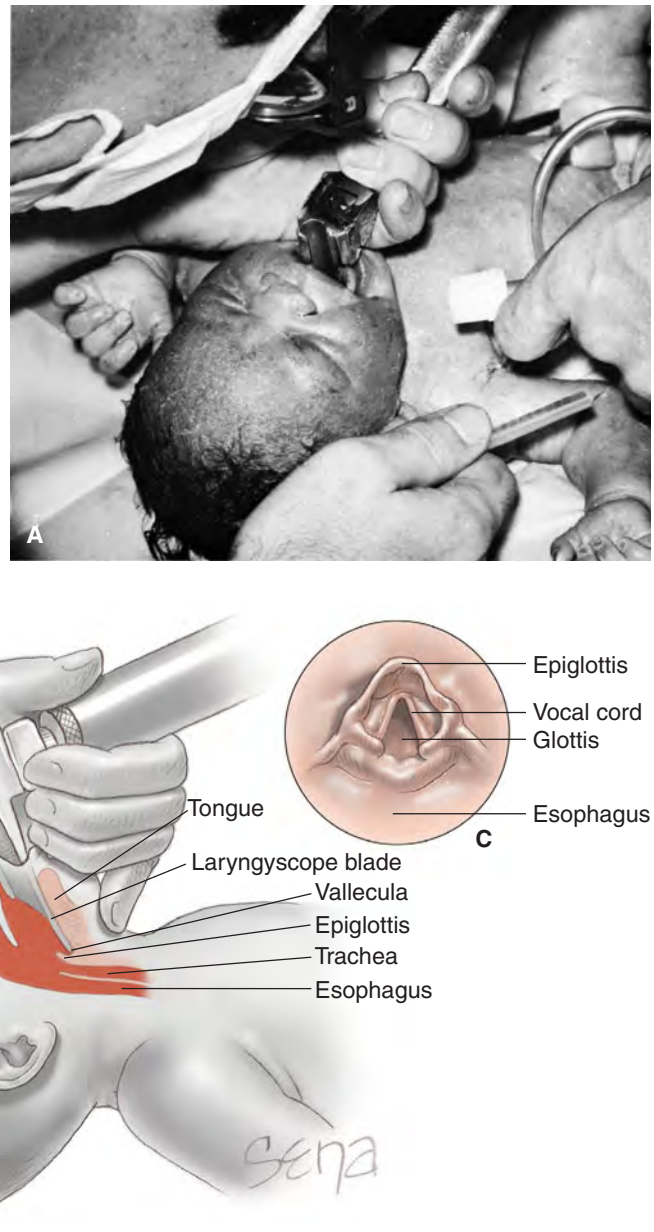

FIGURE 28-4 A. Use of laryngoscope to insert a tracheal tube under direct vision. **B.** Sagittal view during intubation. The laryngoscope blade is inserted between the tongue base and epiglottis. Upward tilting of the tongue also lifts the epiglottis. **C.** The endotracheal tube is then threaded below the epiglottis and between the vocal cords to enter the trachea.

TABLE 28-2. Apgar Scoring System

Sign	0 Points	1 Point	2 Points
Heart rate	Absent	<100 bpm	≥100 bpm
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Flaccid	Some flexion of extremities	Active motion
Reflex irritability	No response	Grimace	Vigorous cry
Color	Blue, pale	Body pink, extremities blue	Completely pink

Data from Apgar (1953).

the contemporaneous significance of the 5-minute score for predicting survival during the first 28 days of life. They found that in term neonates, the risk of neonatal death was approximately 1 in 5000 for those with Apgar scores of 7 to 10. This risk compares with a mortality rate of 1 in 4 for term infants with scores of 3 or less. Low 5-minute scores were comparably predictive of neonatal death in preterm infants. These investigators concluded that the Apgar scoring system is as relevant for the prediction of neonatal survival today as it was almost 50 years ago.

There have been attempts to use Apgar scores to define asphyxial injury and to predict subsequent neurological outcome—uses for which the Apgar score was never intended. Such associations are difficult to measure with reliability given that both asphyxial injury and low Apgar scores are infrequent outcomes. For example, according to United States birth certificate records for 2006, only 1.6 percent of newborns had a 5-minute score below 7 (Martin and co-workers, 2009). Similarly, in a population-based study of more than 1 million term infants born in Sweden between 1988 and 1997, the incidence of 5-minute Apgar scores of 3 or less was approximately 2 per 1000 (Thorngren-Jerneck and Herbst, 2001).

Despite the methodological challenges, erroneous definitions of asphyxia by many groups were established solely based upon low Apgar scores. These prompted the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics to issue a joint statement in 1986 concerning "Use and Abuse of the Apgar Score." The statement was updated in 1996 and has been reaffirmed several times, the most recent in 2006. Important caveats regarding Apgar score interpretation addressed in this statement include the following:

1. Because certain elements of the Apgar score are partially dependent on the physiological maturity of the newborn, a healthy preterm infant may receive a low score only because of immaturity (Amon and associates, 1987; Catlin and co-workers, 1986).
2. Given that Apgar scores may be influenced by a variety of factors including, but not limited to, fetal malformations, maternal medications, and infection, to equate the presence of a low Apgar score solely with asphyxia or hypoxia represents a misuse of the score.
3. Correlation of the Apgar score with adverse future neurological outcome increases when the score remains 3 or less at 10, 15, and 20 minutes, but still does not indicate the cause of future disability (Freeman and Nelson, 1988; Nelson and Ellenberg, 1981).
4. The Apgar score alone cannot establish hypoxia as the cause of cerebral palsy (Chap. 29, p. 613). A neonate who has had an asphyxial insult proximate to delivery that is severe enough to result in acute neurological injury should demonstrate all of the following: (1) profound acidemia with cord artery blood pH < 7 and acid-base deficit $\geq$ 12mmol/L; (2) Apgar score of 0–3 persisting for 10 minutes or longer; (3) neurological manifestations such as seizures, coma, or hypotonia; and (4) multisystem organ dysfunction—cardiovascular, gastrointestinal, hematological, pulmonary, or renal.

Umbilical Cord Blood Acid–Base Studies

Blood taken from umbilical vessels may be used for acid-base studies to assess the metabolic status of the neonate. Blood collection is performed following delivery by immediately isolating a 10- to 20-cm segment of cord with two clamps near the neonate and two clamps nearer the placenta. The importance of clamping the cord is underscored by the fact that delays of 20 to 30 seconds can alter both the P_{CO_2} and pH (Lievaart and de-Jong, 1984). The cord is then cut between the two proximal and two distal clamps.

Arterial blood is drawn from the isolated segment of cord into a 1- to 2-ml commercially prepared plastic syringe containing lyophilized heparin or a similar syringe that has been flushed with a heparin solution containing 1000 U/mL. The needle is capped and the syringe transported, on ice, to the laboratory. Although efforts should be made for prompt transport, neither the pH nor P_{CO_2} change significantly in blood kept at room temperature for up to 60 minutes (Duerbeck and associates, 1992). In fact, Chauhan and colleagues (1994) developed mathematical models allowing reasonable prediction of birth acid–base status in properly collected cord blood samples analyzed as late as 60 hours after delivery.

Fetal Acid-Base Physiology

The fetus produces both carbonic and organic acids. Carbonic acid (H_2CO_3) is formed by oxidative metabolism of CO_2. The fetus usually rapidly clears CO_2 through the placental circulation, which limits the buildup of carbonic acid. When H_2CO_3 accumulates in fetal blood and there is no concurrent increase in organic acids—as occurs in impaired placental exchange—the result is termed *respiratory acidemia.*

Organic acids primarily include lactic and β-hydroxybutyric acids. Increased levels of these acids follow persistent placental exchange impairment and result from anaerobic glycolysis. These organic acids are cleared slowly from fetal blood, and when they accumulate without a concurrent increase in H_2CO_3, the result is termed *metabolic acidemia.* With the development of metabolic acidemia, bicarbonate (HCO_3^-) decreases because it is used to buffer the organic acid. An increase in H_2CO_3 accompanied by an increase in organic acid reflected by decreased HCO_3^- causes *mixed respiratory-metabolic acidemia.*

In the fetus, respiratory and metabolic acidemia, and ultimately tissue acidosis, are most likely part of a progressively worsening continuum. This is different from the adult pathophysiology, in which distinct conditions result in either respiratory (pulmonary disease) or metabolic (diabetes) acidemia. In the fetus, the placenta serves as both the lungs and to a certain degree, the kidneys. One principal cause of developing fetal acidemia is a decrease in uteroplacental perfusion. This results in the retention of CO_2 (respiratory acidemia), and if protracted and severe enough, a mixed or metabolic acidemia.

Assuming that maternal pH and blood gases are normal, the actual pH of fetal blood is dependent on the proportion of carbonic and organic acids as well as the amount of bicarbonate,

which is the major buffer in blood. This can best be illustrated by the Henderson–Hasselbalch equation:

$$pH = pK + \log \frac{[base]}{[acid]} \quad \text{or,} \quad pH = pK + \log \frac{HCO_3^-}{H_2CO_3}$$

For clinical purposes, HCO_3^- represents the metabolic component and is reported in mEq/L. The H_2CO_3 concentration represents the respiratory component and is reported as the P_{CO_2} in mm Hg. Thus:

$$pH = pK + \log \frac{\text{metabolic } (HCO_3^- \text{ mEq/L})}{\text{respiratory } (PCO_2 \text{ mmHg})}$$

The result of this equation is a pH value. However, pH is a logarithmic term and does not give a linear measure of acid accumulation. For example, a change in hydrogen ion concentration associated with a fall in pH from 7.0 to 6.9 is almost twice that which is associated with a fall in pH from 7.3 to 7.2. For this reason, the *delta base* offers a more linear measure of the degree of accumulation of metabolic acid (Armstrong and Stenson, 2007). The change in base, or delta base, is a calculated number used as a measure of the change in buffering capacity of bicarbonate (HCO_3^-). For example, HCO_3^- concentration will be decreased with a metabolic acidemia as it is consumed to maintain a normal pH. A *base deficit* occurs when HCO_3^- concentration decreases to below normal levels, and a *base excess* occurs when HCO_3^- values are above normal. Importantly, a mixed respiratory–metabolic acidemia with a large base deficit and a low HCO_3^-—less than 12 mmol/L—is more often associated with a depressed neonate than is a mixed acidemia with a minimal base deficit and a more nearly normal HCO_3^-. A nomogram for calculating the delta base has been published by Siggaard-Anderson (1963).

Clinical Significance of Acidemia

Fetal oxygenation and pH generally decline during the course of normal labor (Dildy and co-workers, 1994). Normal umbilical cord blood pH and blood gas values at delivery in term newborns are summarized in **Table 28-3**. Similar values have been measured in preterm infants (Dickinson and co-workers, 1992; Ramin and associates, 1989; Riley and Johnson, 1993). Using data from more than 19,000 deliveries, the lower limits of normal pH in the newborn have been found to range from 7.04 to 7.10 (Boylan and Parisi, 1994). Thus, these values should be considered to define neonatal acidemia. Most fetuses will tolerate intrapartum acidemia with a pH as low as 7.00 without incurring neurological impairment (Freeman and Nelson, 1988; Gilstrap and associates, 1989). Supportive of this threshold, Goldaber and associates (1991) found that there were significantly more neonatal deaths and infants with neurological dysfunction below a pH of 7.00 (**Table 28-4**).

Another important prognostic consideration is the direction of pH change from birth to the immediate neonatal period. Casey and co-workers (2001a) found that the risk of seizures during the first 24 hours of life was reduced fivefold if an umbilical artery cord pH below 7.2 normalized within 2 hours after delivery.

In the fetus, *metabolic acidemia* develops when oxygen deprivation is of sufficient duration and magnitude to require anaerobic metabolism for fetal cellular energy needs. Low and associates (1997) defined fetal acidosis as a base deficit of greater than 12 mmol/L and severe fetal acidosis as a base deficit greater than 16 mmol/L. In the study of more than 150,000 newborns cited earlier, Casey and associates (2001b) defined metabolic acidemia using umbilical cord blood gas cutoffs that were 2 standard deviations below the mean, that is, an umbilical artery blood pH less than 7.00 accompanied by a P_{CO_2} of no more than 76.3 mm Hg

(higher values indicate a respiratory component), HCO_3^- concentration of no more than 17.7 mmol/L, and base deficit of at least 10.3 mEq/L. From the standpoint of *possible* cerebral palsy causation, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2003), in their widely endorsed monograph, defined metabolic acidosis as umbilical arterial pH <7.0 and a base deficit of at least 12 mmol/L.

Metabolic acidemia is associated with a high rate of multiorgan dysfunction. In rare cases, such hypoxia-induced metabolic acidemia may be so severe as to cause subsequent neurological impairment. In fact, a fetus without such acidemia cannot by definition have suffered recent hypoxic-induced injury. Even severe metabolic acidosis, however, is poorly predictive of subsequent neurological impairment in the term neonate. Although metabolic acidosis was associated with an increase in immediate neonatal complications in a group of infants with depressed 5-minute Apgar scores, Socol and colleagues (1994) found no difference in umbilical artery blood gas measurements among infants who subsequently developed cerebral palsy and those with normal long-term neurological outcome. In very-low-birthweight infants—those less than 1000 g—newborn acid-base status may be more closely linked to long-term neurological outcome (Gaudier and co-workers, 1994; Low and associates, 1995). In the study cited above, Casey and associates (2001b) measured the association between metabolic acidemia, low Apgar scores, and neonatal death in term and preterm infants. As shown in **Figure 28-5**, relative to newborns with a 5-minute Apgar score of at least 7, the risk of neonatal death was more than 3200-fold greater in term infants with metabolic acidemia and 5-minute scores of 3 or less.

Respiratory acidemia generally develops as a result of an acute interruption in placental gas exchange with subsequent CO_2 retention. Transient umbilical cord compression is the most common antecedent factor. In general, respiratory acidemia is not harmful to the fetus. Low and co-workers (1994) found no increase in newborn complications after respiratory acidosis. The degree to which pH is affected by P_{CO_2}, the respiratory component of the acidosis, can be calculated. First, the upper normal neonatal P_{CO_2} (49 mm Hg) is subtracted from the cord blood gas P_{CO_2} value. Each 10 additional mm Hg P_{CO_2} will lower the pH by 0.08 units (Eisenberg and colleagues, 1987). Thus, in a mixed respiratory–metabolic acidemia, the benign respiratory component can be calculated as in the following example: During labor, an acute cord prolapse occurred and the fetus was delivered by cesarean 20 minutes later. The umbilical artery blood gas pH was 6.95, with a P_{CO_2} of 89 mm Hg. To calculate the degree to which the cord compression and subsequent impairment of CO_2 exchange affected the pH, the relationship given earlier is applied: 89 mm Hg minus 49 mm Hg = 40 mm Hg (excess CO_2). To correct pH: (40 ÷ 10) × 0.08 = 0.32; 6.95 + 0.32 = 7.27. Therefore, the pH prior to cord prolapse was approximately 7.27, well within normal limits. Thus, the entire pH resulted from respiratory acidosis.

Recommendations for Cord Blood Gas Determinations

A cost-effectiveness analysis for universal cord blood gas measurements has not been conducted. In some centers, cord gas analysis is performed in all neonates at birth. The American

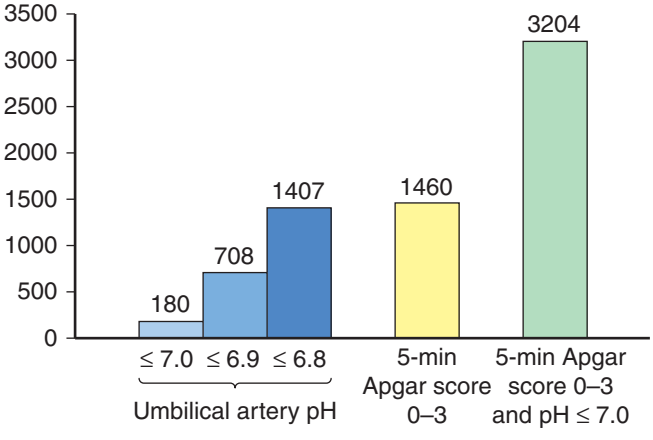

FIGURE 28-5 Relative risk for neonatal death in term infants with low Apgar score or umbilical artery acidemia—or both. Actual number of infants are cited above each bar.

College of Obstetricians and Gynecologists (2006) recommends that cord blood gas and pH analyses be obtained in the following circumstances:

1. Cesarean delivery for fetal compromise
2. Low 5-minute Apgar score
3. Severe growth restriction
4. Abnormal fetal heart rate tracing
5. Maternal thyroid disease
6. Intrapartum fever
7. Multifetal gestation.

Although umbilical cord acid-base blood determinations are poorly predictive of either immediate or long-term adverse neurological outcome, they provide the most objective evidence of the fetal metabolic status at birth.

PREVENTIVE CARE

Eye Infection Prophylaxis

Gonococcal Infection

In the past, blindness was common in children who developed *gonococcal ophthalmia neonatorum* contracted from passage through the infected birth canal (Schneider, 1984). In 1884, Credé, a German obstetrician, introduced a 1-percent ophthalmic solution of silver nitrate that largely eliminated blindness due to *Neisseria gonorrhoeae.* A variety of other antimicrobials have also proven to be effective, and gonococcal ophthalmia neonatorum prophylaxis is now mandatory for all neonates (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2007). The Centers for Disease Control and Prevention (2006) recommendations for gonococcal eye prophylaxis include a single application of either 0.5-percent erythromycin ophthalmic ointment or 1-percent tetracycline ophthalmic ointment soon after delivery. Treatment of presumptive gonococcal ophthalmia—conjunctivitis in a neonate born to a mother with untreated gonorrhea—is given with single-dose ceftriaxone, 25 to 50 mg/kg, either intramuscularly or intravenously, not to exceed 125 mg. Culture for both gonorrhea and chlamydia (an approved non-culture based method may be substituted) should be obtained prior to treatment.

Chlamydial Infection

Adequate neonatal prophylaxis against *chlamydial conjunctivitis* is complex. From 12 to 25 percent of neonates delivered vaginally of mothers with an active chlamydial infection will develop conjunctivitis (Teoh and Reynolds, 2003). Although it is reasonable to expect that tetracycline and erythromycin ophthalmic ointments applied at birth as described above would reduce the incidence of chlamydial conjunctivitis, this is not the case. In a study from Kenya, Isenberg and colleagues (1995) showed that 2.5-percent povidone-iodine solution was superior to either 1-percent silver nitrate solution or 0.5-percent erythromycin ointment in preventing chlamydial conjunctivitis. In another study from Iran, povidone-iodine eye drops were twice as effective in preventing clinical conjunctivitis as erythromycin drops—9 versus 18 percent failure rate, respectively (Ali and associates, 2007). According to the Centers for Disease Control and Prevention (2006), the effectiveness of topical prophylaxis is unclear, and any case of conjunctivitis in a newborn less than 1 month old should prompt consideration for chlamydial infection.

Hepatitis B Immunization

Routine immunization of all newborns against hepatitis B prior to hospital discharge has been recommended since 1991. The Centers for Disease Control and Prevention (2005) recommends thimerosal-free vaccine. This vaccine does not appear to increase the number of febrile episodes, sepsis evaluations, or adverse neurological sequelae (Lewis and associates, 2001). If the mother is seropositive for hepatitis B surface-antigen, the neonate should also be passively immunized with hepatitis B immune globulin (see Chap. 50, p. 1070).

Vitamin K

This injection is provided to prevent vitamin K-dependent hemorrhagic disease of the newborn, which is discussed in Chapter 29 (p. 629). A 0.5- to 1-mg single-dose intramuscular administration of vitamin K within 1 hour of birth is recommended by the American Academy of Pediatrics and American College of Obstetricians and Gynecologists (2007).

Universal Newborn Screening

Newborn screening programs began in the early 1960s when a test for phenylketonuria (PKU) could be carried out on blood samples collected on filter paper (Guthrie and Susi, 1963). Subsequently, screening for a number of other disorders has been mandated by various state laws (American College of Obstetricians and Gynecologists, 2007b).

Technical advances have made a large number of relatively simply performed mass screening tests available for newborn conditions. In response to calls for a uniform national policy, the Maternal and Child Health Bureau (2005) appointed a committee of the American College of Medical Genetics to develop such panels. A *core panel* of 29 congenital conditions in five categories is shown in **Table 28-5**. Most of these are done using *tandem spectroscopy.* Neonatal screening for hearing loss was shown in a Dutch study to diagnose problems a mean of 6 months earlier and improve outcomes (Durieux-Smith and colleagues, 2008).

Most states require that the core panel be performed. Supplemental conditions—*secondary targets*—are also listed on the Maternal and Child Health Bureau web site. Some states require some of these 24 in addition to their mandated core panel. Each practitioner needs to be familiar with their individual state's requirements, available at http://genes-r-us.uthscsa.edu.

ROUTINE NEWBORN CARE

Estimation of Gestational Age

An estimate of newborn gestational age may be made very soon after delivery (**Fig. 28-6**). The relationship between gestational age and birthweight should be used to identify neonates at risk

TABLE 28-5. Newborn Screening Core Panel

Acylcarnitine Disorders[a]				
Organic Acid Metabolism	**Fatty Acid Metabolism**	**Amino Acid Metabolism[a]**	**Hemoglobin Disorders**	**Others**
Isovaleric	Medium-chain acyl-CoA dehydrogenase	Phenylketonuria	SS disease	Congenital hypothyroidism
Glutaric type I	Very long-chain acyl-CoA dehydrogenase	Maple syrup (urine)	S-β-thalassemia	Biotinidase
3-hydroxy-3-methyl glutaric	Long-chain 3-OH acyl-CoA dehydrogenase	Homocystinuria	SC disease	Congenital adrenal hyperplasia
Multiple carboxylase	Trifunctional protein	Citrullinemia		Galactosemia

for complications (McIntire and colleagues, 1999). For example, neonates who are either small- or large-for-gestational-age are at increased risk for hypoglycemia and polycythemia, and measurements of blood glucose and hematocrit are indicated (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2007).

Skin Care

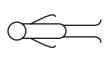
Following delivery, excess vernix, blood, and meconium should be gently wiped off. Any remaining vernix is readily absorbed and disappears entirely within 24 hours. The first bath should be postponed until the temperature of the neonate has stabilized.

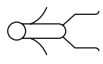
Umbilical Cord

Loss of water from the Wharton jelly leads to mummification of the umbilical cord shortly after birth. Within 24 hours, the cord stump loses its characteristic bluish-white, moist appearance and soon becomes dry and black. Within several days to weeks, the stump sloughs and leaves a small, granulating wound, which after healing forms the umbilicus. Separation usually takes place within the first 2 weeks, with a range of 3 to 45 days (Novack and colleagues, 1988). The umbilical cord dries more quickly and separates more readily when exposed to air. Thus, a dressing is not recommended.

Serious umbilical infections sometimes are encountered. The most likely offending organisms are *Staphylococcus aureus, Escherichia coli,* and group B streptococcus. Because the umbilical stump in such cases may present no outward sign of infection, the diagnosis may be elusive. Strict aseptic precautions should be observed in the immediate care of the cord. In a randomized study of 766 newborns, Janssen and co-workers (2003) showed that triple-dye applied to the cord was superior to soap and water care in preventing colonization and exudate formation. Mullany and colleagues (2006), in a randomized trial of over 15,000 Nepalese newborns, found that cleansing the cord stump with 4-percent chlorhexidine reduced severe omphalitis by 75 percent compared with cleansing with soap and water.

Feeding





According to the American College of Obstetricians and Gynecologists (2007a), exclusive breast feeding is preferred until 6 months. In many hospitals, infants begin breast feeding in the delivery room. Most term newborns thrive best when fed at intervals of every 2 to 4 hours. Preterm or growth-restricted newborns require feedings at shorter intervals. In most instances, a 3-hour interval is satisfactory. The proper length of each feeding depends on several factors, such as the quantity of breast milk, the readiness with which it can be obtained from the breast, and the avidity with which the infant nurses. It is generally advisable for the infant to nurse for 5 minutes at each breast for the first 4 days, or until the mother has a supply of milk. After the fourth day, the newborn nurses up to 10 minutes on each breast.

A goal established by the U.S. Public Health Service for *Healthy People 2010* is to increase the proportion of mothers who breast feed their infants (U.S. Department of Health and Human Services, 2000). Substantial progress toward this goal has been made. In 2008, 74 percent of infants were breast fed at least once, and 31 percent were breast fed exclusively for at least 3 months (Centers for Disease Control and Prevention, 2009). Breast feeding is discussed further in Chapter 30 (p. 651).

Initial Weight Loss

Because most neonates actually receive little nutriment for the first 3 or 4 days of life, they progressively lose weight until the flow of maternal milk has been established or other feeding is

Neuromuscular Maturity

FIGURE 28-6 Ballard score for estimating gestational age. (Reprinted from *The Journal of Pediatrics,* Vol. 119, No. 3, JL Ballard, JC Khoury, K Wedig, et al., New Ballard Score, expanded to include extremely premature infants, pp. 417–423, Copyright 1991, with permission from Elsevier.)

instituted. Preterm infants lose relatively more weight and regain their birthweight more slowly than term newborns. Infants who are small-for-gestational-age but otherwise healthy regain their initial weight more quickly when fed than those born preterm.

If the normal newborn is nourished properly, birthweight usually is regained by the end of the 10th day. Thereafter, the weight typically increases steadily at the rate of about 25 g/day for the first few months. Birthweight doubles by 5 months of age and triples by the end of the first year.

Stools and Urine

For the first 2 or 3 days after birth, the contents of the colon are composed of soft, brownish-green *meconium.* This consists of desquamated epithelial cells from the intestinal tract, mucus,

epidermal cells, and lanugo (fetal hair) that have been swallowed along with amnionic fluid. The characteristic color results from bile pigments. During fetal life and for a few hours after birth, the intestinal contents are sterile, but bacteria quickly colonize the bowel.

Meconium stooling is seen in 90 percent of newborns within the first 24 hours, and most of the rest within 36 hours. Newborns first void usually shortly after birth, but may not until the second day. The passage of meconium and urine indicates patency of the gastrointestinal and urinary tracts. Failure of the newborn to stool or urinate after these times suggests a congenital defect, such as imperforate anus or a urethral valve. After the third or fourth day, as the consequence of ingesting milk, meconium is replaced by light-yellow homogenous feces with a consistency similar to peanut butter.

Icterus Neonatorum

Between the second and fifth day of life approximately one third of all neonates develop so-called *physiological jaundice of the newborn.* Serum bilirubin levels at birth are normally 1.8 to 2.8 mg/dL. These levels increase during the next few days but with wide individual variation. Between the third and fourth day, the bilirubin in term newborns commonly exceeds 5 mg/dL, the concentration at which jaundice is usually noticeable. Most of the bilirubin is free, that is, unconjugated. In the liver, bilirubin is bound or conjugated to glucuronic acid and excreted into bile. With hepatic immaturity, less bilirubin is conjugated with glucuronic acid and leads to reduced excretion in bile (see Chap. 29, p. 625). By an alternate method, reabsorption of free bilirubin may result from the enzymatic splitting of bilirubin glucuronide by intestinal conjugase activity in the newborn intestine. This effect also appears to contribute significantly to transient hyperbilirubinemia. In preterm neonates, jaundice is more common and usually more severe and prolonged than in term newborns, because of even lower hepatic conjugation rates. Increased erythrocyte destruction from any cause also contributes to hyperbilirubinemia.

The standard and noninvasive treatment of an affected newborn is phototherapy. With this, the neonate is exposed to a specific light wavelength that is absorbed by the bilirubin molecule. As a result, unconjugated bilirubin in the skin is converted to a water-soluble stereoisomer, which is then excreted in bile.

Circumcision

This subject has been controversial for the past 20 years. For centuries, newborn male circumcision has been performed as a religious ritual. That said, current scientific evidence suggests that several medical benefits accrue from circumcision. A review by the American Academy of Pediatrics Task Force on Circumcision (1989) reported that the procedure prevented phimosis, paraphimosis, and balanoposthitis, and it decreased the incidence of penile cancer. The Task Force also cited an increased incidence of cervical cancer among sexual partners of uncircumcised men infected with human papillomavirus (HPV). The associations between circumcision and reduced risks of penile human papillomavirus infection and cervical cancer in sexual partners have been corroborated by Castellsagué and associates (2002).

Ten years later, however, the American Academy of Pediatrics (1999) concluded that existing evidence is insufficient to recommend *routine* neonatal circumcision—a position that is endorsed by the American College of Obstetricians and Gynecologists (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2007). Others have argued that the existing data support a recommendation for routine circumcision (Schoen and associates, 2000). In two large randomized trials from regions of Africa with a high prevalence of human immunodeficiency virus (HIV), adult male circumcision was found to lower the risk of HIV acquisition by half (Bailey and co-workers, 2007; Gray and colleagues, 2007). Tobian and associates (2009) found adult male circumcision also decreased incidences of HIV, HPV, and herpesvirus-2 infections.

It is currently recommended that parents should make an informed choice after being given accurate and unbiased information. Nelson and associates (2005) estimated that from 1997 to 2000, 61 percent of newborn males in the United States were circumcised. Another problem is who should provide these services—obstetricians, pediatricians, urologists, or midlevel providers (Johnson and colleagues, 2007).

Surgical Technique

Newborn circumcision should be performed only on a healthy neonate. Other contraindications include any genital abnormalities such as hypospadias and a family history of a bleeding disorder unless excluded in the infant. The most commonly used instruments are shown in Figure 28-7 and include Gomco and Mogen clamps and the Plastibell device. Compared with the

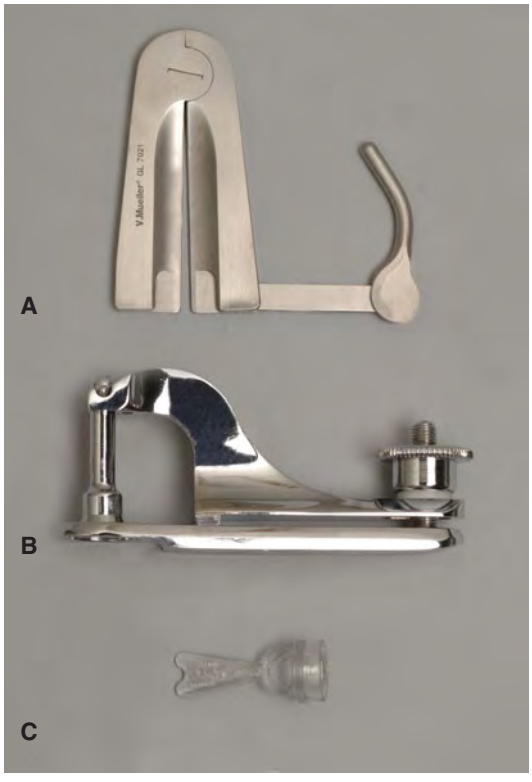

FIGURE 28-7 A. Mogen clamp. The arms of the clamp open to 3 mm maximum width. **B.** Gomco clamp, assembled. **C.** Plastibell clamp.

Gomco procedure, Kaufman and colleagues (2002) reported that the Mogen technique required less time to perform and was associated with less apparent discomfort for the newborn. Regardless of the method used, the goal is to remove enough shaft skin and inner preputial epithelium so that the glans is exposed sufficiently to prevent phimosis. In all techniques: (1) the amount of external skin to be removed must be accurately estimated, (2) the preputial orifice must be dilated to visualize the glans and ensure that it is normal, (3) the inner preputial epithelium must be freed from the glans epithelium, and (4) the circumcision device must be left in place long enough to produce hemostasis before amputating the prepuce (Lerman and Liao, 2001). For a detailed description of surgical techniques see the second edition of *Operative Obstetrics* (Gilstrap and colleagues, 2002).

Anesthesia for Circumcision. The American Academy of Pediatrics (1999) recommends that if circumcision is performed, procedural analgesia should be provided. A variety of techniques for pain relief have been described, including lidocaine-prilocaine topical cream, local analgesia infiltration, and dorsal penile nerve block and ring block. Stang and colleagues (1988) reported that dorsal penile nerve block reduced behavioral distress and modified the adrenocortical stress response in neonates undergoing circumcision. This observation was confirmed in subsequent clinical studies (Arnett and co-workers, 1990; Fontaine and Toffler, 1991). The results of these studies favor the dorsal penile nerve block or the ring block techniques compared with topical analgesia (Hardwick-Smith, 1998; Lander, 1997; Taddio, 1997, and their colleagues). The use of a pacifier dipped in sucrose also appears beneficial (Kaufman and colleagues, 2002).

After appropriate penile cleansing, the *ring block technique* consists of placing a wheal of 1-percent lidocaine at the base of the penis and advancing the needle in a 180-degree arc around the base of the penis first to one side and then the other to achieve a circumferential ring of analgesia. The maximum dose of lidocaine is 1.0 mL. The addition of a buffering agent does not appear to offer a benefit (Newton and co-workers, 1999). **No vasoactive compounds such as epinephrine should ever be added to the local analgesic agent.**

Complications of Circumcision. As with any surgical procedure, there is a risk of bleeding, infection, and hematoma formation. These risks, however, are low (Christakis and colleagues, 2000). Unusual complications reported as isolated cases include amputation of the distal glans (Neulander and colleagues, 1996), infection with human immunodeficiency virus-1 (HIV-1) and other sexually transmitted diseases (Nicoll, 1997), meatal stenosis (Upadhyay and associates, 1998), penile denudation (Orozco-Sanchez and Neri-Vela, 1991), penile destruction with electrosurgical coagulation (Gearhart and Rock, 1989), subsequent epidermal inclusion cyst and urethrocutaneous fistula (Amukele and associates, 2003), and ischemia following the inappropriate use of lidocaine with epinephrine (Berens and Pontus, 1990).

Rooming-In

This model of maternity care place newborns in their mothers' rooms instead of central nurseries. Termed *rooming-in*, this approach first appeared in hospitals in the United States in the early 1940s (Temkin, 2002). In part, rooming-in stems from a trend to make all phases of childbearing as natural as possible and to foster mother-child relationships at an early date. By 24 hours, the mother is generally fully ambulatory. Thereafter, with rooming-in, she can usually provide routine care for herself and her newborn. An obvious advantage is her increased ability to assume full care of the infant when she arrives home.

Hospital Discharge

Traditionally, the newborn is discharged with its mother, and in most cases, maternal stay has determined that of the neonate. From 1970 to the mid-1990s, average maternal postpartum length of stay declined steadily, and many mothers were discharged in under 48 hours. Although it is clear that most newborns can be safely discharged within 48 hours, this is not uniformly true. For example, using data from the Canadian Institute for Health Information, Liu and colleagues (2000) examined readmission rates in more than 2.1 million neonatal discharges. As the length of hospital stay decreased from 4.2 days in 1990 to 2.7 days in 1997, the readmission rate increased from 27 to 38 per 1000 births. Dehydration and jaundice accounted for most of these readmissions. Using Washington state neonatal discharge data, Malkin and co-workers (2000) found that the 28-day mortality rate was increased fourfold and the 1-year mortality rate increased twofold in newborns discharged within 30 hours of birth.

Because of the increased scrutiny regarding short hospital stays, federal legislation—*The Newborns' and Mothers' Health Protection Act of 1996*—was enacted to prohibit insurers from restricting hospital stays for mothers and newborns to less than 2 days for vaginal delivery or 4 days for cesarean delivery. As a result, the average length of hospital stay for childbirth increased from 2.1 days in 1995 to 2.5 days in 2000. This increase reflected the reduced number of very short hospital stays following childbirth (Hall and Owings, 2002). Although Mosen and associates (2002) found that implementation of the new legislation was associated with a 6-percent increase in cost, readmission rates within 7 days of discharge decreased by nearly half. In their analysis of over 662,000 births in California, Datar and Sood (2006) found decreased rates of readmission of 9, 12, and 20 percent, respectively, at 1, 2, and 3 years after the legislation was implemented.

CHAPTER 29

Diseases and Injuries of the Fetus and Newborn

DISEASES COMMON IN THE PRETERM FETUS AND NEWBORN 605
DISEASES OF THE TERM FETUS AND NEONATE 628
FETAL DEATH 630
INJURIES OF THE FETUS AND NEWBORN 633

The fetus and newborn infant are susceptible to a large number of diseases. Because many disorders have a different presentation and course in term as compared with preterm infants, they are considered separately (see Chap. 36, p. 804). Disorders that are the direct consequence of maternal disease are discussed in chapters pertinent to specific maternal conditions. Because most perinatal infections arise as a result of maternal infection or colonization, they are considered in Chapters 58 and 59.

DISEASES COMMON IN THE PRETERM FETUS AND NEWBORN

Respiratory Distress Syndrome

To provide blood gas exchange immediately following delivery, the lungs must rapidly fill with air while being cleared of fluid. Concurrently, pulmonary arterial blood flow must increase remarkably. Some of the fluid is expressed as the chest is compressed during vaginal delivery, and the remainder is absorbed through the pulmonary lymphatics. Sufficient surfactant, synthesized by type II pneumocytes, is essential to stabilize the air-expanded alveoli. It lowers surface tension and thereby prevents lung collapse during expiration (see Chap. 4, p. 95). If surfactant is inadequate, hyaline membranes form in the distal bronchioles and alveoli, and respiratory distress develops.

Although *respiratory distress syndrome (RDS)* is generally a disease of preterm neonates, it does develop in term newborns, especially in the setting of sepsis or meconium aspiration. In recent years, mortality rates from RDS have decreased because of antenatal corticosteroid and newborn surfactant therapy (Jobe, 2004; Martin, 2004). Male infants are more likely to develop RDS than females, and white infants are more frequently and severely affected than black infants.

Clinical Course

In typical RDS, tachypnea develops, the chest wall retracts, and expiration is accompanied by *grunting* and *nostril flaring.* Shunting of blood through nonventilated lung contributes to hypoxemia and metabolic and respiratory acidosis. Poor peripheral circulation and systemic hypotension may be evident. The chest radiograph shows a diffuse reticulogranular infiltrate and an air-filled tracheobronchial tree—*air bronchogram.*

Respiratory insufficiency also can be caused by sepsis, pneumonia, meconium aspiration, pneumothorax, persistent fetal circulation, heart failure, and malformations involving thoracic structures, such as diaphragmatic hernia. Evidence is also accruing that there may be common mutations in surfactant protein production that cause RDS (Garmany and colleagues, 2008; Shulenin and associates, 2004).

Pathology

With inadequate surfactant, alveoli are unstable, and low pressures cause collapse at end expiration. Pneumocyte nutrition is compromised by hypoxia and systemic hypotension. There may be partial persistence of the fetal circulation that leads to pulmonary hypertension and a relative right-to-left shunt. Eventually, there is ischemic necrosis of alveolar cells. When oxygen therapy is initiated, the pulmonary vascular bed dilates, and the shunt reverses. Protein-filled fluid leaks into the alveolar ducts, and the cells lining the ducts slough. Hyaline membranes composed of fibrin-rich protein and cellular debris line the dilated

alveoli and terminal bronchioles. The epithelium underlying the membrane becomes necrotic. Following hematoxylin-eosin staining, these membranes appear amorphous and eosinophilic, like hyaline cartilage. Because of this, respiratory distress in the newborn is also termed *hyaline membrane disease.*

Treatment

The most important factor influencing survival is neonatal intensive care. Although hypoxemia is indicative of the need for oxygen, excess oxygen can damage the pulmonary epithelium and the retina. Advances in mechanical ventilation technology have improved neonatal survival. For example, *continuous positive airway pressure (CPAP)* prevents the collapse of unstable alveoli and allows high inspired-oxygen concentrations to be reduced, thereby minimizing toxicity. Disadvantages include disturbance of the endothelium and epithelium—caused by overstretching, which results in barotrauma and impaired venous return (Verbrugge and Lachmann, 1999). *High-frequency oscillatory ventilation* may reduce the risk of barotrauma by using a constant, low-distending pressure and small variations or oscillations to promote alveolar patency. This technique allows optimal lung volume to be maintained and carbon dioxide to be cleared without damaging alveoli. Although mechanical ventilation has undoubtedly improved survival, it is also an important factor in the genesis of chronic lung disease—*bronchopulmonary dysplasia.*

Treatment of the ventilator-dependent neonate with *glucocorticoids* was used for many years to prevent chronic lung disease. The American Academy of Pediatrics (2002) now recommends against their use because of limited benefits and increased adverse neuropsychological effects. Yeh and colleagues (2004) described significantly impaired motor and cognitive function and school performance in exposed neonates. The results of a Cochrane Review by Halliday and co-workers (2009) support late postnatal corticosteroid treatment only for infants who could not be weaned from mechanical ventilation.

In some studies, *inhaled nitric oxide* was shown to be associated with improved outcomes for infants undergoing mechanical ventilation (Ballard, 2006; Kinsella, 2006; Mestan, 2005; Schreiber, 2003, and all their colleagues). Another study done by van Meurs and associates (2005) showed no benefits. Currently, such treatment is considered investigational (Chock and co-workers, 2009; Stark, 2006).

Surfactant Prophylaxis

Exogenous surfactant products can prevent hyaline membrane disease. They contain biological or animal surfactants such as bovine—*Survanta*, calf—*Infasurf*, porcine—*Curosurf*, or synthetic—*Exosurf.* In a Cochrane Review, Pfister and associates (2007) found that animal-derived and synthetic surfactant were comparable. Lucinactant—*Surfaxin R*—is a synthetic form that contains sinulpeptide KL4 to diminish lung inflammation (Zhu and co-workers, 2008).

Surfactant therapy has been credited for the largest drop in infant mortality rates observed in 25 years (Jobe, 1993). It has been used for *prophylaxis* of preterm at-risk infants and for *rescue* of those with established disease. Antenatal corticosteroids and surfactant given together result in an even greater reduction in the overall death rate. In a Cochrane Review, Seger and Soll (2009) found that infants who receive prophylactic surfactant had a decreased risk of pneumothorax, pulmonary interstitial emphysema, bronchopulmonary dysplasia, and mortality.

Complications

Persistent hyperoxia injures the lung, especially the alveoli and capillaries. High oxygen concentrations given at high pressures can cause *bronchopulmonary dysplasia.* With this, alveolar and bronchiolar epithelial damage leads to hypoxia, hypercarbia, and chronic oxygen dependence from peribronchial and interstitial fibrosis. According to Baraldi and Filippone (2007), most cases are now seen in infants born before 30 weeks and represent a developmental disorder secondary to alveolarization injury. Severe disease and death rates are decreasing, however, long-term pulmonary dysfunction is later encountered. *Pulmonary hypertension* is another frequent complication. If hyperoxemia is sustained, the infant also is at risk of developing *retinopathy of prematurity,* formerly called *retrolental fibroplasia* (see p. 607). When any of these develop, the likelihood of subsequent neurosensory impairment is substantively increased (Schmidt and colleagues, 2003).

Prevention

With the possible exception of progesterone therapy to prevent recurrent preterm birth, there are no methods to prevent or treat preterm labor (see Chap. 36, p. 816). The National Institutes of Health (1994, 2000) concluded that a single course of antenatal corticosteroid therapy reduced respiratory distress and intraventricular hemorrhage in preterm infants born between 24 and 34 weeks (see p. 609). The American College of Obstetricians and Gynecologists and American Academy of Pediatrics (2003) considers all women at risk for preterm birth in this gestational age range to be potential candidates for therapy. This is discussed further is Chapter 36 (p. 821). After 34 weeks, approximately 4 percent of infants develop respiratory distress syndrome (Fuchs and colleagues, 2009).

Amniocentesis for Fetal Lung Maturity

Delivery for fetal indications is necessary when the risks to the fetus from a hostile intrauterine environment are greater than the risk of severe neonatal problems, including respiratory distress, even if the fetus is preterm. If this degree of risk is not present and the criteria for elective delivery at term are not met, then amniocentesis and amnionic fluid analysis are used to confirm fetal lung maturity. To accomplish this, several methods can be used to determine the relative concentration of surfactant-active phospholipids in this amnionic fluid. Fluid acquisition is similar to that described for second-trimester amniocentesis (see Chap. 13, p. 299). Complications requiring urgent delivery arise in up to 1 percent of procedures (American College of Obstetricians and Gynecologists, 2008a). Following analysis, the probability of respiratory distress developing in a given infant depends on the test used and fetal gestational age. Importantly, administration of corticosteroids to induce pulmonary maturation has variable effects on some of these tests.

Lecithin–Sphingomyelin (L/S) Ratio. Although not used nearly as much as in the past, the labor-intensive *L/S ratio* for

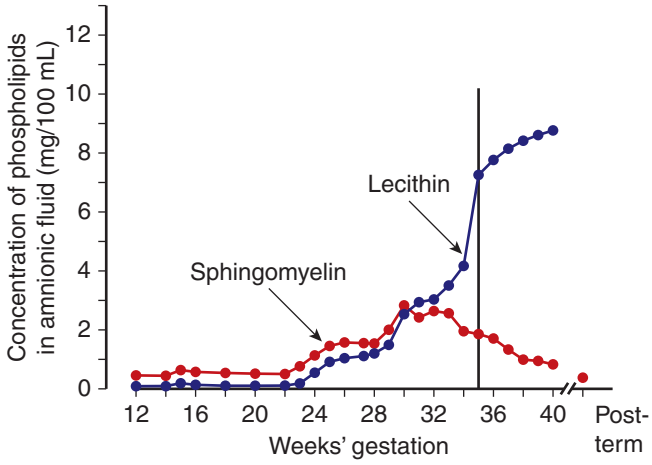

FIGURE 29-1 Changes in mean concentrations of lecithin and sphingomyelin in amniotic fluid during gestation in normal pregnancy. (This figure was published in *American Journal of Obstetrics & Gynecology,* Vol. 115, No. 4, L Gluck and MV Kulovich, Lecithin-sphingomyelin ratios in amniotic fluid in normal and abnormal pregnancy, pp. 539–546, Copyright Elsevier 1973.)

many years was the gold-standard test. Dipalmitoylphosphatidylcholine—DPPC, that is, lecithin—along with phosphatidylinositol and especially phosphatidylglycerol is an important component of the surface-active layer that prevents alveolar collapse (see Chap. 4, p. 96). Before 34 weeks, lecithin and sphingomyelin are present in amniotic fluid in similar concentrations. At 32 to 34 weeks, the concentration of lecithin relative to sphingomyelin begins to rise (Fig. 29-1).

Gluck and co-workers (1971) reported that the risk of neonatal respiratory distress is slight whenever the concentration of lecithin is at least twice that of sphingomyelin (L/S ratio). Conversely, there is increased risk of respiratory distress when this ratio is below 2 (Table 29-1). Because lecithin and sphingomyelin are found in blood and meconium, contamination with these substances may lower a mature L/S ratio (Buhi and Spellacy, 1975).

Phosphatidylglycerol (PG). It was held for many years that respiratory distress may develop despite an L/S ratio greater than 2 in infants of women with diabetes. Some recommend that phosphatidylglycerol be documented in amniotic fluid of these women. At this time, it is unclear if either diabetes, per se, or its level of control causes false-positive phospholipid test results for lung maturity (American College of Obstetricians and Gynecologists, 2008a).

Fluorescence Polarization. This automated assay measures the surfactant-to-albumin ratio in uncentrifuged amniotic fluid and gives results in approximately 30 minutes. When a ratio of 50 or greater was obtained with the commercially available *TDx-FLM* test, Steinfeld and colleagues (1992) predicted fetal lung maturity in 100 percent of cases. Subsequent investigators found the TDx-FLM to be equal or superior to the L/S ratio, foam stability index, or phosphatidylglycerol assessment, including in diabetic pregnancies (Eriksen and associates, 1996; Karcher and co-workers, 2005). The recently modified *TDx-FLM II* is used by many hospitals as their first-line test of pulmonary maturity with a threshold value of 55 mg/g ratio (see Table 29-1).

Other Tests. The *foam stability* or *shake test* depends on the ability of surfactant in amniotic fluid, when mixed appropriately with ethanol, to generate stable foam at the air–liquid interface (Clements and associates, 1972). Problems include errors caused by slight contamination and frequent false-negative test results. Alternatively, the *Lumadex-FSI test, fluorescent polarization (microviscometry),* and *amniotic fluid absorbance at 650-nm wavelength* have all been used with variable success. The *lamellar body count* is a rapid, simple, and accurate method of assessing fetal lung maturity and is comparable to TDx-FLM and L/S ratio (Karcher and colleagues, 2005).

Retinopathy of Prematurity

Formerly known as *retrolental fibroplasia,* by 1950, retinopathy of prematurity had become the largest single cause of blindness in this country. After the discovery that the disease resulted from hyperoxemia, its frequency decreased remarkably. The fetal retina vascularizes centrifugally from the optic nerve starting at approximately the fourth month and continues until shortly after birth. During vascularization, excessive oxygen induces severe retinal vasoconstriction with endothelial damage and vessel obliteration, especially in the temporal portion. Neovascularization results, and the new vessels penetrate the retina and extend into the vitreous. Here, they are prone to leak proteins or burst with subsequent hemorrhage. Adhesions then form, which detach the retina.

Precise levels of hyperoxemia that can be sustained without causing retinopathy are not known. Preterm birth results in a "relative" hyperoxia compared with in utero oxygen content even in infants not exposed to higher FiO_2.

Intraventricular Hemorrhage

There are four major categories of intracranial hemorrhage in the neonate (Volpe, 1995). *Subdural hemorrhage* is usually the result of trauma. *Subarachnoid hemorrhage* and *intracerebellar hemorrhage* usually result from trauma in term infants and hypoxia in preterm infants. *Periventricular-intraventricular hemorrhage* results from either trauma or asphyxia in half of term infants and has no discernible cause in a fourth. In preterm neonates, the pathogenesis of periventricular hemorrhage is multifactorial and includes hypoxic-ischemic events, anatomical factors, coagulopathy, and many others. The prognosis after hemorrhage depends on its location and extent. For example, subdural and subarachnoid hemorrhage often result in minimal, if any, neurological abnormalities. Bleeding into the parenchyma, however, can cause serious permanent damage.

Periventricular–Intraventricular Hemorrhage

When the fragile capillaries in the germinal matrix rupture, there is bleeding into surrounding tissues that may extend into the ventricular system and brain parenchyma. This type of hemorrhage is common in preterm neonates, especially those born before 32 weeks, but it can also develop at later gestational ages and even in term neonates.

Most hemorrhages develop within 72 hours of birth, but they have been observed as late as 24 days (Perlman and Volpe, 1986). Because intraventricular hemorrhage usually is recognized

TABLE 29-1. Commonly Used Direct Tests of Fetal Lung Maturity

Test[a]	Technique	Time and Ease of Testing[b]	Threshold	Typical Predictive Value (Percent): Mature Negative-Predictive Value	Typical Predictive Value (Percent): Immature Positive-Predictive Value[c]	Blood Contamination Affects Results	Meconium Contamination Affects Results	Vaginal Pool Sample
Lecithin/sphingomyelin ratio	Thin-layer chromatography	4+	2–3.5	95–100	33–50	Yes	Yes	No
Phosphatidylglycerol	Thin-layer chromatography	4+	Present (usually greater than 3% of total phospholipids)	95–100	23–53	No	No	Yes
	Antisera with AminoStat-FLM	1+	0.5 = low positive; 2 = high positive	95–100	23–53	No	No	Yes
Fluorescence polarization	Fluorescence polarization with TDx-FLM II	1+	≥ 55 mg/g of albumin[d]	96–100	47–61	Yes	Yes	Yes
Foam-stability index	Ethanol added to amnionic fluid, solution shaken, presence of stable bubbles at meniscus noted	2+	≥ 47	95	51	Yes	Yes	No
Optical density at 650 nm	Spectrophotometric reading	1+	Optical density ≥ 0.15	98	13	NA	NA	NA
Lamellar body counts	Counts using counter commercial hematology	2+	30,000–40,000 (investigational)	97–98	29–35	Yes	No	NA

[a]Commercial versions are available for all tests except optical density and lamellar body counts.
[b]Range in complexity: 1+ indicates procedure is simple, procedure is available all the time, procedure time is short, and personnel effort is not intensive; 4+ indicates procedure is complex or difficult, time consuming, and therefore, frequently not available at all times.
[c]Positive-predictive value is the probability of neonatal respiratory distress syndrome when the fetal lung maturity test result is immature.
[d]The manufacturer has reformulated the product and revised the testing procedure. Currently, the threshold for maturity is 55; with the original assay, it was 70.
NA = not available.

within 3 days of delivery, its genesis is often erroneously attributed to birth events. It is important to realize that *prelabor* intraventricular hemorrhage also can occur (Achiron and associates, 1993; Nores and co-workers, 1996).

Almost half of hemorrhages are clinically silent, and most small germinal matrix hemorrhages and those confined to the cerebral ventricles resolve without impairment (Weindling, 1995). Large lesions can result in hydrocephalus or in degenerated cystic areas termed *periventricular leukomalacia* (p. 610). Importantly, the extent of periventricular leukomalacia correlates with the risk of cerebral palsy.

Pathology

There is damage to the germinal matrix capillary network, which predisposes to subsequent extravasation of blood into the surrounding tissue. In preterm infants, this capillary network is especially fragile for several reasons. First, the subependymal germinal matrix provides poor support for the vessels coursing through it. Secondly, venous anatomy in this region causes stasis and congestion, which makes vessels susceptible to bursting with increased intravascular pressure. Thirdly, vascular autoregulation is impaired before 32 weeks (Matsuda and colleagues, 2006; Volpe and Hill, 1987).

Even if extensive hemorrhage or other complications of preterm birth do not cause death, survivors can have major neurodevelopmental handicaps. DeVries and co-workers (1985) attribute most long-term sequelae of intraventricular-periventricular hemorrhage to *periventricular leukomalacia.* These degenerated cystic areas develop *most* commonly as a result of ischemia and *least* commonly in direct response to hemorrhage.

Incidence and Severity

The incidence of ventricular hemorrhage depends on gestational age at birth. Approximately half of all neonates born before 34 weeks but only 4 percent of those born at term will have some evidence of hemorrhage (Hayden and associates, 1985). Very-low-birthweight infants have the earliest onset of hemorrhage, the greatest likelihood of parenchymal tissue involvement, and thus the highest mortality rate (Perlman and Volpe, 1986). Preterm black infants are at disparate risk for intraventricular hemorrhage (Reddick and associates, 2008).

The severity of intraventricular hemorrhage can be assessed by neuroimaging studies. Papile and colleagues (1978) devised the most widely used grading scheme to quantify the extent of a lesion and estimate prognosis.

Grade I—hemorrhage limited to the germinal matrix
Grade II—intraventricular hemorrhage
Grade III—hemorrhage with ventricular dilatation
Grade IV—parenchymal extension of hemorrhage

Jakobi and colleagues (1992) showed that infants with grade I or II intraventricular hemorrhage had a greater than 90-percent survival rate and a 3-percent rate of handicap—similar to control infants of the same age. The survival rate for infants with grade III or IV hemorrhage, however, was only 50 percent. Extremely-low-birthweight infants with grade I or II hemorrhage have poorer neurodevelopmental outcomes at 20 months than controls (Patra and associates, 2006). The most recent data from the Neonatal Research Network indicate that 30 percent of infants born weighing 501 to 1500 g develop intracranial hemorrhage, and 12 percent are grade III or IV (Fanaroff and colleagues, 2007).

Contributing Factors. Events that predispose to germinal matrix hemorrhage and subsequent periventricular leukomalacia are multifactorial and complex. As discussed, the preterm fetus has fragile intracranial blood vessels that make it particularly susceptible. Moreover, preterm birth is frequently associated with infection, which further predisposes to endothelial activation, platelet adherence, and thrombi (Redline and associates, 2008). Luthy and co-workers (1987) reported a threefold increased risk for grade III or IV hemorrhage in neonates with a cord arterial pH < 7.2. Respiratory distress syndrome and mechanical ventilation are commonly associated factors (Sarkar and co-workers, 2009). Lesko and colleagues (1986) reported that heparin, often used to maintain vascular catheter patency in intensive care units, was associated with a fourfold increased risk of geminal matrix hemorrhage.

Prevention with Antenatal Corticosteroids

Administration of corticosteroids at least 24 hours before delivery appears to prevent or reduce the incidence and severity of intraventricular hemorrhage. A Consensus Development Conference of the National Institutes of Health (1994) concluded that such therapy reduced rates of mortality, respiratory distress, and intraventricular hemorrhage in preterm infants born between 24 and 32 weeks and that the benefits were additive with those from surfactant therapy. The consensus panel also concluded that benefits of antenatal steroid therapy probably extend to women with preterm premature membrane rupture. A second consensus statement by the National Institutes of Health (2000) recommended that repeated courses of corticosteroids should not be given because there were insufficient data to prove benefit or to document the safety of multiple courses (see Chap. 36, p. 821).

Subsequently, the Maternal Fetal Medicine Units Network reported that repeated corticosteroid courses were associated with some improved preterm neonatal outcomes, but also with reduced birthweight and increased risk for fetal-growth restriction (Wapner and colleagues, 2006). Surveillance of this cohort through age 2 to 3 years found that children exposed to repeated—versus single-dose steroid courses—did not differ significantly in physical or neurocognitive measures (Wapner and colleagues, 2007). It was worrisome, however, that there was a nonsignificant 5.7-fold relative risk of cerebral palsy in infants exposed to multiple steroid courses. At the same time, the 2-year follow-up of the Australasian Collaborative Trial was reported by Crowther and associates (2007). In more than 1100 infants, the incidence of cerebral palsy was almost identical—4.2 versus 4.8 percent—in those given repeated versus single-course steroids, respectively.

Another possibility is "rescue-dose corticosteroid" therapy. Garite and co-workers (2009) evaluated short-term outcomes in 437 women who completed the initial steroid course before 30 weeks, but at least 14 days had elapsed. These women were

randomized to receive a single additional "rescue dose" of corticosteroid versus placebo. For those delivered < 34 weeks, the steroid group had significantly less respiratory distress syndrome, ventilator support, and surfactant use.

Studies with follow-up of more than 30 years are now being reported from the New Zealand cohort of adults exposed to single-dose antenatal steroids. Treatment was not associated with neuropsychological or cardiovascular dysfunction, but there was a slightly increased rate of insulin resistance compared with that of the placebo group (Dalziel and co-workers, 2005a, b).

As discussed in Chapter 36 (p. 821), at this time, we follow recommendations for single-course therapy by the American College of Obstetricians and Gynecologists (2008b).

Other Preventative Methods. The efficacy of *phenobarbital*, *vitamin K*, *vitamin E*, or *indomethacin* in diminishing the frequency and severity of intracranial hemorrhage, when administered either to the neonate or to the mother during labor, remains controversial (Chiswick, 1991; Hanigan, 1988; Thorp, 1995, and all their colleagues). Data from a variety of sources suggest that *magnesium sulfate* may prevent the sequelae of periventricular hemorrhage, as discussed on page 614.

It is generally agreed that avoiding significant hypoxia both before and after preterm delivery is of paramount importance (Low and co-workers, 1995). There is presently no convincing evidence, however, that routine cesarean delivery for the preterm fetus presenting cephalic will decrease the incidence of periventricular hemorrhage. Anderson and associates (1992) found no significant difference in the overall *frequency* of hemorrhage in infants whose birthweights were below 1750 g and who were delivered without labor compared with those delivered during latent or active labor. Infants delivered of mothers in active labor, however, tended to have more grade III or IV hemorrhages.

Periventricular Leukomalacia

This pathological description refers to cystic areas deep in brain white matter that develop after hemorrhagic *or* ischemic infarction. Tissue ischemia leads to regional necrosis, and because brain tissue does not regenerate, these irreversibly damaged areas appear as echolucent cysts on neuroimaging studies. They generally require at least 2 weeks to develop but have been reported to develop as long as 4 months after the initial insult. Thus, their presence at birth may help to determine the timing of a hemorrhagic event.

Association with Cerebral Palsy

Allan and co-workers (1997) found that the highest rates of cerebral palsy in 505 infants weighing between 600 and 1250 g were associated with periventricular leukomalacia (37 percent) and ventriculomegaly (30 percent). DeVries and colleagues (1993) followed 504 infants born at 34 weeks or less. At least two thirds had localized cystic periventricular leukomalacia, and 100 percent of those with extensive cystic areas developed cerebral palsy. Conversely, only 11 percent of those with transient cysts developed cerebral palsy. Hsu and co-workers (1996) showed that the size of the cyst(s) correlates directly with the risk for cerebral palsy. Fujimoto and colleagues (1994) demonstrated that symmetrical cystic lesions convey the highest risk.

Intraventricular Hemorrhage as a Cause

A variety of clinical and pathological data link severe intraventricular hemorrhage—grade III or IV—and resulting periventricular leukomalacia to cerebral palsy (p. 612). As described earlier, grade I or II hemorrhages usually resolve without extensive tissue injury. Luthy and associates (1987) reported a 16-fold increased risk of cerebral palsy for low-birthweight infants who had grade III or IV hemorrhage compared with the risk in infants who had either none or grade I or II hemorrhage.

Ischemia as a Cause

Consideration of brain development explains why very preterm infants are most susceptible to ischemia and periventricular leukomalacia. Before 32 weeks, the vascular anatomy of the brain is composed of two systems. One penetrates into the cortex—the *ventriculopedal system.* The other reaches down to the ventricles, but then curves to flow outward—the *ventriculofugal system* (Weindling, 1995). There are no vascular anastomoses connecting these two systems. As a result, the area between these systems, through which the pyramidal tracts pass near the lateral cerebral ventricles, is a watershed area vulnerable to ischemia. Vascular insufficiency before 32 weeks leading to ischemia would affect this watershed area first. Resulting damage of the pyramidal tracts would cause spastic diplegia. After 32 weeks, vascular flow shifts toward the cortex. Thus, hypoxic injury after this time primarily damages the cortical region.

Perinatal Infection as a Cause

Periventricular leukomalacia is more strongly linked to infection and inflammation than to intraventricular hemorrhage. Zupan and associates (1996) studied 753 infants born between 24 and 32 weeks, 9 percent of whom developed periventricular leukomalacia. Those born before 28 weeks or who had inflammatory events during the last days to weeks before delivery or who had both were at highest risk. Perlman and co-workers (1996) found that periventricular leukomalacia was strongly associated with prolonged membrane rupture, chorioamnionitis, and neonatal hypotension. Bailis and associates (2009) reported that chronic—and not acute—placental inflammation was associated with leukomalacia.

Fetal infection may be the key element in the pathway between preterm birth, intracranial hemorrhage, periventricular leukomalacia, and cerebral palsy (Dammann and Leviton, 1997; Yoon and colleagues, 1997a, 2000, 2001). In the pathway proposed in **Figure 29-2**, antenatal reproductive tract infection evokes the production of cytokines such as tumor necrosis factor and interleukins-1, -6, and -8. These in turn stimulate prostaglandin production and preterm labor (see Chap. 36, p. 812). Preterm intracranial blood vessels are susceptible to rupture and damage, and the cytokines that stimulate preterm labor also have direct toxic effects on oligodendrocytes and myelin. Vessel rupture, tissue hypoxia, and cytokine-mediated damage result in massive neuronal cell death. Glutamate is released, stimulating membrane receptors to allow excess calcium to enter the neurons. High intracellular calcium levels are toxic to white matter, and glutamate may be directly toxic to oligodendrocytes (Oka and associates, 1993).

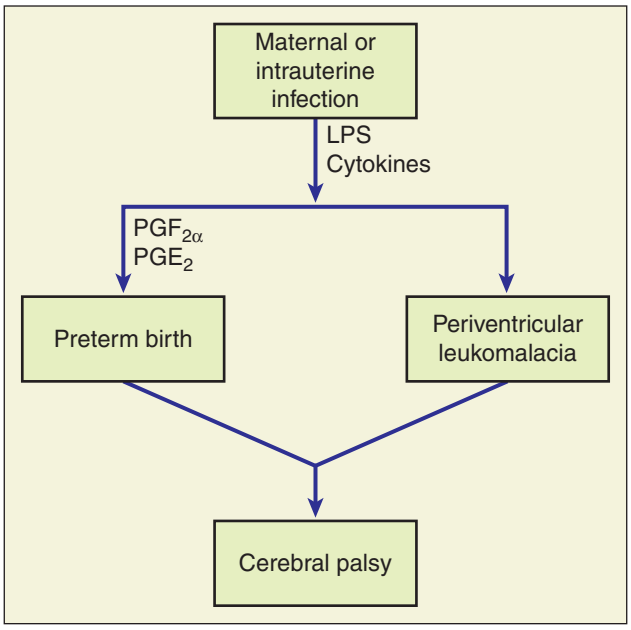

FIGURE 29-2 Schematic representation of the hypothesized pathway between maternal or intrauterine infection and preterm birth or periventricular leukomalacia. Both potentially lead to cerebral palsy. LPS = lipopolysaccharide; PG = prostaglandin.

Many studies have shown that infection and cytokines can directly damage the immature brain. Inoculation of rabbit embryos with *Escherichia coli* causes histological damage in white matter (Yoon and colleagues, 1997a). Moreover, tumor necrosis factor and interleukin-6 were more frequently found in the brains of infants who died with periventricular leukomalacia (Yoon and co-workers, 1997b). Cytokines are strongly linked to white matter lesions even when organisms cannot be demonstrated (Yoon and associates, 2000).

Infection appears to be important even when separated from preterm birth. Verma and colleagues (1997) studied outcomes in 285 infants born after preterm labor and 279 infants born after preterm prematurely ruptured membranes. These researchers compared these outcomes with those of 149 infants who were delivered preterm for other reasons. The incidence and severity of intraventricular hemorrhage and periventricular leukomalacia were highest in those infants with spontaneous labor or membrane rupture and were increased even more with chorioamnionitis. Grether and Nelson (1997) studied children whose birthweight was greater than 2500 g and found a ninefold increased risk of cerebral palsy with either intrapartum maternal fever or chorioamnionitis. They noted a 19-fold risk if there was neonatal infection. Wu and co-workers (2003) studied more than 231,500 singletons born at ≥ 36 weeks and reported a fourfold increased risk of cerebral palsy with clinical chorioamnionitis. Finally, Stoll and colleagues (2004) studied 6093 extremely-low-birthweight infants and found neonatal infections to be associated with a 50-percent rate of neurodevelopmental impairment.

Andrews and co-workers (2008) recently provided data that raise questions regarding an increased incidence of adverse neurodevelopmental outcomes related to chorioamnionitis. In a cohort of infants born between 23 and 32 weeks, they studied a number of surrogate indicators and direct markers of in utero inflammation that included clinical findings, cytokine levels, histological findings, and microbial culture results. Infants undergoing comprehensive psychoneurological testing had similar incidences of IQ < 70, cerebral palsy, or both, regardless of these markers. They interpreted their findings to support current practices that employ efforts to delay delivery with preterm pregnancies in the absence of overt intrauterine infection. This does not apply to preterm pregnancies in which *clinical chorioamnionitis* is diagnosed as illustrated by the Canadian Neonatal Network study reported by Soraisham and co-workers (2009). Of 3094 singletons born < 33 weeks, 15 percent had evidence of clinical chorioamnionitis—foul-smelling amnionic fluid, maternal fever, uterine tenderness, fetal tachycardia, and maternal leukocytosis. Compared with noninfected infants, those in the latter group had significantly increased rates of early-onset sepsis—4.8 versus 0.9 percent—and some intraventricular hemorrhage—22 versus 12 percent.

Brain Disorders

Few events evoke more fear and apprehension in parents and obstetricians than the specter of "brain damage." This term immediately conjures visions of disabling cerebral palsy and hopeless mental retardation. Although most brain disorders or injuries are less horrific, they nevertheless are a major source of psychological and economical damage.

The persistence for so many years of the presumed birth-injury etiology for cerebral damage was a major reason for the escalating rate of cesarean delivery through the 1970s and 1980s. Because in most cases, the injury for cerebral palsy does not occur peripartum, increases in cesarean delivery rates did not result in a significant decline in cerebral palsy rates.

Brain disorders or damage, including cerebral palsy, are a complex and multifactorial process caused by a combination of genetic, physiological, environmental, and obstetrical factors. For years, the term *birth asphyxia*—indicating a neurological injury during birth—was inappropriately applied to many infants. Fortunately, objective definitions have subsequently evolved. To clarify the potential role of intrapartum events in causing permanent neurological injury, the American College of Obstetricians and Gynecologists (1998, 2004) developed a precise definition of birth asphyxia that includes all of these three:

1. Profound metabolic or mixed acidemia (pH < 7.0) determined on an umbilical cord arterial blood sample
2. Persistent Apgar score of 0 to 3 for longer than 5 minutes
3. Evidence of neonatal neurological sequelae such as seizures, coma, or hypotonia or of dysfunction of one or more of the following systems: cardiovascular, gastrointestinal, hematological, pulmonary, or renal.

When these three factors are associated with brain injury, they suggest that perinatal *hypoxic ischemic encephalopathy* developed. More importantly, their absence helped to forge the crucial link between *antepartum* events that cause most cases of cerebral palsy.

Neonatal Encephalopathy

The American College of Obstetricians and Gynecologists and the American Academy of Pediatrics (2003) convened the Task Force on Neonatal Encephalopathy and Cerebral Palsy to review scientific data on these topics. It defined encephalopathy as some combination of abnormal consciousness, tone, reflexes, feeding, respiration, or seizures in the term or near-term infant. The Task Force concluded that there were many different causes, which may or may not result in permanent sequelae—cerebral palsy being but one. Moreover, cerebral palsy can be attributed to an intrapartum event only if the affected child develops *hypoxic ischemic encephalopathy.* Further, of the several forms of cerebral palsy, only the spastic quadriplegic type can result from an acute interruption of blood supply prior to delivery. Hemiparetic or hemiplegic cerebral palsy, spastic diplegia, and ataxia are unlikely to result from an intrapartum event. Purely dyskinetic or ataxic cerebral palsy, especially when accompanied by a learning disorder, usually has a genetic origin (Nelson and Grether, 1998).

Although there is no doubt that some cases of cerebral palsy arise from intrapartum hypoxic–ischemic events, accumulated data indicate that at least 70 percent of all cases of neonatal encephalopathy result from an event *prior* to the onset of labor. To address this, the Task Force developed four essential criteria that, if all are present, define an acute intrapartum event sufficient to cause cerebral palsy:

1. Evidence of metabolic acidosis in fetal umbilical arterial blood obtained at delivery: pH < 7.0 *and* base deficit of ≥ 12 mmol/L
2. Early onset of severe or moderate neonatal encephalopathy in infants born at 34 or more weeks
3. Cerebral palsy of spastic quadriplegic or dyskinetic type
4. Exclusion of other possible etiologies such as trauma, coagulation disorders, infections, or genetic disorders.

The Task Force also developed five criteria that, if occurring together, suggest that the supposed insult occurred within 0 to 48 hours of delivery:

1. A sentinel hypoxic event occurring immediately before or during labor
2. Sudden and sustained fetal bradycardia or the absence of fetal heart rate variability in the presence of persistent, late, or variable decelerations, usually after a hypoxic sentinel event when the fetal heart rate pattern was previously normal
3. Apgar scores of 0 to 3 beyond 5 minutes
4. Onset of multisystem dysfunction within 72 hours of birth
5. Early imaging study showing evidence of acute, nonfocal cerebral abnormality.

Strijbis and associates (2006) applied these criteria to 213 children with cerebral palsy and found them useful to audit causation and to exclude primary intrapartum hypoxia.

Prophylactic Hypothermia. Recent trials have demonstrated the efficacy of hypothermia for hypoxic ischemic encephalopathy to prevent death and moderate-to-severe disability in term infants (Gluckman and colleagues, 2005; Shankaran and associates, 2005). Total body cooling therapy to 33.5°C is based on extensive animal literature, which shows that a reduction in brain temperature immediately after a hypoxic-ischemic insult improves outcome. Its use is currently investigational pending outcomes from ongoing randomized trials (Blackmon and Stark, 2006).

Cerebral Palsy

This term refers to a group of conditions that are characterized by chronic movement or posture abnormalities that are cerebral in origin, arise early in life, and are nonprogressive (Nelson, 2003). Epilepsy and mental retardation frequently accompany cerebral palsy but seldom are associated with perinatal asphyxia in the absence of cerebral palsy.

Cerebral palsy is commonly classified by the type of neurological dysfunction—spastic, dyskinetic, or ataxic—as well as the number and distribution of limbs involved—quadriplegia, diplegia, hemiplegia, or monoplegia. The major types and their frequencies are:

- *Spastic quadriplegia,* which has a strong association with mental retardation and seizure disorders—20 percent
- *Diplegia,* which is common in preterm or low-birthweight infants—30 percent
- *Hemiplegia*—30 percent
- *Choreoathetoid types*—15 percent
- *Mixed varieties* (Freeman and Nelson, 1988; Rosen and Dickinson, 1992).

Significant mental retardation, defined as an intelligence quotient (IQ) of less than 50, is associated with 25 percent of cerebral palsy cases.

Incidence and Epidemiological Correlates. According to the Centers for Disease Control and Prevention, the prevalence of cerebral palsy in the United States was 3.1 per 1000 children in 2000 (Bhasin and co-workers, 2006). Importantly, this rate either has remained essentially unchanged or has increased since the 1950s (Torfs and colleagues, 1990; Winter and associates, 2002). In some countries, the incidence has risen because advances in the care of very preterm infants have improved their survival, but not their neurological prognosis. For example, Moster and co-workers (2008) presented long-term follow-up studies of more than 900,000 births in Norway entered into the compulsory national registry. Of nonanomalous term infants, the rate of cerebral palsy was 0.1 percent compared with 9.1 percent in those born at 23 to 27 weeks. The figures for mental retardation for infants born in these epochs were 0.4 versus 4.4 percent, respectively.

Nelson and Ellenberg (1984, 1985, 1986a, b) have made seminal observations to our understanding of cerebral palsy. Their studies included data from the Collaborative Perinatal Project, which followed offspring of almost 54,000 pregnancies until age 7. They found that the important antecedents and most commonly associated risk factors for cerebral palsy were: (1) evidence of genetic abnormalities, such as maternal mental retardation, fetal microcephaly, and fetal congenital malformations; (2) birthweight less than 2000 g; (3) gestational age at birth less than 32 weeks; and (4) infection. Obstetrical complications were not strongly predictive of cerebral palsy. Indeed, only approximately

TABLE 29-2. Prenatal and Perinatal Risk Factors in Children with Cerebral Palsy

Risk Factors	Risk Ratio	95% CI
Long menstrual cycle (>36 days)[a]	9.0	2.2–37.1
Hydramnios[a]	6.9	1.0–49.3
Premature placental separation[a]	7.6	2.7–21.1
Intervals between pregnancies < 3 months or > 3 years	3.7	1.0–4.4
Birthweight < 2000 g[a]	4.2	1.8–10.2
Spontaneous preterm labor	3.4	1.7–6.7
Preterm delivery at 23–27 weeks	78.9	56.5–110
Breech, face, or transverse lie[a]	3.8	1.6–9.1
Severe birth defect[a]	5.6	8.1–30.0
Nonsevere birth defect	6.1	3.1–11.8
Time to cry > 5 minutes[a]	9.0	4.3–18.8
Low placental weight[a]	3.6	1.5–8.4

[a]Also associated with cerebral palsy in the Collaborative Perinatal Project.
From Livinec (2005), Moster (2008), Nelson and Ellenberg (1985, 1986a, b), Torfs (1990), and all their colleagues.

20 percent of affected children had markers of perinatal asphyxia. By contrast, more than half had associated congenital malformations, low birthweight, microcephaly, or another explanation for the brain disorder. They concluded that the causes of most cerebral palsy cases were unknown and that no foreseeable single intervention would likely prevent a large proportion of cases.

Torfs and associates (1990) reported similar findings in 55 children with cerebral palsy from more than 19,000 enrolled in the California Child Health and Development Studies. The strongest predictors of cerebral palsy included a congenital anomaly, low birthweight, low placental weight, or abnormal fetal position. These factors were similar to those identified in the Collaborative Perinatal Project (Table 29-2). Interestingly, cesarean delivery or low-, mid-, and even high-forceps delivery did not correlate with cerebral palsy (see Chap. 25, p. 545). Similarly, the Maternal Fetal Medicine Units Network studied nearly 800 infants with birthweights less than 1000 g and showed that only low birthweight and early gestational age correlated with neonatal neurological morbidity (Goepfert and associates, 1996). From Sweden, Thorngren-Jerneck and Herbst (2006) studied 2306 infants with cerebral palsy and found that preterm birth was a factor in a third. Other risk factors included fetal-growth disorders, placental abruption, type 1 diabetes, preeclampsia, and maternal age older than 40 years (Wu and associates, 2006). A high incidence of microcephaly in neonates with isolated congenital heart lesions was reported by Barbu and co-workers (2009). This finding led them to speculate that brain injury was due to chronic fetal hypoxemia.

Redline (2005, 2008) has made important observations concerning correlation of placental lesions with neurodevelopmental abnormalities (see Chap. 27, p. 585). Perhaps related, Gibson and associates (2005) found that some inherited fetal thrombophilias were associated with cerebral palsy.

Intrapartum Events. The Task Force on Neonatal Encephalopathy and Cerebral Palsy determined that only 1.6 cases of cerebral palsy per 10,000 deliveries are attributable solely to intrapartum hypoxia. This finding is supported by many studies. For example, Stanley and Blair (1991) performed a case-control study of all cases of cerebral palsy in Western Australia from 1975 to 1980. They reported that intrapartum injury as the cause of cerebral palsy was unlikely in 92 percent of cases; in 3.3 percent, it was possible; and in only 4.9 percent was it likely. Phelan and associates (1996) reviewed fetal monitor tracings from 209 infants with neonatal neurological impairment and classified 75 percent as nonpreventable. Strijbis and associates (2006) could attribute only 2 percent of 213 cases of cerebral palsy to intrapartum hypoxia.

Consistent with this, data from a variety of sources indicate that continuous electronic fetal monitoring in labor neither predicts nor reduces the risk of cerebral palsy compared with intermittent auscultation (Clark and Hankins, 2003; Grant, 1989; MacDonald, 1985; Thacker, 1995, and all their associates). These and other studies led the American College of Obstetricians and Gynecologists (2005) to conclude that electronic fetal monitoring does not reduce the incidence of long-term neurological impairment.

Importantly, there does not appear to be any specific fetal heart rate pattern that predicts cerebral palsy, and a number of studies have found no relationship between the clinical response to abnormal fetal heart rate patterns and neurological outcome (Melone, 1991; Nelson, 1996; Niswander, 1984, and all their colleagues). In fact, an abnormal heart rate pattern in fetuses who ultimately develop cerebral palsy may reflect preexisting neurological abnormality and not ongoing, remedial injury (Phelan and Ahn, 1994).

Apgar Scores. A variety of data show that Apgar scores alone are generally poor predictors of neurological impairment. Nelson and Ellenberg (1984) reported that in the absence of obstetrical complications, low Apgar scores alone were not associated with a high level of risk. In infants who had 5-minute

Apgar scores of 3 or less combined with a complicated birth, however, the incidence of cerebral palsy was increased appreciably. Dijxhoorn and colleagues (1986) reported similar findings. The American College of Obstetricians and Gynecologists (1996) concluded that low Apgar scores at 1 and 5 minutes identify infants who need resuscitation, but that alone these are not evidence for hypoxia sufficient to result in neurological damage (see Chap. 28, p. 594). Exceptions are survivors with Apgar scores of zero at 10 minutes. Harrington and colleagues (2007) reviewed 94 such infants admitted alive to the neonatal intensive care unit—78 died, and all survivors who were assessed had long-term disabilities.

Umbilical Cord Blood Gas Studies. An important part of the definition of neonatal asphyxia is metabolic acidosis (see Chap. 28, p. 595). In its absence, significant intrapartum hypoxia or asphyxia generally is excluded. When used alone, however, umbilical cord acid-base determinations have proven no more helpful than the 1- and 5-minute Apgar scores in predicting long-term neurological sequelae. Dijxhoorn and associates (1986) studied 805 term newborns delivered vaginally. They reported that the largest number of neurologically abnormal infants had low Apgar scores but a normal cord arterial pH. This indicated that intrapartum hypoxia was not the major cause of neurological morbidity.

Data from several studies demonstrate that a pH < 7.0 is the threshold for clinically significant acidemia (Gilstrap and associates, 1989; Goldaber and colleagues, 1991). In a later study of more than 150,000 infants, Casey and co-workers (2001) used umbilical artery pH to assess the predictability of neonatal death within 28 days. As the pH fell to 7.0 or less, the likelihood of neonatal death escalated and increased 1400-fold with a cord pH of 6.8 or lower in term newborns. When the cord pH was 7.0 or less and the 5-minute Apgar score was 0 to 3, the relative risk of neonatal death was increased by 3204!

Newborn complications increase coincident with the severity of acidemia at birth. According to the American College of Obstetricians and Gynecologists (2006c), encephalopathy develops in 10 percent of newborns whose umbilical arterial base deficit is 12 to 16 mmol/L, and in 40 percent whose deficit is > 16 mmol/L.

Nucleated Red Blood Cells. These immature red cells enter the circulation in response to hypoxia or hemorrhage. Their quantification has been proposed as a measure of hypoxia. And because increased production of nucleated red cells takes place over time, it has been suggested that these counts can be used to measure the duration of hypoxia (Naeye and Localio, 1995). Most studies do not support this, and others have not been able to reproduce these findings (Hankins and co-workers, 2002; Silva and colleagues, 2006). As summarized by the Task Force on Neonatal Encephalopathy and Cerebral Palsy, the significance of both nucleated erythrocytes and lymphocytes as markers for hypoxic injury is currently imprecise and unclear.

Prevention

In preterm infants, corticosteroid therapy may reduce the incidence of intraventricular hemorrhage as discussed on page 609. In addition, prophylaxis or aggressive treatment of infection may protect against neurological injury.

Because epidemiological evidence suggested that maternal magnesium sulfate therapy had a fetal neuroprotective effect, three large randomized trials have been performed to investigate this hypothesis. An Australian randomized trial by Crowther and colleagues (2003) included 1063 women at imminent risk of delivery before 30 weeks. A multicenter French trial reported by Marret and associates (2008) included 573 pregnancies at < 33 weeks. The most convincing evidence for magnesium neuroprotection is from the National Institute of Child Health and Human Development (NICHD) Maternal-Fetal Medicine Units Network study reported by Rouse and colleagues (2008). The *Beneficial Effects of Antenatal Magnesium Sulfate—BEAM—Study* randomized more than 2220 women at 24 to 31 weeks, most with either preterm labor or preterm prematurely ruptured membranes. Mortality rates were not affected, but rates of *moderate or severe cerebral palsy* were significantly lower in the magnesium-exposed children whose mothers were enrolled between 24 and 27 weeks. Doyle and co-workers (2009) performed a Cochrane database meta-analysis of these and two other studies, totaling 6145 women at risk for preterm birth. They reported significantly decreased rates of cerebral palsy—RR 0.68 (0.54 to 0.87) as well as gross motor dysfunction—RR 0.61 (0.44 to 0.85) in infants exposed to magnesium compared with those in nonexposed infants. These results are discussed in detail in Chapter 36 (p. 824).

Neuroimaging Studies

The use of sonography, computed-tomography, and magnetic-resonance imaging studies has greatly added to the understanding of the etiology and evolution of perinatal brain lesions, including hypoxic-ischemic encephalopathy. According to the Task Force, imaging studies are generally normal if performed on the day of birth in an infant with perinatal asphyxia (American College of Obstetricians and Gynecologists, 2003). Magnetic resonance (MR) with diffusion-weighted imaging (DWI) will show evidence of injury by approximately 24 hours. Abnormal diffusion peaks at approximately 5 days and disappears within 2 weeks. Computed tomography (CT) scans show decreased density in the thalami or basal ganglia after 24 hours, and these persist for 5 to 7 days. On sonography, there is increasing echogenicity in the thalami and basal ganglia, which progresses over 2 to 3 days and persists for 5 to 7 days. The Task Force concluded that imaging studies are helpful in timing an injury, but provide only a window in time without absolute precision.

MR imaging is the best diagnostic method to identify and characterize neonatal strokes (Nelson and Lynch, 2004; Raju and colleagues, 2007). Woodward and associates (2006) studied 167 infants born before 30 weeks. In 21 percent, moderate-to-severe abnormalities of white matter were identified by MR imaging done at term-equivalent weeks of age. These abnormalities were associated with three- to 10-fold increases in cognitive and motor delay, cerebral palsy, and neurosensory impairment. Wu and co-workers (2006) studied 273 infants born after 36 weeks who were later diagnosed with cerebral palsy. Of these, 227 were studied by MR imaging and 46 by CT

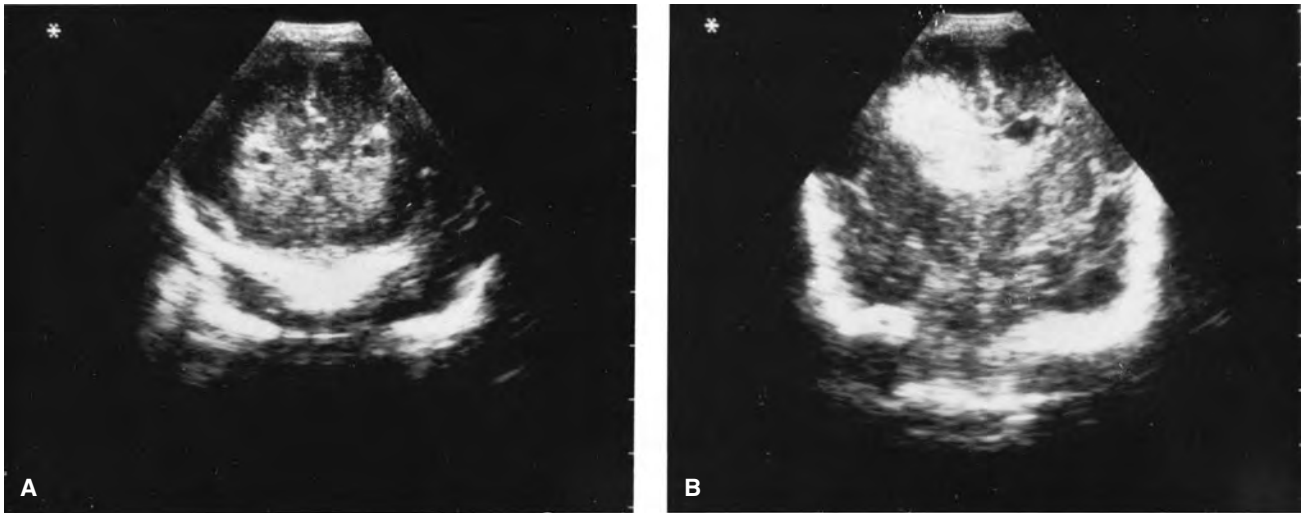

FIGURE 29-3 Preterm infant delivered at 27 weeks because of placental abruption. **A.** Sonogram of the head performed on the first postnatal day shows small bilateral cysts in the periventricular white matter and bilateral germinal-matrix hemorrhages. These findings indicate a much older lesion than one caused by perinatal asphyxia. **B.** A second sonographic evaluation on day 3 of life showed bilateral intraventricular hemorrhage and a large right-sided intraparenchymal echodensity. (Used with from Dr. Jeffrey M. Perlman.)

scanning. A third of all of these studies were normal; focal arterial infarction was seen in 22 percent; brain malformations in 14 percent; and periventricular white-matter injuries in 12 percent. Bax and co-workers (2006) used MR imaging to study 351 children who had cerebral palsy. Almost 88 percent of MR scans were abnormal. The most common finding was white-matter damage including periventricular leukomalacia—43 percent, basal ganglia lesions—13 percent, cortical and subcortical lesions—9 percent, malformations—9 percent, and focal infarcts—7 percent.

Cranial sonography also provides useful information. For example, Locatelli and colleagues (2009) found a significantly increased incidence of neurological damage in the 20 percent of 225 preterm infants who had intraventricular hemorrhage, periventricular leukomalacia, or both. The development of periventricular leukomalacia is shown in **Figure 29-3**. In this case, because cysts take days to weeks to develop, a sonographic examination performed on day 1 was critical in diagnosing *antenatal* brain injury. Intraventricular hemorrhage was found to be a secondary insult that developed in the nursery. In some infants, sonography provides findings different but complementary to those of CT scanning. In **Figure 29-4**, grade III intraventricular hemorrhage was seen at birth by CT scanning, but sonographic examination done the same day also identified periventricular leukomalacia from an injury well before birth.

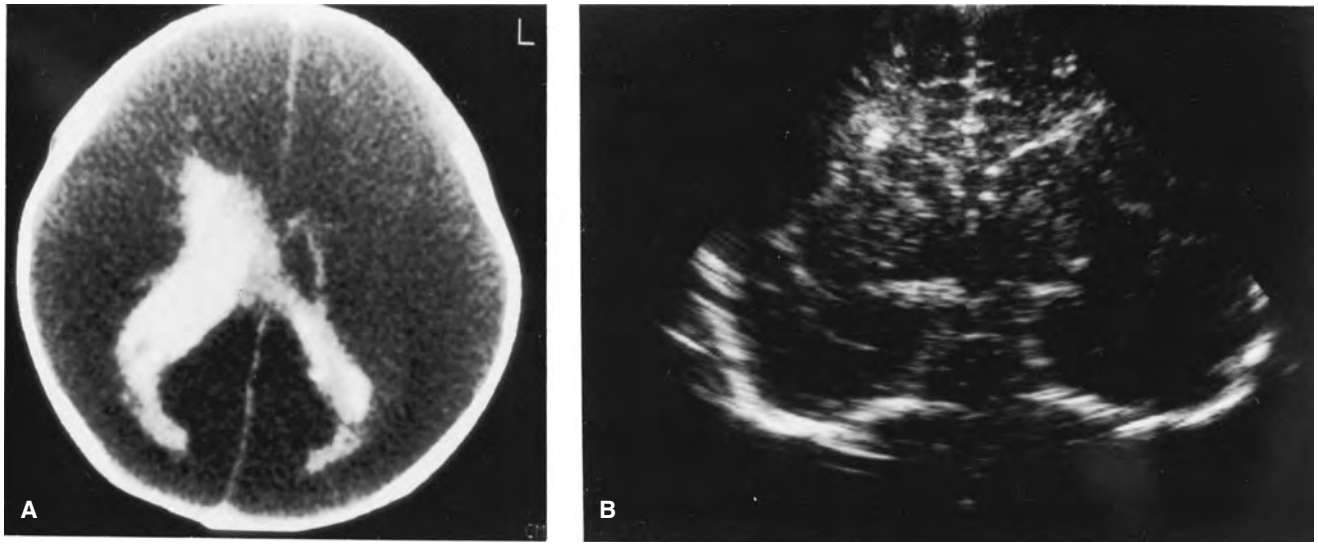

FIGURE 29-4 This term infant was born depressed. **A.** The computed tomographic (CT) scan done on day 1 demonstrates a grade III intraventricular hemorrhage. **B.** Sonogram confirmed intraventricular hemorrhage, however, bilateral cystic periventricular leukomalacia was also seen, which was not observed on the CT scan. These findings documented a severe antenatal brain insult of 4 to 5 weeks' duration. (From Perlman and Cunningham, 1993.)

Computed tomographic and MR imaging have also been used in older children to define the timing of cerebral injury. Some children were born preterm, but others were at term. For example, Wiklund and colleagues (1991a, b) studied children between 5 and 16 years of age with hemiplegic cerebral palsy—28 of these had been born preterm, whereas 83 were born at term. Almost 75 percent of all 111 children had abnormal CT findings. In more than half of term infants, CT findings suggested a *prenatal* injury. In contrast, as many as 70 percent of those delivered preterm had findings that confirmed an insult in early *postnatal* life. Cortical and subcortical injury suggestive of a perinatal injury was found in 19 percent.

Neonatal Encephalopathy in Term Infants

Mature infants also can suffer neurological insults, resulting in permanent compromise. Recall that neonatal encephalopathy is a defined syndrome of disturbed neurological function consisting of difficulty in initiating and maintaining respiration, depressed tone and reflexes, subnormal level of consciousness, and frequently, seizures. It generally is believed to be the consequence of a hypoxic-ischemic insult, although the timing of the insult is not always known. *Mild encephalopathy* is generally defined as hyperalertness, irritability, jitteriness, and hypertonia and hypotonia. *Moderate encephalopathy* includes lethargy, severe hypertonia, and occasional seizures, whereas *severe encephalopathy* is defined by coma, multiple seizures, and recurrent apnea.

Severe encephalopathy is a more important predictor of cerebral palsy and future cognitive defects than either mild or moderate types (Robertson and Finer, 1985). Poor postnatal brain growth is an early sign of neurological compromise. In one study, Cordes and colleagues (1994) performed serial head circumference measurements of 54 term infants with hypoxic-ischemic encephalopathy. They found that a 3.1-percent difference in the expected/observed head circumference in the first 4 months of life was predictive of microcephaly. Permanent impairment was predictable with 90-percent specificity.

Mental Retardation

Severe mental retardation has a prevalence of 3 per 1000 children. Etiological factors are shown in Table 29-3. Some genetic causes are discussed throughout Chapter 12. Preterm birth is a common association (Moster and colleagues, 2008). Isolated mental retardation—without epilepsy or cerebral palsy—is seldom associated with perinatal hypoxia (Nelson and Ellenberg, 1984, 1985, 1986a, b).

Seizure Disorders

The incidence of seizure disorders in infants < 1000 g was reported to be 9 percent in an Italian study (Falchi and colleagues, 2009). Although these may accompany cerebral palsy, isolated seizure disorders or epilepsy usually are not caused by perinatal hypoxia. Nelson and Ellenberg (1986b) determined that the major predictors of seizure disorders were fetal malformations—cerebral and noncerebral; family history of seizures; and neonatal seizures.

TABLE 29-3. Some Etiological Factors for Severe Mental Retardation

Factor	Percent	
Prenatal		**73**
Chromosomal	36	
Mutant genes	7	
Multiple congenital anomalies	20	
Acquired—infections, diabetes, growth restriction	10	
Perinatal		**10**
Asphyxia or hypoxia	5	
Unidentified causes	5	
Postnatal		**11**
Unknown		**6**

Necrotizing Enterocolitis

This newborn bowel disorder has clinical findings of abdominal distention, ileus, and bloody stools. There is usually radiological evidence of *pneumatosis intestinalis*—bowel wall gas derived from invading bacteria. Bowel perforation may prompt resection.

The disease is seen primarily in low-birthweight infants but occasionally is encountered in mature neonates. Various hypothesized causes include perinatal hypotension, hypoxia, sepsis, umbilical catheterization, exchange transfusions, and the feeding of cow milk and hypertonic solutions (Kliegman and Fanaroff, 1984). All of these can ultimately lead to intestinal ischemia, and reperfusion injury also likely has a role (Czyrko and associates, 1991). The unifying hypothesis for these pathological processes is the uncontrolled inflammatory response to bacterial colonization of the preterm intestine (Grave and coworkers, 2007).

Treatment for necrotizing enterocolitis is controversial. A randomized trial of laparotomy versus peritoneal drainage found no difference in survival in preterm infants (Moss and associates, 2006). In an observational study, however, Blakely and colleagues (2006) found that laparotomy had a more favorable outcome than drainage for death rates and neurodevelopmental outcomes assessed at 18 to 22 months.

Infant Outcomes in Extreme Preterm Birth

All of the concerns previously described are amplified in infants born at 22 to 25 weeks. Currently, depending on many factors, this gestational age range is considered the threshold of viability. This is discussed in detail in Chapter 36 (p. 807). Also discussed there are perinatal outcomes of these very- and extremely low-birthweight infants.

The Neonatal Research Network reviewed 4446 infants born at 22 to 25 weeks' gestation (Tyson and associates, 2008). They reported that the likelihood of a favorable outcome with intensive care can be estimated by consideration of gestational age, sex, exposure to antenatal corticosteroids, singleton versus

multifetal birth, and birthweight. Based on this, a tool is available for clinicians to utilize these factors (www.nichd.nih.gov/neonatal_estimates).

Anemia

After 35 weeks, the mean cord hemoglobin concentration is approximately 17 g/dL and values below 14 g/dL are abnormal. The neonatal hemoglobin value may rise as much as 20 percent if blood is transfused from the placenta. McDonald and Middleton (2008) performed a systematic review of 11 trials with nearly 3000 deliveries and compared early with late cord clamping. Late clamping was associated with a mean increase in hemoglobin concentration of 2.2 g/dL, however, it almost doubled the incidence of hyperbilirubinemia requiring phototherapy. Alternatively, if the placenta is cut or torn, if a fetal vessel is perforated or lacerated, or if the infant is held well above the level of the placenta for some time before cord clamping, the hemoglobin concentration may fall.

Fetal-to-Maternal Hemorrhage

Fetal red cells in the maternal circulation can be identified by use of the acid elution principle first described by Kleihauer, Brown, and Betke, or by any of several modifications. Fetal erythrocytes contain hemoglobin F, which is more resistant to acid elution than hemoglobin A. After exposure to acid, only fetal hemoglobin remains. Fetal red cells can then be identified by uptake of a special stain and quantified on a peripheral smear (Fig. 29-5). This test is accurate unless the maternal red cells carry excess fetal hemoglobin as the result of a hemoglobinopathy.

During all pregnancies, very small volumes of blood cells escape from the fetal compartment into the maternal intervillous space. This is important for several reasons. It is the cause of maternal red cell isoimmunization, as discussed on page 618. Second, routine fetal-to-maternal cell transfer may someday serve as the basis for a screening test for fetal aneuploidy using maternal peripheral blood (see Chap. 13, p. 302). Lastly, it is now known that fetal stem cells or lymphocytes persist in certain maternal tissues. Such maternal-fetal *hybridization* or *microchimerism* can incite an immune response that may be the instigating factor in certain autoimmune diseases such as thyroiditis, scleroderma, and lupus erythematosus (see Chap. 54, p. 1146).

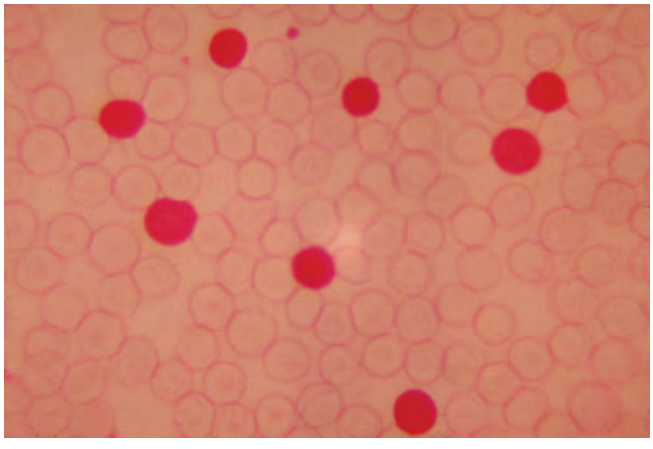

FIGURE 29-5 Massive fetal-to-maternal hemorrhage. After acid-elution treatment, fetal red cells rich in hemoglobin F stain darkly, whereas maternal red cells with only very small amounts of hemoglobin F stain lightly.

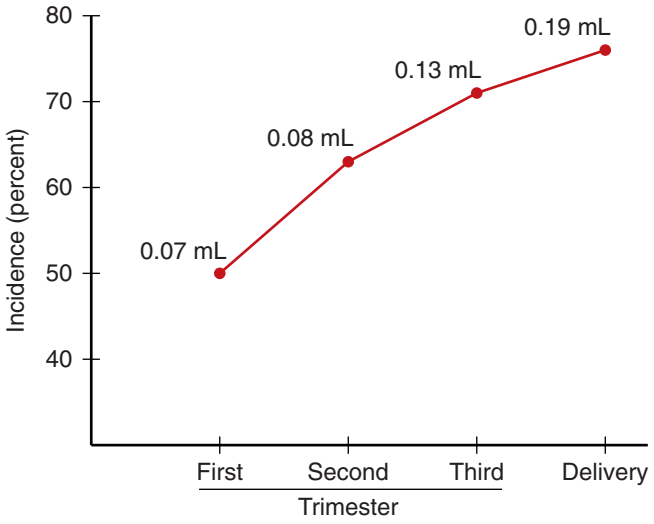

FIGURE 29-6 Incidence of fetal-to-maternal hemorrhage during pregnancy. The numbers at each data point represent total volume of fetal blood estimated to have been transferred into the maternal circulation. (Data from Choavaratana and colleagues, 1997.)

Choavaratana and colleagues (1997) performed serial Kleihauer–Betke tests in 2000 pregnant women and found that, although the *incidence* of fetal-maternal hemorrhage in each trimester was high, the *volume transfused* was very small (Fig. 29-6). How often fetomaternal hemorrhage exceeds 30 mL is controversial. Bowman (1985) reported that only 21 of 9000 women had fetal hemorrhage of this magnitude. Salim and associates (2005) studied fetomaternal hemorrhage of this magnitude in more than 800 women. Their original estimates were calculated erroneously because of an error in the 21st edition of *Williams Obstetrics*. When calculated using the correct formula, almost 4 percent of women had fetomaternal hemorrhages of 30 mL or greater whether delivered vaginally or by cesarean (Salim and Shalev, 2006). Other events that may cause sufficient hemorrhage to incite isoimmunization are shown in Table 29-4.

D-positive fetal red blood cells in D-negative maternal blood can also be detected, albeit nonquantitatively, by the *rosette test*. Maternal red cells are mixed with anti-D antibodies, which coat any D-positive fetal cells present in the sample. Indicator red cells bearing the D-antigen are then added, and rosettes form around the fetal cells as the indicator cells attach to them by the antibodies. Rosettes indicate that fetal D-positive cells are present.

Sequelae

If the fetus becomes severely anemic, a sinusoidal heart rate pattern may develop (see Chap. 18, p. 419). Although not

pathognomonic of fetal anemia, it should prompt immediate evaluation. In general, anemia occurring gradually or chronically, as in isoimmunization, is better tolerated by the fetus than anemia that develops acutely. Chronic anemia may not produce fetal heart rate abnormalities until the fetus is moribund. In contrast, significant acute hemorrhage is poorly tolerated by the fetus and often causes profound neurological fetal impairment, usually from hypotension and cerebral hypoperfusion, ischemia, and infarction.

Because such pathophysiological organ damage occurs acutely, subsequent obstetrical management usually will not change the outcome. De Alemida and Bowman (1994) described 27 cases of fetal-maternal hemorrhage exceeding 80 mL. Despite appropriate management, almost half of these infants died or developed spastic diplegia. Indeed, in the study by Samadi and colleagues (1996), severe fetal-to-maternal hemorrhage caused 5 percent of all stillbirths. This likely is an underestimate because in some cases—about 20 percent—ABO incompatibilities would cause maternal isoagglutinins to rapidly destroy ABO-incompatible fetal erythrocytes. In most cases, the etiology of such hemorrhage is undetermined. For example, placental abruption seldom is the cause. Trauma, however, such as with vehicular accidents can cause placental tearing or "fracture" with significant fetal hemorrhage (see Chap. 42, p. 936). The fetal effects of acute hemorrhage also are illustrated by monochorionic twinning complicated by *twin-twin transfusion syndrome* (see Chap. 39, p. 874). Arterial and venous anastomoses are found in virtually all monochorionic twins. If there is an acute transfer of blood from the donor to the recipient twin, hypotension with hypoperfusion and cerebral infarction, as well as death, can occur.

Management

Once fetal-maternal hemorrhage is recognized, the volume of fetal blood loss can be quantified. The volume may influence obstetrical management and is essential to determining the appropriate dose of D-immunoglobulin when the woman is D-negative. Using basic physiological principles, the amount of fetal hemorrhage may be calculated from the results of a Kleihauer–Betke (KB) stain using the formula:

$$\text{Fetal blood volume} = \frac{\text{MBV} \times \text{maternal Hct} \times \%\ \text{fetal cells in KB}}{\text{newborn Hct}}$$

where MBV = maternal blood volume (approximately 5000 mL in normal-sized normotensive women at term) and Hct = hematocrit. Thus, for 1.7-percent positive KB-stained cells in a woman of average size with a hematocrit of 35 percent giving birth to a term infant weighing 3000 g and whose hematocrit is 0.5:

$$\text{Fetal blood volume} = \frac{5000 \times 0.35 \times 0.017}{0.5} = 60\ \text{mL}$$

The fetal-placental blood volume at term is 125 mL/kg, which is 375 mL for this 3000-g fetus. Thus, this fetus has lost 30 mL of red cells over time into the maternal circulation. This is equivalent to 60 mL of whole blood, because the hematocrit is 50 percent in a term fetus. This amount represents approximately 15 percent (60 ÷ 375 mL) of the fetal-placental volume. This loss should be well tolerated hemodynamically, but would require two 300-μg doses of anti-D immunoglobulin to prevent isoimmunization.

Isoimmunization

Pathophysiology

There are currently 29 blood groups and more than 600 red cell antigens that are recognized by the International Society of Blood Transfusing (Hosoi, 2008). Although some of them are immunologically and genetically important, many are so rare as to be of little clinical significance. Any individual who lacks a specific red cell antigen may produce an antibody when exposed to that antigen. Such antibodies can prove harmful to that individual if she receives a blood transfusion, or they may be harmful to her fetus during that pregnancy. Accordingly, blood banks routinely screen for erythrocyte antigens.

Most persons carry at least one red cell antigen inherited from their father but lacking in their mother. Thus, the mother could be sensitized if enough fetal erythrocytes reached her circulation to elicit an immune response. Even so, isoimmunization is actually rare for the following reasons: (1) low prevalence of incompatible red cell antigens; (2) insufficient transplacental passage of fetal antigens or maternal antibodies; (3) maternal-fetal ABO incompatibility, which leads to rapid clearance of fetal cells before they elicit an immune response; (4) variable antigenicity; and (5) variable maternal immune response to the antigen, with some antigens provoking only minimal response. Considering all these factors, it is not surprising that for all pregnant women there is only a 1-percent chance of D-isoimmunization by 6 months postpartum and that isoimmunization does not always lead to erythroblastosis fetalis.

The incidence of sensitization to red cell antigens at each stage of pregnancy has been studied most extensively in D-negative women. A D-negative woman delivered of a D-positive, ABO-compatible infant has a likelihood of isoim-

munization of 16 percent. Two percent will be immunized by the time of delivery, 7 percent will have anti-D antibody by 6 months postpartum, and the remaining 7 percent will be "sensibilized" (Bowman, 1985). In sensibilized women, anti-D antibodies are produced at such a low level that they are not detected during or after the index pregnancy. Instead, they are identified early in a subsequent pregnancy when rechallenged by another D-positive fetus.

ABO Blood Group System

Although incompatibility for the major blood group antigens A and B is the most common cause of hemolytic disease in the newborn, the resulting anemia is usually mild. Approximately 20 percent of all infants have an ABO maternal blood group incompatibility, but only 5 percent are clinically affected. ABO incompatibility is different from CDE incompatibility for several reasons:

- ABO disease frequently is seen in firstborn infants. This is because most group O women have anti-A and anti-B isoagglutinins antedating pregnancy. These are attributed to exposure to bacteria displaying similar antigens
- Most species of anti-A and anti-B antibodies are immunoglobulin M (IgM), which cannot cross the placenta and therefore cannot reach fetal erythrocytes. In addition, fetal red cells have fewer A and B antigenic sites than adult cells and are thus less immunogenic. Thus, there is no need to monitor for fetal hemolysis, and there is no justification for early delivery
- The disease is invariably milder than D-isoimmunization and rarely results in significant anemia. Affected infants typically do not have erythroblastosis fetalis, but rather have neonatal anemia and jaundice, which can be treated with phototherapy
- ABO isoimmunization can affect future pregnancies, but unlike CDE disease, it rarely becomes progressively more severe. Katz and co-workers (1982) identified a recurrence in 87 percent. Of these, 62 percent required treatment, most often limited to neonatal phototherapy.

Because of these reasons, ABO isoimmunization is a disease of pediatric rather than obstetrical concern. Although there is no need for antenatal monitoring, careful neonatal observation is essential because hyperbilirubinemia may require treatment. Treatment usually consists of phototherapy or simple or exchange transfusion with O-negative blood (see p. 625).

CDE (Rhesus) Blood Group System

This system includes five red cell proteins or antigens: C, c, D, E, and e. No "d" antigen has been identified, and Rh- or D-negativity is defined as the absence of the D-antigen. There are, however, D-antigen variants that cause hemolytic disease (Bush and associates, 2003; Cannon and colleagues, 2003). Some of these include weak D, D^u, and partial D (Prasad and co-workers, 2006).

The CDE antigens are of considerable clinical importance because many D-negative individuals become isoimmunized after a single exposure. The two responsible genes—D and CE—are located on the short arm of chromosome 1 and are inherited together, independent of other blood group genes. Like many genes, their incidence varies according to racial origin. Native Americans, Inuits, and Chinese and other Asiatic peoples have 99-percent D positivity. Approximately 93 percent of African-Americans are D-positive, but only 87 percent of Caucasians are. Of all racial and ethnic groups studied thus far, the Basques show the highest incidence of D-negativity at 34 percent.

The C-, c-, E-, and e-antigens have lower immunogenicity than the D-antigen, but they too can cause erythroblastosis fetalis. **All pregnant women should be tested routinely for D-antigen erythrocytes and for irregular antibodies in their serum.** Barss and colleagues (1988) demonstrated that this need be done only once during each pregnancy in D-positive women, and this is currently recommended by the American Association of Blood Banks.

Other Blood Group Incompatibilities

Because routine administration of anti-D immunoglobulin prevents most cases of anti-D-isoimmunization, proportionately more cases of significant antenatal hemolytic disease are now caused by the less common red cell antigens. Such sensitization is suggested by a positive indirect Coombs test performed to screen for abnormal antibodies in maternal serum (**Table 29-5**).

Several large studies indicate that anti-red cell antibodies are found in 1 percent of pregnancies (Bowell and colleagues, 1986; Howard and associates, 1998). From 40 to 60 percent of these are directed against the CDE antibodies. Anti-D is the most common, followed by anti-E, anti-c, and anti-C. A third of fetuses with either anti-C or anti-Ce alloimmunization described by Bowman and colleagues (1992b) had hemolysis but none had severe disease. In contrast, Hackney and co-workers (2004) reported that 12 of 46 anti-c isoimmunized fetuses had serious hemolysis, and eight of these 12 required transfusions.

Anti-Kell antibodies are also frequent. A fourth of all antibodies found are from the *Lewis system.* These do not cause hemolysis because Lewis antigens do not develop on fetal erythrocytes and are not expressed until a few weeks after birth.

Kell Antigen. Approximately 90 percent of Caucasians are Kell negative. Kell type is not routinely determined, and 90 percent of cases of anti-Kell sensitization result from transfusion with Kell-positive blood. As with CDE antigens, Kell sensitization also can develop as the result of maternal–fetal incompatibility. Kell sensitization may be clinically more severe than D-sensitization because anti-Kell antibodies also attach to fetal bone marrow erythrocyte precursors, thus preventing a hemopoietic response to anemia. Thus, there usually is a more rapid and severe anemia than with anti-D sensitization (Weiner and Widness, 1996).

Because fewer erythrocytes are produced, there is less hemolysis and less amnionic fluid bilirubin. As a result, severe anemia may not be predicted by either the maternal anti-Kell titer or the level of amnionic fluid bilirubin. Caine and Mueller-Heubach (1986) described 13 Kell-sensitized pregnancies with a Kell-positive fetus. Five of these resulted in hydrops or perinatal death despite favorable amnionic fluid studies 1 week before

TABLE 29-5. Atypical Antibodies and Their Relationship to Fetal Hemolytic Disease

Blood Group System	Antigens Related to Hemolytic Disease	Hemolytic Disease Severity	Proposed Management

delivery. Bowman and colleagues (1992a) reviewed 20 Kell-sensitized pregnancies, in which exchange transfusions were required in four, and four fetuses died. Because of this disparate severity of Kell sensitization, some investigators recommend evaluation when the maternal anti-Kell titer is 1:8 or greater. In addition, Weiner and Widness (1996) suggest that the initial evaluation be accomplished by cordocentesis instead of amniocentesis, because fetal anemia from Kell sensitization is usually more severe than indicated by the amnionic fluid bilirubin level. Determination of fetal middle cerebral artery (MCA) velocity by Doppler obviates this, as discussed subsequently. Van Wamelen and associates (2007) studied 41 women and concluded that for timely detection of severe fetal anemia, pregnancies in women with anti-Kell titers ≥ 1:2 should be closely monitored by peak MCA systolic velocity beginning at 16 to 17 weeks.

Other Antigens. Kidd (Jk^a), Duffy (Fy^a), c-, E-, and to a lesser extent C-antigens can all cause erythroblastosis as severe as that associated with sensitization to D-antigen (see Table 29-5). Two Duffy antigens have been identified, Fy^a and Fy^b, and some African-Americans lack both. Fy^a is the most immunogenic. The Kidd system also has two antigens, Jk^a and Jk^b, with the population distribution as follows: Jk (a+b–), 26 percent; Jk (a–b+), 24 percent; and Jk (a+b+), 50 percent (Alper, 1977). In their report of 20 cases of Jk^a isoimmunization, Franco and colleagues (2009) reported that all but one were mild.

If an IgG red cell antibody is detected and there is any doubt as to its significance, the clinician should err on the side of caution, and the pregnancy should be evaluated. As shown in Table 29-5, many rare or *private antigens* have been associated with severe isoimmunization (Rouse and Weiner, 1990).

Immune Hydrops

The abnormal collection of fluid in more than one area of the fetal body, such as ascites and pleural effusion, is termed *hydrops fetalis.* Its causes usually are categorized as immune and nonim-

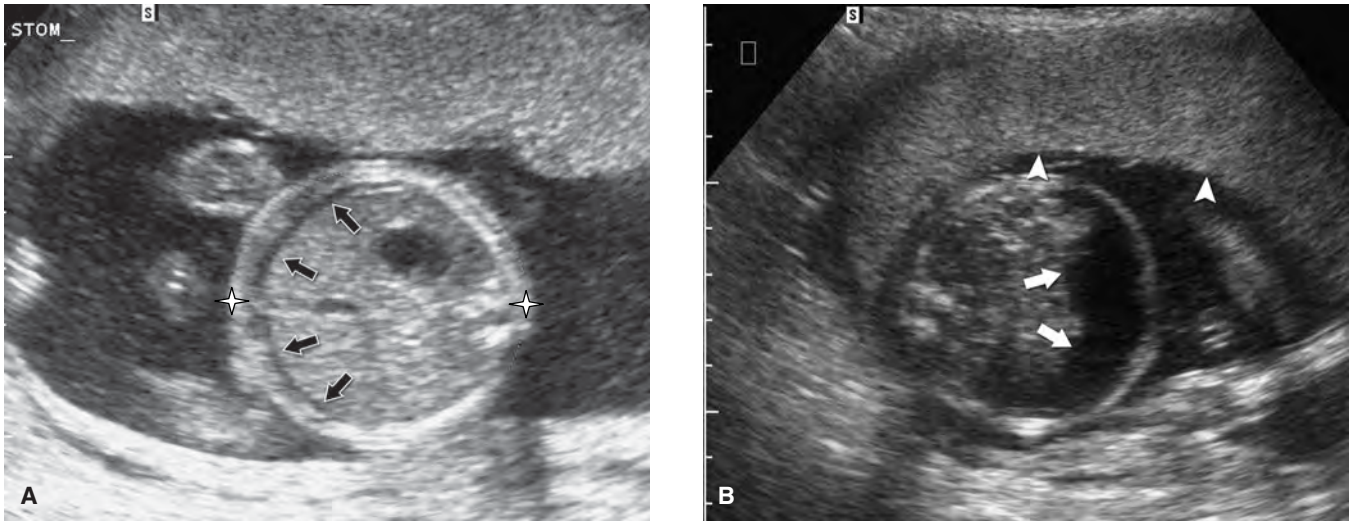

FIGURE 29-7 Hydropic fetus. **A.** Fetal ascites (*black arrows*) beneath the anasarca of the fetal abdominal wall (*white cursors*). **B.** Placental thickening (*arrowheads*) and marked pelvic ascites (*arrows*) are also seen in another image of the same fetus.

mune. In immune hydrops such as that with D-isoimmunization, excessive and prolonged hemolysis causes anemia, which in turn stimulates marked marrow erythroid hyperplasia. It also stimulates extramedullary hematopoiesis in the spleen and liver with eventual hepatic dysfunction. There may be cardiac enlargement and pulmonary hemorrhage. Fluid collects in the fetal thorax, abdominal cavity, or skin. The placenta is markedly edematous, enlarged, and boggy. It contains large, prominent cotyledons and edematous villi. Pleural effusions may be so severe as to restrict lung development, which causes pulmonary compromise after birth. Ascites, hepatomegaly, and splenomegaly may lead to severe labor dystocia. Severe hydropic changes are easily seen with sonography (Fig. 29-7).

The precise pathophysiology of hydrops remains unknown. Theories include heart failure from profound anemia and hypoxia, portal hypertension due to hepatic parenchymal disruption caused by extramedullary hemopoiesis, and decreased colloid oncotic pressure resulting from liver dysfunction and hypoproteinemia. The data from several studies indicate that in most cases, the degree and duration of anemia is the major factor causing and influencing the severity of ascites (Pasman and associates, 2006). Secondary factors include hypoproteinemia caused by liver dysfunction and capillary endothelial leakage resulting from tissue hypoxia. Both of these lead to protein loss and decreased colloid oncotic pressure, which worsen hydrops. For example, Nicolaides and colleagues (1985) performed percutaneous umbilical artery blood sampling in 17 severely D-isoimmunized fetuses at 18 to 25 weeks. All fetuses with hydrops had hemoglobin values less than 3.8 g/dL, plasma protein concentrations less than 2 standard deviations below the normal mean, and substantive protein concentrations in ascitic fluid. Conversely, none of the fetuses with hemoglobin values exceeding 4 g/dL were hydropic, even though six of 10 also had hypoproteinemia of the same magnitude as the hydropic fetuses.

Weiner and co-workers (1989) evaluated umbilical venous pressure during 20 antenatal transfusions in isoimmunized pregnancies. Significantly elevated pressures found in hydropic fetuses normalized within 24 hours of transfusion. Because portal hypertension cannot resolve so rapidly, this suggests that the elevated pressure was actually due to hypoxic myocardial dysfunction, which was reversed by transfusions.

Fetuses with hydrops may die in utero from profound anemia and circulatory failure (Fig. 29-8). One sign of severe anemia and impending death is the sinusoidal fetal heart rate pattern (see Chap. 18 p. 419). In addition, hydropic placental changes

FIGURE 29-8 Severe erythroblastosis fetalis. Hydropic, macerated stillborn infant and characteristically large placenta.

leading to placentomegaly can cause preeclampsia. Ironically, the preeclamptic mother may develop severe edema mimicking that of the fetus—this is referred to as the *mirror syndrome* (see p. 627).

The liveborn hydropic infant appears pale, edematous, and limp at birth and usually requires resuscitation. The spleen and liver are enlarged, and there may be widespread ecchymosis or scattered petechiae. Dyspnea and circulatory collapse are common. Hyperbilirubinemia is discussed subsequently on page 625.

Perinatal Mortality

Perinatal deaths from hemolytic disease caused by D-isoimmunization have decreased dramatically since adoption of the policy of routine preventative administration of D-immunoglobulin to all D-negative women during or immediately after pregnancy. Survival also has been increased by antenatal transfusions or preterm delivery of affected fetuses if necessary (Bowman and colleagues, 1977; Fretts and co-workers, 1992). The advent of fetal transfusion therapy has resulted in survival rates exceeding 90 percent for severe anemia alone, and 70 percent if hydrops has developed (Moise, 2008).

Identification of the Isoimmunized Pregnancy

It is routine practice to perform blood typing and antibody screen at the first prenatal visit, and unbound antibodies in maternal serum are detected by the *indirect Coombs test.* If positive, specific antibodies are identified, and their immunoglobulin subtype is determined as either IgG or IgM. Only IgG antibodies are concerning because IgM antibodies cannot cross the placenta. If the IgG antibodies are known to cause fetal hemolytic anemia as shown in Table 29-5, the titer is quantified. The *critical titer* is the level for a particular antibody that requires further evaluation. This may be different for each antibody and is determined individually by each laboratory. For example, the critical titer for anti-D antibodies is usually 1:16. Thus, a titer of ≥ 1:16 indicates the possibility of severe hemolytic disease. The critical titers for other antibodies are often assumed to be 1:16 as well, although most laboratories have insufficient data to support this assumption. An important exception is Kell sensitization. The critical titer for anti-Kell antibody is 1:8 or even less as discussed on page 619.

Determining Fetal Genotype. The presence of maternal anti-D antibodies does not necessarily mean that the fetus will be affected or is even D-positive. This may be for several reasons. For example, in a previously sensitized or sensibilized woman, the antibody titer may rise to high levels during a subsequent pregnancy even when the fetus is D-negative—the *amnestic response.* Additionally, half of all fetuses with antigen-positive Caucasian fathers are D-antigen negative, because half of D-positive Caucasian males are D-antigen heterozygous (Race and Sanger, 1975). Moreover, many women sensitized to non-D red cell antigens become immunized after a blood transfusion, and the antigen may not be present on paternal erythrocytes. Examples include other CE group and Kell antigens.

Determining zygosity of the father for the D-antigen is helpful, and DNA-based analysis will establish this. **But before paternal testing is pursued, it is imperative that any possibility of nonpaternity be disclosed.** If the father is homozygous for D, then there is a 100-percent chance of a D-positive fetus, and fetal genotyping is not necessary. Paternal heterozygosity can be estimated by co-inheritance of CcEe phenotypes, but this is inexact (Moise, 2008).

If the father is heterozygous or if paternal DNA-based testing cannot be performed, fetal genotyping is performed on samples of chorionic villous amniocytes or fetal blood. Reference laboratories are also able to analyze amniocytes for E, c, Kell, Kidd, M, and Duffy antigens. Likely, others will also soon be available. Noninvasive fetal D genotyping by using *cell-free fetal DNA* in maternal plasma is currently used in some European countries (Gautier and colleagues, 2005; Hahn and Chitty, 2008). Fetal DNA from maternal plasma or fetal cells is 85- to 95-percent accurate for D-antigen determination (Arntfield, 2009; Bianchi, 2005; Geifman-Holtzman, 2006, and all their co-workers). Currently, there are no such FDA-approved testing strategies available in the United States (see also Chap. 13, p. 302).

Management of Isoimmunization

Management is individualized and consists of maternal antibody titer surveillance, sonographic monitoring of the fetal middle cerebral artery peak systolic velocity, amnionic fluid bilirubin studies, or fetal blood sampling. Accurate pregnancy dating is critical. The gestational age at which fetal anemia developed in the last pregnancy is important because anemia tends to occur earlier and be sequentially more severe. In the first sensitized pregnancy, a positive antibody screen with a titer below the critical level should be followed with repeated titers at timely intervals, usually monthly. Once the critical titer has been met or exceeded, subsequent titers are not helpful, and further evaluation is required. If this is not the first sensitized pregnancy, then the pregnancy is considered to be at risk, and maternal antibody titers are unreliable.

Middle Cerebral Artery (MCA) Peak Systolic Velocity. In most specialized centers, serial measurement of the peak systolic velocity of the fetal middle cerebral artery has replaced amniocentesis for detection of fetal anemia (American College of Obstetrics and Gynecology, 2006b). The technique is discussed in Chapter 16 (p. 364). The anemic fetus shunts blood preferentially to the brain to maintain adequate oxygenation. The peak MCA systolic velocity increases because of increased cardiac output and decreased blood viscosity (Moise, 2008). In a collaborative study, Mari and colleagues (2000) measured this velocity serially in 111 fetuses at risk for anemia and in 265 normal fetuses. A threshold of > 1.5 MoM correctly identified all fetuses with moderate or severe anemia. The sensitivity was 100 percent, and false-positive rate was 12 percent. A Doppler waveform illustrating this is shown in Chapter 16 (Fig. 16-28, p. 365). More recently, Oepkes and co-workers (2006) compared Doppler velocimetry to amnionic-fluid bilirubin studies. They reported that Doppler studies had an 88-percent sensitivity and 85-percent accuracy, whereas bilirubin studies had a 76 percent sensitivity, 77-percent specificity, and 76-percent accuracy. As discussed on page 624, velocimetry is less sensitive to predict anemia following fetal transfusions. Doppler results are shown in **Figure 29-9.** From a retrospective analysis, Sau and

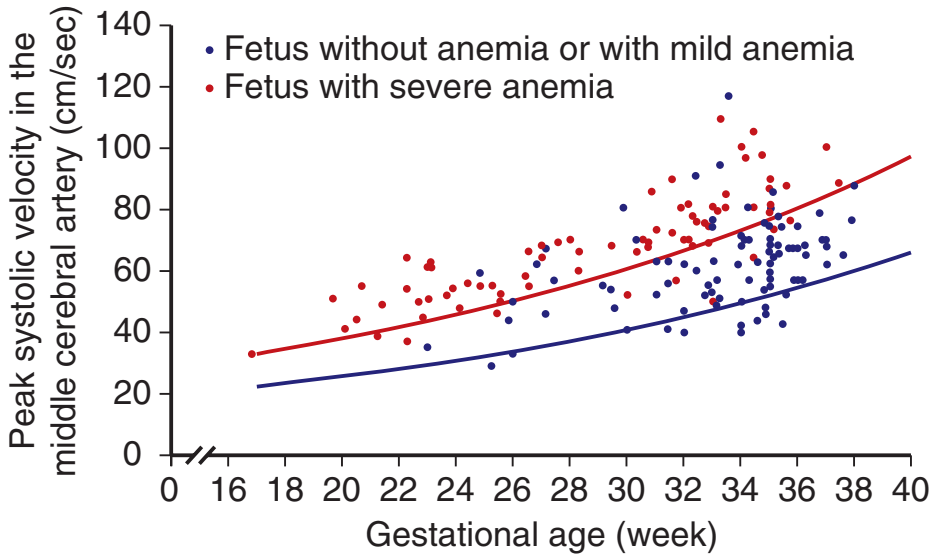

FIGURE 29-9 Doppler measurements of the peak systolic velocity in the middle cerebral artery in 165 fetuses at risk for severe anemia. The blue line indicates the median peak systolic velocity in normal pregnancies, and the red line shows 1.5 multiples of the median. (Reprinted from Oepkes D, Seaward PG, Vandenbussche FP, et al: Doppler ultrasonography versus amniocentesis to predict fetal anemia. *N Engl J Med* 355(2):156–164, with permission. Copyright © 2006 Massachusetts Medical Society. All rights reserved.)

colleagues (2009) also suggested that the noninvasive method was preferred.

If the MCA peak systolic velocity exceeds 1.5 MoM, the fetus is likely to be anemic. Further evaluation by fetal blood sampling is then necessary to determine the need for transfusions.

Amnionic Fluid Spectral Analysis

Almost 50 years ago, Liley (1961) demonstrated the utility of amnionic fluid spectral analysis to measure the bilirubin concentration to estimate the severity of hemolysis, and thus to indirectly assess anemia. It is less widely used now, but Moise (2008) recommends its parallel use initially with MCA Doppler flow studies to verify accuracy as centers gain experience with velocimetry. It is also used when Doppler velocimetry is not readily available.

Because amnionic fluid bilirubin levels are low, the concentration is measured by a spectrophotometer and is demonstrable as a change in absorbance at 450 nm—this difference is referred to as ΔOD_{450}. The likelihood of fetal anemia is determined by plotting the ΔOD_{450} value on a graph that is divided into several zones. The original Liley graph is valid from 27 to 42 weeks and contains three zones. Zone 1 generally indicates a D-negative fetus or one with only mild disease. Zone 2 indicates that anemia is present. In lower zone 2, the anticipated hemoglobin level is 11.0 to 13.9 g/dL, whereas in upper zone 2, hemoglobin values range from 8.0 to 10.9 g/dL. Zone 3 indicates severe anemia with hemoglobin values below 8.0 g/dL (Liley, 1961). Recently, Pasman and colleagues (2008) have observed a closer correlation of severe fetal anemia with a bilirubin/albumin ratio compared with the Liley or Queenan graphs.

Use of the "Liley curve" allowed decisions regarding management. At that time, the options were fetal intraperitoneal transfusions or preterm delivery. The Liley graph was subsequently modified by Queenan and associates (1993). These investigators studied 845 amnionic fluid samples from 75 D-immunized and 520 unaffected pregnancies and constructed a Liley-type curve that begins at 14 weeks (Fig. 29-10). As can be seen, the naturally high amnionic fluid bilirubin level at midpregnancy results in a large *indeterminate zone*. Importantly, bilirubin concentrations in this zone do not accurately predict fetal hemoglobin concentration. For this reason, when evaluation indicates that severe fetal anemia or hydrops before 25 weeks is likely, many forego amniocentesis and instead perform fetal blood sampling.

Fetal Blood Transfusions. With evidence of fetal anemia, hepatomegaly, or hydrops or with nonreassuring fetal testing, management is determined by gestational age. The near-mature fetus should be delivered. The preterm fetus can be evaluated using fetal blood sampling, and transfusions are given as necessary as described in Chapter 13 (p. 301). Fetal hemoglobin, hematocrit, reticulocyte count, and indirect Coombs titer are determined to predict the onset of anemia if the fetus is not yet affected (Weiner and associates, 1991a).

Nicolaides and co-workers (1988) recommend that transfusions be commenced when the hemoglobin level is at least 2 g/dL below the mean for normal fetuses of corresponding gestational age (see Chap. 4, p. 91). Others recommend transfusions when the fetal hematocrit is below 30 percent—2 standard deviations below the mean at all gestational ages (Weiner and associates, 1991b). Fetal

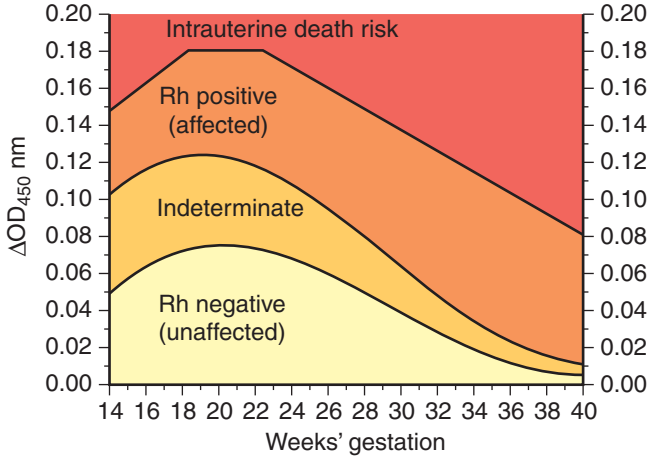

FIGURE 29-10 Proposed amnionic fluid ΔOD_{450} management zones in pregnancies from 14 to 40 weeks. (This figure was published in *American Journal of Obstetrics & Gynecology*, Vol. 168, No. 5, JT Queenan, PT Thomas, TP Tomai, et al., Deviation of amniotic fluid optical density at a wavelength of 450 nm in Rh isoimmunized pregnancies from 14 to 40 weeks' gestation: A proposal for clinical management, pp. 1370–1376, Copyright Elsevier 1993.)

intraperitoneal and intraumbilical blood transfusions are discussed in detail in Chapter 13 (p. 302). With severe early-onset hemolytic disease, intraperitoneal transfusions are done because it is technically difficult to gain vascular access in the cord (Howe and Michaitidis, 2007). With an older and larger fetus, most prefer intravascular transfusions.

Over the past decade or so, perinatal outcomes have been reasonably good. From the Netherlands, van Kamp and colleagues (2005) reported outcomes of 254 fetuses treated with intravascular transfusions. Overall survival was 89 percent, and 12 of 19 perinatal deaths were procedure related. Of 740 transfusions, 15 percent were performed before 24 weeks. Howe and Michaitidis (2007) performed intraperitoneal transfusions in five severely affected fetuses with D-isoimmunization beginning at 15 to 16 weeks. Each fetus received four or five transfusions before umbilical cord size allowed access. All five were delivered at 34 to 35 weeks and survived. Scheier (2006) and Klumper (2009) and their associates reported that MCA peak velocity is less accurate in predicting anemia after one transfusion, and even less so after two or more. As a rule, to predict the next transfusion, the fetal hematocrit decreases 1 volume percent per day.

Treatments that have not been effective include plasmapheresis, administration of promethazine or D-positive erythrocyte membranes in enteric capsules, and immunosuppression with corticosteroids.

Delivery. The goal of management is delivery of a reasonably mature healthy fetus. When management includes serial amnionic fluid ΔOD_{450} measurement or fetal transfusions, fetal well-being should be closely monitored with techniques discussed in Chapter 15. According to the American College of Obstetricians and Gynecologists (2006b), with appropriate management, extremely preterm delivery usually can be avoided.

Neonatal Care and Outcome. Some advocate that the last transfusion for the severely affected fetus be given at 30 to 32 weeks with antenatal corticosteroid administration and delivery at 32 to 34 weeks. Others continue transfusion until 36 weeks. In either case, cord blood is obtained at delivery for hemoglobin concentration and direct Coombs testing. If the infant is overtly anemic, it is often best to complete the initial exchange transfusion promptly with recently collected type-O, D-negative red cells. For infants who are not overtly anemic, the need for exchange transfusion is determined by the rate of increase in bilirubin concentration, the maturity of the infant, and the presence of other complications.

Most fetal transfusion survivors develop normally. In one long-term follow-up study, Grab and colleagues (1999) reported outcomes of 35 fetuses who had severe isoimmunization or immune hydrops and who were given antenatal intravascular transfusions. At age 1, only one had mild psychomotor disabilities, and another had delayed speech development. At up to age 6 years, however, none of the survivors, including those with hydrops, had either moderate or severe neurological impairment. Harper and associates (2006) provided a mean 10-year follow-up of 18 hydropic fetuses who underwent intravascular transfusions. Two fetuses died, two of the 16 survivors had major neurological handicaps, but the remainder had neuropsychological findings similar to those of their siblings.

Anti-D Immunoglobulin

D-isoimmunization is prevented by administration of high-titer anti-D antibodies extracted by cold alcohol plasma fractionation and ultrafiltration. A standard intramuscular dose provides 300 μg of D-antibody as determined by radioimmunoassay. It is given to the D-negative nonsensitized mother to prevent sensitization after pregnancy-related events that could result in fetal-maternal hemorrhage as discussed on page 617 and listed in Table 29-4. Although sensitization can follow spontaneous miscarriage as well as early elective pregnancy termination, the precise incidence is not known (Hannafin and colleagues, 2006). Still, most recommend that D-negative women receive anti-D immunoglobulin (American College of Obstetricians and Gynecologists, 1999b). A 50-μg "mini dose" is available for these early pregnancy indications.

Routine Antepartum Administration. One dose of anti-D immunoglobulin is given prophylactically to all D-negative women at approximately 28 weeks, and a second dose is given after delivery if the infant is D-positive (American College of Obstetricians and Gynecologists, 1999b). Without such prophylaxis, Bowman and Pollock (1978) showed that 1.8 percent of D-negative women will become isoimmunized by silent fetal-maternal hemorrhage. When such prophylaxis is given, only 0.07 percent of susceptible women are sensitized. Despite a policy for antepartum immunoglobin administration, MacKenzie and associates (2006a) reported that the "real world" sensitization rate was 0.4 percent.

Regardless of antepartum administration at 28 weeks, a second dose is required after delivery because the half-life of immunoglobulin is only 24 days and protective levels predictably persist for only 6 weeks or so. In addition, fetal-maternal hemorrhage is more likely at delivery (see Fig. 29-6). Each 300-μg dose will protect the average-sized mother from a fetal hemorrhage of up to 15 mL of D-positive red cells or 30 mL of fetal whole blood. The initial 300-μg dose will produce a weakly positive—1:1 to 1:4—indirect Coombs titer in the mother. As the body mass index increases above 27 to 40 kg/m^2, serum antibody levels decrease by 30 to 60 percent (MacKenzie and associates, 2006b; Woelfer and co-workers, 2004). Rarely, a small amount of antibody crosses the placenta and results in a weakly positive direct Coombs test in cord and infant blood. This small amount causes negligible fetal hemolysis.

D-negative women who receive blood products are also at risk of becoming sensitized. Although they should be given only D-negative red cells, platelet transfusions and plasmapheresis can provide sufficient D-antigen to cause sensitization. This can be prevented by an injection of D-immunoglobulin. And most recommend routine administration when there is blunt maternal trauma, although its necessity has not been proven (Thorp, 2008). In many cases, anticipated fetomaternal hemorrhage is mild and likely protected by the 28-week dose of immunoglobulin. For example, Boucher and colleagues (2008) demonstrated this in more than 1300 trials of external cephalic version. **Still, when there is doubt about**

whether to give anti–D immunoglobulin, it should be given. Even if not needed, it will cause no harm, but failing to give it when needed can have severe consequences.

Large Fetal-to-Maternal Hemorrhage. With more severe fetal-maternal hemorrhage, one 300-μg dose of D-immunoglobulin may not be sufficient. Ness and colleagues (1987) studied 800 D-negative mothers and reported that the incidence of fetal-maternal transfusion exceeding 30 mL of whole blood, the quantity neutralized by one dose of immunoglobulin, was 1 percent. Another 5.6 percent of these pregnancies had fetal-maternal hemorrhage of between 11 and 30 mL. Adeniji and colleagues (2008) recently reported similar findings. Thus, at least 1 percent, and perhaps more, of susceptible mothers would have been given insufficient immunoglobulin if not tested. Importantly, these investigators determined that if extra D-immunoglobulin is considered only for women with risk factors such as abdominal trauma, placental abruption, placenta previa, intrauterine manipulation, multifetal gestation, or manual removal of the placenta, half of women requiring more than the 300-μg dose would be missed. Stedman and co-workers (1986) used the erythrocyte rosette test and reported similar results.

Because of the above observations, the American Association of Blood Banks recommends that all D-negative women be tested at delivery with the Kleihauer-Betke or rosette test (Snyder, 1998). The dosage of anti-D immunoglobulin is calculated from the estimated volume of the fetal-to-maternal hemorrhage described on page 618. One 300-μg ampule is given for each 30 mL of fetal whole blood to be neutralized. To determine if the dose was adequate after it is given, the indirect Coombs test is performed. A positive result indicates that there is excess anti–D-immunoglobulin in maternal serum, thus demonstrating that the dose was sufficient.

D^u-Antigen. Identification of the D^u-antigen may cause confusion or result in designation of the blood type as "weak D-positive." The D^u-antigen is actually a variant of the D-antigen, and women confirmed to be D^u-positive are therefore D-positive and do not need immunoglobulin (American College of Obstetricians and Gynecologists, 1999b). If a D-negative woman delivers a D^u-positive infant, she should be given D-immunoglobulin. As before, if there is any doubt about D-antigen status, then immunoglobin should be given.

Maternal-to-Fetal Hemorrhage

It is now recognized that in virtually all pregnancies, small amounts of maternal blood enter the fetal circulation. Unlike *fetal-to-maternal* bleeding, physiologically significant *maternal-to-fetal* hemorrhage is uncommon. Rarely, the D-negative fetus is exposed to maternal D-antigen and becomes sensitized. When such a female fetus reaches adulthood, she will produce anti-D antibodies even before or early in her first pregnancy. This mechanism of isoimmunization is called the *grandmother theory* because the fetus in the current pregnancy is jeopardized by antibodies initially provoked by its grandmother's erythrocytes. Major blood group (ABO) incompatibility offers appreciable protection against D-sensitization of the fetus. D-negative infants born to D-positive mothers are not routinely given D-immunoglobulin prophylaxis.

Hyperbilirubinemia

Unconjugated or free bilirubin is readily transferred across the placenta from mother to fetus, if the maternal plasma level is high. Although conjugated bilirubin glucuronide is water soluble and normally is excreted into bile and urine when the plasma level is elevated, unconjugated bilirubin is not excreted this way.

Kernicterus

This condition may result from unconjugated hyperbilirubinemia in the newborn—especially if preterm. Bilirubin deposition and staining in the basal ganglia and hippocampus results in profound neuronal degeneration in these regions. Surviving infants show spasticity, muscular incoordination, and varying degrees of mental retardation. There is a positive correlation between unconjugated bilirubin levels above 18 to 20 mg/dL and kernicterus. Despite this, kernicterus may develop at much lower concentrations, especially in very preterm infants. In a follow-up study from the Collaborative Perinatal Project, levels of total serum bilirubin ≥25 mg/dL correlated with kernicterus only in those infants with a positive Coombs test (Kezniewicz and Newman, 2009).

Physiological Jaundice

By far the most common form of unconjugated nonhemolytic jaundice is so-called *physiological jaundice*. In the mature infant, serum bilirubin usually increases for 3 to 4 days to levels up to 10 mg/dL, and then concentrations fall rapidly. Perhaps 15 percent of infants are diagnosed with jaundice (Burke and associates, 2009). In one large study, 1 to 2 percent of infants 35 weeks or older had a serum bilirubin level > 20 mg/dL (Eggert and colleagues, 2006). In preterm infants, the rise is greater and more prolonged.

Treatment

Phototherapy is now widely used to treat hyperbilirubinemia because light increases oxidation of bilirubin. This enhances renal clearance and lowers serum bilirubin levels. Light that penetrates the skin also increases peripheral blood flow, which further enhances photo-oxidation. The randomized trial of 1974 extremely low-birthweight infants treated by the Neonatal Research Network showed that aggressive phototherapy reduced rates of neurodevelopmental impairment even further (Norris and colleagues, 2008).

Rarely, exchange transfusion is required. Newman and associates (2006) showed that when serum bilirubin levels in near-term or term infants exceed 25 mg/dL, therapy will prevent adverse neurodevelopmental outcomes. According to Burke and colleagues (2009), hospitalizations for kernicterus in term infants decreased from 5.1 per 100,000 in 1988 to 1.5 per 100,000 in 1994 and has remained at this level since then. Maisels and McDonagh (2008) recently provided a scholarly treatise on bilirubin metabolism and phototherapy.

Nonimmune Hydrops Fetalis

As defined on page 620, hydrops is characterized by excess fluid in two or more body areas such as the thorax, abdomen, or skin. It is often associated with hydramnios and a hydropic, thickened placenta. Because obstetrical sonographic examination has become routine, hydrops is frequently identified prenatally, and in many cases, the etiology can be determined. The reported incidence varies. Santolaya and colleagues (1992) identified hydrops in 0.6 percent of 12,572 pregnancies undergoing sonographic evaluation and were able to determine the etiology in 77 percent. Nonimmune causes were by far the most common—87 percent—and two thirds were due to intrinsic fetal or placental abnormalities. Heinonen and colleagues (2000) reported a much lower incidence of 1 per 1700 pregnancies, and they were able to determine etiology in 95 percent. In some cases, fetal ascites develops without other features of hydrops, and the overall prognosis is better (Favre and co-workers, 2004).

Bellini and co-workers (2009) recently performed a systematic review of 51 relevant publications describing 5437 pregnancies complicated by nonimmune hydrops. They classified these into 14 categories that are shown in Table 29-6. Cardiovascular disorders comprised almost 22 percent and included structural and functional abnormalities. Although chromosomal anomalies—13 percent—were varied, hematological causes—10 percent—usually had a final common pathophysiological pathway with anemia and heart failure. Other causes are shown in Table 29-6.

Etiology

There is an ever-lengthening list of specific disorders that can lead to nonimmune hydrops (Table 29-7). *Cystic hygromas* are one of the most common associations, especially when hydrops is identified in the first or early second trimester (see Table 29-6). As discussed in Chapter 16 (p. 356), most of these are the result of aneuploidy. *Cardiac anomalies* have been implicated in 20 to 45 percent of nonimmune hydrops cases (Allan, 1986; Castillo, 1986; Gough, 1986; Santolaya, 1992, and all their co-workers). Fetal heart failure also can result from arrhythmias, arterial-venous malformations or immune- or infection-related myocarditis.

Perhaps another one third of fetal hydrops results from *multiple malformations* or *chromosomal anomalies.* Shulman and colleagues (2000) reported that more than 80 percent of cases of dramatic and extensive subcutaneous edema—*space-suit hydrops*—recognized in the first trimester are associated with chromosomal abnormalities.

In multifetal pregnancies, hydrops of one twin is usually from the *twin-twin transfusion syndrome* (see Chap. 39, p. 874). Hydrops can be due to heart failure either from volume overload and hypertensive cardiomyopathy in the recipient twin or from myocardial dysfunction secondary to severe anemia in the donor twin.

Other causes of severe anemia that can lead to hydrops include parvovirus infection, chorioangioma, acute fetal-maternal hemorrhage, and α_4-thalassemia (American College of Obstetricians and Gynecologists, 1999a; Duff and associates, 2009). In San Francisco, which has a large Asian population, 10 percent of hydrops was caused by α_4-thalassemia (Holzgreve and associates, 1984). *Inborn errors of metabolism* such as Gaucher disease, GM 1 gangliosidosis, and sialidosis can cause recurrent hydrops (Lefebvre and colleagues, 1999). Rarely, a *lymphatic anomaly* can result in isolated chylothorax or chylous ascites. Although these fluid collections alone do not qualify as hydrops, chylothorax can ultimately result in a treatable cause of hydrops.

TABLE 29-6. Categories of Disorders Causing Nonimmune Hydrops Fetalis in 5437 Pregnancies

Category	Percent
Cardiovascular	21.7
Chromosomal	13.4
Hematological	10.4
Infections	6.7
Thoracic	6.0
Lymphatic	5.7
Twin-twin transfusion	5.6
Syndromic	4.4
Urinary tract	2.3
Others	6.0
Idiopathic	17.8

Data from Bellini and colleagues, 2009

Prognosis

Overall, the outcome for fetal hydrops of any cause is generally poor, however, the later it develops, the better the prognosis. In a study of 82 hydropic fetuses, McCoy and colleagues (1995) observed that if hydrops was evident before 24 weeks, the fetal mortality rate was 95 percent. Conversely, euploid fetuses with hydrops who survived to at least 24 weeks and who had structurally normal hearts had a survival rate of 20 percent.

Diagnosis

In some cases, targeted sonographic and laboratory evaluations will identify the cause of fetal hydrops—for example, those caused by a congenital anomaly, arrhythmia, or twin complication. Depending on the circumstances, helpful maternal blood tests might include hemoglobin electrophoresis, Kleihauer-Betke stain, indirect Coombs test, and serological tests for syphilis, toxoplasmosis, cytomegalovirus, rubella, and parvovirus B19. Amniocentesis is considered for karyotyping and for evidence of infection. Middle cerebral artery peak systolic velocity may suggest fetal anemia, which may prompt fetal blood sampling.

Management

In only a few instances is fetal hydrops amenable to treatment. For example, some tachyarrhythmias can be treated pharmacologically (see Chap. 13, p. 303). Severe anemia can be treated with blood transfusions. In addition, hydrops of one fetus in twin-twin transfusion syndrome may resolve with laser ablation of abnormal vascular anastomoses (see Chap. 13, p. 306

TABLE 29-7. Some Causes of Nonimmune Hydrops Fetalis

Fetal causes	
Anomalies	
Cardiac	Atrial or ventricular septal defect, hypoplastic left heart, pulmonary valve insufficiency, Ebstein subaortic stenosis, dilated heart, A-V canal defect, single ventricle, Fallot tetralogy, premature closure of foramen ovale, subendocardial fibroelastosis
Thoracic	Diaphragmatic hernia, cystic adenomatous malformation, pulmonary hypoplasia, lung hamartoma, mediastinal teratoma, chylothorax
Gastrointestinal	Jejunal atresia, midgut volvulus, intestinal malrotation or duplication, meconium peritonitis
Urological	Urethral stenosis or atresia, posterior bladder neck obstruction, bladder perforation, prune belly, neurogenic bladder, ureterocele
Syndromes	Thanatophoric dwarfism, arthrogryposis multiplex congenita, asphyxiating thoracic dystrophy, hypophosphatasia, osteogenesis imperfecta, achondroplasia, achondrogenesis, recessive cystic hygroma, and Neu-Laxova, Saldino-Noonan, and Pena-Shokeir type I syndromes
Conduction defects	Supraventricular tachycardias, heart block (including with maternal lupus erythematosus)
Miscellaneous	Cystic hygroma, congenital lymphedema, polysplenia syndrome, neuroblastoma, tuberous sclerosis, sacrococcygeal teratoma
Aneuploidies	Trisomy 21 and other trisomies, Turner syndrome, triploidy
Vascular	A-V shunts, large vessel thromboses (cava, portal, or femoral vein), Kasabach-Merritt syndrome
Infections	Cytomegalovirus, toxoplasmosis, syphilis, listeriosis, hepatitis, rubella, parvovirus, leptospirosis, Chagas disease
Multifetal pregnancy	Twin-twin transfusion syndrome, twin reverse-arterial perfusion (TRAP) syndrome
Miscellaneous	α_4-thalassemia (Bart hemoglobin), twisted ovarian cyst, fetal trauma, anemia, Gaucher disease, gangliosidosis, sialidosis
Placental causes	Chorioangioma, fetomaternal hemorrhage, A-V shunts, placenta trauma with fetal hemorrhage, twin-twin transfusion syndrome
Maternal causes	
Medications	Indomethacin

and Chap. 39, p. 872). In most cases, however, hydrops cannot be treated and ultimately proves fatal for the fetus or newborn. In general, if nonimmune hydrops persists and cardiac abnormalities and aneuploidy have been excluded and if the fetus is mature enough that survival is likely, delivery should be accomplished. Very preterm fetuses usually are managed expectantly. Although hydrops usually persists or worsens with time, it occasionally resolves spontaneously (Mueller-Heubach and Mazer, 1983).

Maternal Complications

Preterm labor is common because of associated hydramnios. Placental abruption or uterine atony sometimes follows sudden decompression of an overdistended uterus, and retained placenta is common. Fetal hydrops was associated with a significant 2.3-fold increased risk for preeclampsia (Wu and colleagues, 2009). In one variant—the maternal *mirror syndrome*—the mother develops preeclampsia along with severe edema that is similar to that of the fetus. This unique complication of hydrops is believed to be caused by vascular changes in the swollen, hydropic placenta (Midgley and Hardrug, 2000). The observations of Kusanovic and co-workers (2008) show that this likely is related to antiangiogenic factors produced by hyperplacentosis (see Chap. 34, p. 714). Duthie and Walkinshaw (1995) and Goeden and Worthington (2005) each describe a woman with parvovirus-associated fetal hydrops and severe preeclampsia at midpregnancy that resolved a few weeks after fetal anemia and hydrops had resolved.

Fetal Cardiac Arrhythmias

Abnormal fetal heart rhythms are now recognized frequently because of extensive use of real-time sonography and Doppler technology. Most arrhythmias are transient and benign, but some tachyarrhythmias, if sustained, can result in heart failure and fetal death. Fetal arrhythmias and their treatment are discussed in Chapter 13 (p. 303).

Congenital Heart Block

Brucato and co-workers (2003) reviewed 1825 cases of congenital heart block from 38 studies. They reported that antenatal diagnosis is associated with a much poorer prognosis and a higher risk of late-onset dilated cardiomyopathy than a diagnosis made in childhood. The recurrence risk of congenital heart block in subsequent pregnancy is high because this defect is associated with anticardiac antibodies. Many of these women have, or subsequently develop, systemic lupus erythematosus or another connective-tissue disease. Conversely, of all the women who

produce anti–SS-A, only 1 in 20 have fetuses with cardiac disease (see Chap. 54, p. 1150).

Approximately half of cases of congenital heart block are caused by maternal anti-SS-A (anti-Ro) antibody that binds to tissue in the conduction tracts (Taylor and colleagues, 1986). Conduction tissue inflammation provoked by these antibodies can lead to permanent damage, and symptomatic survivors frequently require a pacemaker at birth. Not all affected fetuses have heart block, and anti-SS-A antibodies can affix to other cardiac tissues as well. If there is extensive myocarditis, the prognosis is poor. Cuneo and associates (2009) showed that if these antibodies are associated with effusions, bradyarrhythmias, or endocardial fibroelastosis, then progressive worsening may occur after birth. There are intriguing data from Stevens and associates (2003) that provide evidence that these affected myocytes may arise from maternal cell engraftment. Such *microchimerism* is discussed in Chapter 54 (p. 1146).

Fetal Treatment. Robinson and co-workers (2001) used terbutaline to transiently increase the heart rate of seven fetuses with a ventricular rate below 60. Fetal pacemaker placement may be an option. Saleeb and colleagues (1999) reviewed the treatment of 50 fetuses with heart block caused by maternal SS-A and SS-B antibodies. They concluded that fluorinated steroids significantly improved outcome and resulted in the resolution of pleural effusions, ascites, or hydrops in 13 of 18 treated cases. Currently, there are no completed controlled trials from which to draw conclusions.

DISEASES OF THE TERM FETUS AND NEONATE

Respiratory Distress Syndrome

Term infants can have respiratory complications, although these are much less frequent than in those born preterm. Common causes in term infants include sepsis, especially from group B streptococcal disease and intrauterine-acquired pneumonia; persistent pulmonary hypertension of the newborn; meconium aspiration syndrome; and pulmonary hemorrhage.

Advances in neonatal care have improved survival with these conditions. High-frequency oscillatory and jet ventilation improves oxygenation without high ventilatory pressures. Moreover, nitric oxide is a specific pulmonary vasodilator. Finer and Barrington (2000) reported a meta-analysis of 11 trials of therapy in infants 34 weeks or older with respiratory failure. They found that nitric oxide significantly improved oxygenation, reduced mortality rates, and decreased the need for extracorporeal membrane oxygenation (p. 606).

Meconium Aspiration Syndrome

This disorder results from peripartum inhalation of meconium-stained amnionic fluid. Inhalation leads to chemical pneumonitis with inflammation of pulmonary tissues, mechanical airway obstruction, and hypoxia. Singh and colleagues (2009) reported its incidence to be 1.8 percent in more than 162,000 term neonates. In severe cases, it progresses to persistent pulmonary hypertension, other morbidity, and death. Even with prompt and appropriate therapy, seriously affected infants frequently die or suffer long-term neurological sequelae.

Risk Factors

In up to 20 percent of pregnancies at term, amnionic fluid is contaminated by meconium. Its passage into a normal amnionic fluid volume results in light meconium staining, and its aspiration before labor is relatively common. In healthy, well-oxygenated fetuses, this diluted meconium is readily cleared from the lungs by normal physiological mechanisms. In some, however, the inhaled meconium is not cleared, and meconium aspiration syndrome results. It can occur after normal labor, but is more likely when the meconium is thick, the pregnancy is postterm, or the fetus is growth-restricted. Putting these together, pregnancies at highest risk are those with diminished amnionic fluid volume and with cord compression or uteroplacental insufficiency that may cause meconium passage (Leveno and colleagues, 1984). In these cases, the meconium remains thick and undiluted, and the compromised fetus cannot clear it.

Prevention

Unfortunately, pathological meconium aspiration cannot be predicted by the fetal heart rate tracing (Chap. 18, p. 431) (Dooley and colleagues, 1985). Early studies reported that the incidence of meconium aspiration syndrome could be reduced by *oropharyngeal suctioning* following delivery of the fetal head, but before delivery of the chest. Accordingly, this became the standard of care. Subsequently, however, several reports showed that strict adherence to this protocol did not reduce the incidence of meconium aspiration syndrome (Davis and colleagues, 1985; Wiswell and coworkers, 1990). Moreover, it was noted that associated pulmonary hypertension is characterized by abnormal arterial muscularization that begins well before birth. Because of such findings, Katz and Bowes (1992) concluded that only chronically asphyxiated fetuses develop meconium aspiration syndrome. They postulated that chronic antepartum asphyxia leads to pulmonary vascular damage, pulmonary hypertension, and persistent fetal circulation. Similarly, Richey (1995) and Bloom (1996) and their associates found no correlation between markers of *acute* asphyxia, such as umbilical artery acidosis, and meconium aspiration.

To settle this issue, an 11-center randomized trial of intrapartum suctioning versus no suctioning with meconium-stained amnionic fluid was done. Results reported by Vain and colleagues (2004) showed an identical 4-percent incidence of meconium aspiration syndrome in both groups. This led to a recommendation against routine intrapartum oropharyngeal and nasopharyngeal suctioning in the presence of meconium-stained fluid by the American Heart Association and American Academy of Pediatrics (2006) as well as the American College of Obstetricians and Gynecologists (2007). Instead, depressed newborns should be intubated and suctioned to remove meconium or other aspirated material from beneath the glottis. This is also discussed in Chapter 28 (p. 591).

Amnioinfusion

Saline infused into the amnionic cavity may be beneficial when meconium staining is thick and there are recurrent variable

decelerations (Spong and associates, 1994). The technique is described in Chapters 18 (p. 433) and 21 (p. 497). Amnioinfusion probably poses little or no increased risk (Wenstrom and co-workers, 1995). Unfortunately, it does not benefit fetuses in whom meconium aspiration syndrome has already developed before labor (Byrne and Gau, 1987). A multicenter randomized trial of almost 2000 women who were laboring at 36 weeks or later and who had thick meconium-stained fluid was designed to evaluate amnioinfusion. Pregnancies were stratified by presence or absence of variable decelerations (Fraser and colleagues, 2005). Amnioinfusion did not reduce the perinatal death rate—0.5 percent in both groups. There was no difference in the rate of moderate or severe meconium aspiration—4.4 versus 3.1 percent, with and without amnioinfusion, respectively. Finally, there was not a significant reduction in cesarean delivery—32 versus 29 percent, respectively. For these reasons, the American College of Obstetrics and Gynecologists (2006a) does not recommend amnioinfusion to reduce meconium aspiration syndrome.

Hemorrhagic Disease of the Newborn

This disorder is characterized by spontaneous internal or external bleeding beginning any time after birth. Most hemorrhagic disease results from abnormally low levels of the vitamin K-dependent clotting factors—V, VII, IX, X, prothrombin, and proteins C and S (Zipursky, 1999). Early bleeding may begin within 48 hours after birth in infants whose mothers took anticonvulsants during pregnancy. In these cases, the depressed factor levels result from their decreased maternal hepatic synthesis and from the generally poor transplacental passage of vitamin K. Classic hemorrhagic disease, which becomes apparent from 2 to 5 days after birth, develops in infants not treated with vitamin K at birth. Late hemorrhage occurs at 2 to 12 weeks in infants who are exclusively breast fed, because breast milk contains very low levels of vitamin K. Other causes include hemophilia, congenital syphilis, sepsis, thrombocytopenia purpura, erythroblastosis, and intracranial hemorrhage.

Prophylaxis

Hemorrhagic disease can be avoided by the intramuscular injection of 1 mg of vitamin K_1 (phytonadione) at delivery. Oral administration is not effective, and maternal administration of vitamin K prior to delivery results in very little transport to the fetus. For treatment of active bleeding, vitamin K is injected intravenously. Reports of an association between the administration of vitamin K to newborns and subsequent development of childhood leukemia have been disproved (Zipursky, 1999).

Thrombocytopenia

There are a number of causes of neonatal thrombocytopenia, and these include immune disorders, infections, some drugs, and congenital syndromes. For example, parvovirus-related hydrops, discussed on page 626, is associated with severe thrombocytopenia in a third of cases (Segata and co-workers, 2007). Thrombocytopenia affects a third of all infants admitted to neonatal intensive care units (Sola-Visner and associates, 2009). It is more common in those with respiratory distress complicated by hypoxia or sepsis.

Immune Thrombocytopenia

Rarely, antiplatelet IgG is transferred from the mother, causing thrombocytopenia in the fetus-neonate. In these cases, fetal thrombocytopenia is usually mild and is found in association with maternal autoimmune disease, especially immune thrombocytopenia. Importantly, neonatal platelet levels often fall rapidly after birth, reaching a nadir at 48 to 72 hours of life. Although corticosteroid therapy usually increases maternal platelet levels, it generally does not affect fetal platelets. Despite this, fetal platelet counts are usually adequate to allow vaginal delivery without an increased risk of intrapartum hemorrhage and without the need for fetal platelet sampling (see Chap. 51, p. 1094).

Alloimmune Thrombocytopenia

This condition is also referred to as *AIT* or *NAIT—neonatal AIT*—and it differs from immune thrombocytopenia in several important ways. It is caused by maternal isoimmunization to fetal platelet antigens in a manner similar to D-antigen isoimmunization discussed on page 618. Thus, the maternal platelet count is normal and isoimmunization is not suspected until after the birth of an affected child. In some cases, antepartum fetal intracranial hemorrhage is diagnosed. Of note, isoimmune thrombocytopenia, even in the first affected infant, is frequently severe and commonly develops before the third trimester. Fetal intracranial hemorrhage develops in up to 20 percent of severely affected fetuses, even as early as 20 weeks. Chronic villitis has been described in untreated cases (Althaus and colleagues, 2005).

Maternal isoimmunization is most often against the platelet antigen HPA-1a—formerly called PL A1—which is found in 98 percent of the population. The susceptible mother lacks this common antigen and becomes immunized when exposed to the fetal platelet antigen. Recall that some degree of fetal-maternal hemorrhage occurs in most pregnancies (see p. 617). Based on the incidence of HPA-1a negativity, 1 in 50 pregnancies is at risk. Yet the incidence of isoimmune thrombocytopenia is only 1 in 1000 to 1 in 5000 pregnancies (Berkowitz and associates, 2006a; Bussel and Primiani, 2008). The paucity of expected cases is explicable because fetal-maternal hemorrhage sufficient to provoke an immune response occurs in only 5 to 10 percent of pregnancies.

Antibodies other than anti-HPA-1a are responsible for 20 percent of cases. These include HPA-1b, HPA-3a, and HPA-5b (Davoren and associates, 2004). An extensive list of these was provided by Berkowitz and co-workers (2006a).

Diagnosis and Management. Progress in identification and treatment of affected fetuses was reviewed by Berkowitz and colleagues (2006b). The diagnosis is usually made after the first pregnancy in a woman with a normal platelet count. There is no evidence of immunological disorder, and her infant has unexplained severe thrombocytopenia. Fetal alloimmune thrombocytopenia recurs in 70 to 90 percent of subsequent pregnancies, is often severe, and usually develops earlier with each successive pregnancy. Indeed, half of such fetuses who undergo cordocentesis blood sampling will have a platelet count $< 20{,}000/\mu L$.

Because of severe thrombocytopenia in fetuses in subsequent pregnancies, invasive therapy such as platelet transfusions is problematic. Fortunately, weekly maternal intravenous infusions of immunoglobulin (IVIG), 1 g/kg/week, usually result in fetal platelet levels high enough to prevent spontaneous hemorrhage. For nonresponders, maternal prednisone therapy is given also. Although Berkowitz and colleagues (2006b) recommend cesarean delivery in most cases, van den Akker and associates (2006) reported vaginal delivery to be safe in women given weekly immunoglobulin infusions and whose previous infant did not have intracranial hemorrhage. According to the Medical Letter, in 2006, such therapy cost $40 to $55 per gram. Despite this, Thung and Grobman (2005) calculated that it is cost effective.

Preeclampsia and Eclampsia

Fetal thrombocytopenia is not caused by preeclampsia–eclampsia. Pritchard and colleagues (1987) at Parkland Hospital studied a large number of mother-infant pairs in pregnancies complicated by hypertension and identified no cases in which neonatal thrombocytopenia correlated with maternal thrombocytopenia (see Chap. 34, p. 717).

Polycythemia and Hyperviscosity

Neonatal polycythemia and blood hyperviscosity develop as the result of chronic hypoxia in utero, from acute transfusion from the placenta or a twin at delivery, or more rarely, from maternal-fetal hemorrhage. As the hematocrit rises above 65, blood viscosity markedly increases. Signs and symptoms include plethora, cyanosis, and neurological aberrations. Laboratory findings include hyperbilirubinemia, thrombocytopenia, fragmented erythrocytes, and hypoglycemia. Treatment consists of partial exchange transfusion with plasma to lower the hematocrit.

FETAL DEATH

From the foregoing sections, it is apparent that a number of maternal and fetal conditions can result in fetal demise. With advances in obstetrics, clinical genetics, maternal-fetal and neonatal medicine, and perinatal pathology, a number of stillbirths that previously would have been categorized as "unexplained" can now be attributed to specific causes. In many cases, this information makes management of subsequent pregnancies easier. Sonography allows rapid confirmation of fetal death, which frequently prompts labor induction (see Chap. 22, p. 500).

Definition of Fetal Mortality

Statistics on perinatal outcome compiled by the Centers for Disease Control and Prevention and the Vital Statistics Reports include only those dead fetuses and neonates born at after 19 weeks, or if gestational age is not available, weighing 350 g or more (MacDorman and Kirmeyer, 2009). As shown in **Figure 29-11**, stillbirths are more common with decreasing gestational age. The fetal mortality rate for the United States has steadily declined since 1985 from 7.8 to 6.2 per 1000 live births. Before this, an even more impressive decline was likely because deaths of infants with anomalies were "prevented" by early pregnancy terminations (Fretts and associates, 1992). There are a number of risk factors for stillbirth that were recently reviewed by Reddy (2007) and Silver (2007). These include black race, increasing maternal age, obesity, smoking, prior stillbirth, fetal-growth restriction, and maternal diseases. And Bukowski and associates (2009) linked excessive rates of stillbirth infants with fetal macrosomia defined as growth potential > 90th percentile. In some of these—for example, advancing maternal age, multiple factors are likely interactive (Huang and colleagues, 2008). Finally, the fetal death rate is increased fourfold in multifetal pregnancies (American College of Obstetricians and Gynecologists, 2009).

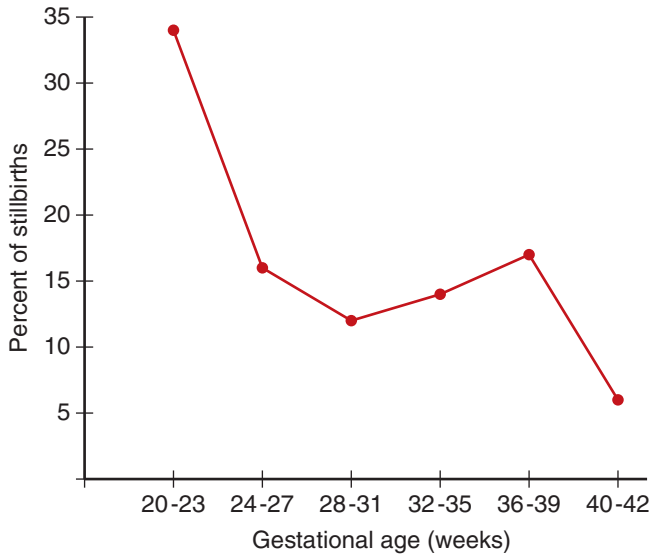

FIGURE 29-11 Proportion of 25,653 stillbirths according to gestational-age epochs in the United States in 2003—National Vital Statistics Reports. (Data from MacDorman and colleagues, 2007.)

Causes of Fetal Death

The three general categories of fetal death shown in **Table 29-8** are fetal, placental, and maternal. Autopsy performed by a pathologist with expertise in fetal and placental disorders, assisted by a team including maternal-fetal medicine, genetic, and pediatric specialists, often can determine the cause of death. Faye-Petersen (1999), Horn (2004), and their associates reviewed autopsies performed by such teams and found that the cause of death was identified in as many as 94 percent of cases. Determining the cause of preterm deaths is more difficult (Yudkin and colleagues, 1987).

Fetal Causes

Some type of fetal abnormality accounts for 25 to 40 percent of all stillbirths (see Table 29-8). The reported incidence of *major congenital malformations* in stillborns is highly variable because of ascertainment bias. It depends on whether autopsy was performed and if so, the experience, interest, and training of the pathologist (Cartlidge and co-workers, 1995a). For example, most stillbirths attributed to fetal causes in Wisconsin had a major structural malformation identified at autopsy (Pauli and

TABLE 29-8. Categories and Causes of Fetal Death

Fetal—25 to 40 percent
Chromosomal anomalies
Nonchromosomal birth defects
Nonimmune hydrops
Infections—viruses, bacteria, protozoa
Placental—25 to 35 percent
Prematurely ruptured membranes
Abruption
Fetomaternal hemorrhage
Cord accident
Placental insufficiency
Intrapartum asphyxia
Previa
Twin-twin transfusion
Chorioamnionitis
Maternal—5 to 10 percent
Diabetes
Hypertensive disorders
Obesity
Age > 35 years
Thyroid disease
Renal disease
Antiphospholipid antibodies
Thrombophilias
Smoking
Illicit drugs and alcohol
Infections and sepsis
Preterm labor
Abnormal labor
Uterine rupture
Postterm pregnancy
Unexplained—15 to 35 percent

From Cunningham and Hollier (1997), Eller and colleagues (2006), Reddy (2007), and Silver (2007).

Reiser, 1994). Conversely, in a study of 403 stillbirths reported by Copper and colleagues (1994), malformations were identified prenatally in only 5.6 percent. Faye-Petersen and associates (1999) found that a third of fetal deaths were caused by structural anomalies. Neural-tube defects, hydrops, isolated hydrocephalus, and complex congenital heart disease were the most common. Major structural anomalies, hydrops, and aneuploidy are particularly amenable to antenatal diagnosis.

Stillbirths caused by fetal infection are also common, especially when ascending bacterial infections of amnionic fluid and placental sources are considered. In indigent and inner-city women, congenital syphilis can be a common cause of fetal death (see Chap. 59, p. 761). Other potentially lethal infections include those caused by cytomegalovirus and parvovirus B19, as well as rubella, varicella, listeriosis, borreliosis, toxoplasmosis, and many more (Duff and colleagues, 2009; McClure and Goldenberg, 2009).

Placental Causes

Many fetal deaths due to placental abnormalities could also be categorized as having maternal or fetal causes. For example, placental abruption is associated with hypertension in approximately half of cases and could thus be considered a "maternal" cause. Placental insufficiency from aneuploidy could be considered a "fetal" cause. With these caveats in mind, perhaps 15 to 25 percent of fetal deaths are attributed to problems of the placenta, membranes, or cord (Fretts and Usher, 1997).

Placental abruption is the most common single identifiable cause of fetal death (see Chap. 35, p. 761). Fretts and Usher (1997) determined abruption to be the cause of death in 14 percent of stillborns. At Parkland Hospital, approximately 10 percent of third-trimester stillbirths are from abruption.

Significant *placental* and *membrane infection* is usually associated with fetal infection. Exceptions include tuberculosis and malaria. In some cases, microscopic examination of the placenta and membranes may help to identify an infectious cause (Duff and associates, 2009). Chorioamnionitis is characterized by mononuclear and polymorphonuclear leukocytes infiltrating the chorion (see Chap. 27, p. 581). Preterm stillbirths are more likely to be associated with these infections that include aerobic and anaerobic bacterial species as well as mycoplasma and ureaplasma (Goldenberg and associates, 2008; Onderdonk and coworkers, 2008).

Placental infarcts appear as areas of fibrinoid trophoblastic degeneration, calcification, and ischemic infarction from spiral artery occlusion. Marginal and subchorionic infarcts are common and usually of no import. These lesions and their clinical significance are discussed further in Chapter 27 (p. 579).

Fetal-maternal hemorrhage sufficient to cause fetal death was reported in 4.7 percent of 319 fetal deaths at Los Angeles County Women's Hospital in which Kleihauer-Betke stains of maternal blood had been performed (Samadi and associates, 1996). Although usually spontaneous, such hemorrhage is common with severe maternal trauma (see Chap. 42, p. 936).

Twin-twin transfusion syndrome is a common cause of fetal death in monochorionic multifetal pregnancy (see Chap. 39, p. 874).

Maternal Causes

Although they appear to make only a small contribution to fetal deaths, maternal factors may be underestimated. Some pathologies with a strong maternal component—for example, placental abruption or isoimmunization—often are attributed to placental or fetal causes. *Hypertensive disorders* and *diabetes* are the two most commonly cited maternal diseases and are associated with 5 to 8 percent of stillbirths (Alessandri and colleagues, 1992; Fretts and Usher, 1997). As discussed in Chapter 45 (p. 988), chronic hypertension is especially associated with increased fetal death (Aagaard-Tillery and co-workers, 2006; August and Lindheimer, 2009). Perhaps related, overweight and obese women have an increased risk of stillbirth (Chu and associates, 2007; Getahun and co-workers, 2007). Extremes of reproductive age—even when adjusted for known associations such as anomalies and maternal medical disorders—are complicated by a higher fetal death rate (Bateman and Simpson, 2006;

Reddy and associates, 2006; Wyatt and colleagues, 2005). The concept of severe maternal morbidity is discussed in Chapter 1 (p. 6). In developing countries, and intuitively so in developed nations, the stillbirth rate may be increased manyfold with severe maternal morbidities (Cham and associates, 2009).

Lupus anticoagulant and *anticardiolipin antibodies* are associated with decidual vasculopathy, placental infarction, fetal-growth restriction, recurrent abortion, and fetal death (see Chap. 54, p. 1151). Although women with these autoantibodies and other *thrombophilias* clearly are at increased risk for adverse pregnancy outcomes, very few otherwise unexplained stillbirths can be attributed solely to such antibodies (Reddy, 2007). These disorders are discussed in detail in Chapter 47 (p. 1014) and Chapter 54 (p. 1154).

Evaluation of the Stillborn

Determining the cause of fetal death aids the psychological adaptation to a significant loss, helps to assuage the guilt that is part of grieving, makes counseling regarding recurrence more accurate, and may prompt therapy or intervention to prevent a similar outcome in the next pregnancy (American College of Obstetricians and Gynecologists, 2009). Identification of inherited syndromes also provides useful information for other family members.

Clinical Examination

A thorough examination of the fetus, placenta, and membranes should be performed at delivery and recorded in the chart. The details of relevant prenatal events should be provided. Photographs should be taken for the record whenever possible, and a full radiograph of the fetus—a "fetogram"—may be performed. MR imaging and sonography may also be considered (American College of Obstetricians and Gynecologists, 2009). These are especially important in providing anatomical information if parents decline a full autopsy. The checklist used at Parkland Hospital to format the stillbirth note is outlined in Table 29-9.

TABLE 29-9. Protocol for Examination of Stillborns

Infant Description
- Malformations
- Skin staining
- Degree of maceration
- Color—pale, plethoric

Umbilical Cord
- Prolapse
- Entanglement—neck, arms, legs
- Hematomas or strictures
- Number of vessels
- Length
- Wharton jelly—normal, absent

Amnionic Fluid
- Color—meconium, blood
- Consistency
- Volume

Placenta
- Weight
- Staining—meconium
- Adherent clots
- Structural abnormalities—circumvallate or accessory lobes, velamentous insertion
- Edema—hydropic changes

Membranes
- Stained—meconium, cloudy
- Thickening

From Cunningham and Hollier (1997).

Laboratory Evaluation

If autopsy and chromosomal studies are performed, up to 35 percent of stillborns are discovered to have major structural anomalies (Faye-Petersen and associates, 1999). Approximately 20 percent have dysmorphic features or skeletal abnormalities, and 8 percent have chromosomal abnormalities (Pauli and Reiser, 1994; Saller and colleagues, 1995). The American College of Obstetricians and Gynecologists (2009) recommends ideally karyotyping all stillborns. In the absence of morphological anomalies, up to 5 percent of stillborns will have a chromosomal abnormality (Korteweg and associates, 2008).

Appropriate consent must be obtained to take fetal tissue samples, including fluid obtained postmortem by needle aspiration. A total of 3 mL of fetal blood, obtained from the umbilical cord (preferably) or by cardiac puncture, is placed into a sterile, heparinized tube for cytogenetic studies. If blood cannot be obtained, the American College of Obstetricians and Gynecologists (2009) recommends at least one of the following samples: (1) a placental block about 1 × 1 cm taken below the cord insertion site in the unfixed specimen; (2) umbilical cord segment about 1.5 cm long; or (3) internal fetal tissue specimen such as costochondral junction or patella (skin is no longer recommended). Tissue is washed with sterile saline prior to placement in lactated Ringer solution or sterile cytogenetic medium. Placement in formalin or alcohol kills remaining viable cells and prevents cytogenetic analysis.

A full karyotype may not be possible in cases with prolonged fetal death. Still, Korteweg and co-workers (2008) reported that in a third of macerated fetuses, they successfully performed cytogenetic analysis. Fluorescence in situ hybridization might be used to exclude numerical abnormalities or to look for certain common deletions such as that causing DiGeorge syndrome. Maternal blood should be obtained for Kleihauer-Betke staining, for antiphospholipid antibodies and lupus anticoagulant testing if indicated, and for serum glucose measurement to exclude overt diabetes.

Autopsy

Patients should be offered and encouraged to allow a full autopsy, but valuable information also can be obtained from limited studies. A gross external examination, combined with photography, radiography, MR imaging, bacterial cultures, and selective use of chromosomal and histopathological studies often can aid in determining the cause of death (Reddy, 2007; Silver, 2007).

A complete autopsy is much more likely to yield valuable information. An analysis of 400 consecutive fetal deaths in Wales found that autopsy altered the presumed cause of death in 13 percent and provided new information in another 26 percent (Cartlidge and Stewart, 1995b). Studies show that autopsy results changed the recurrence risk estimates and parental counseling in 25 to 50 percent of cases (Faye-Petersen and colleagues, 1999; Silver, 2007).

In many centers, maternal records and autopsy findings are reviewed on a monthly basis by a stillbirth committee composed of maternal-fetal medicine specialists, neonatologists, clinical geneticists, and perinatal pathologists. If possible, the cause of death is assigned based on available evidence. Most importantly, parents should then be contacted and offered counseling regarding the cause of death, the recurrence risk if any, and strategies to avoid recurrence in future pregnancies.

Psychological Aspects

Fetal death is psychologically traumatic for the woman and her family. Further stress results from an interval of more than 24 hours between the diagnosis of fetal death and the induction of labor, not seeing her infant for as long as she desires, and having no tokens of remembrance (Radestad and colleagues, 1996). The woman experiencing a stillbirth or even an early miscarriage is at increased risk for postpartum depression and should be closely monitored (see Chap. 55, p. 1176).

Pregnancy After Previous Stillbirth

In a population-based Missouri study, Sharma and associates (2006) reported a stillbirth rate of 22.7 per 1000 in women with a prior fetal death. That said, there are very few conditions associated with recurrent stillbirth. According to Silver (2007), losses associated with placental insufficiency and preterm labor are more likely to recur, whereas those due to infection and multifetal pregnancy are less likely to do so. In fact, Surkan and co-workers (2004) found that delivery of a growth-restricted *liveborn* term infant was associated with a twofold increased risk of a subsequent stillbirth. With a growth-restricted preterm *liveborn*, this risk was increased fivefold. According to the American College of Obstetricians and Gynecologists (2009) the low-risk woman who has had an unexplained stillborn has a pregnancy-risk increased about tenfold. Because most occur earlier in gestation, the risk of a stillborn after 37 weeks is only 1.8 per 1000.

Other than hereditary disorders, only maternal conditions such as diabetes, chronic hypertension, or some thrombophilias increase the risk of recurrence. Losses that occur early in pregnancy are associated with a higher risk. Goldenberg and colleagues (1993) studied 95 women with a pregnancy loss at 13 to 24 weeks and found that in their next pregnancy, almost 40 percent delivered preterm, 5 percent had a stillbirth, and 6 percent had a neonatal death.

Prenatal Evaluation

Knowledge of the cause of fetal death results in a more precise calculation of individual recurrence risk and in many cases, allows a management plan to be made. For example, a cord accident would not be expected to recur. In contrast, aneuploidy generally has a 1-percent recurrence risk, and familial DiGeorge syndrome has a 50-percent recurrence. The latter two could be detected in subsequent pregnancies by chorionic villous sampling or amniocentesis. As discussed, infectious causes are unlikely to recur.

Maternal medical disorders associated with prior stillbirth are often easily identified. In some cases, intervention either preconceptionally or early in pregnancy improves outcome in subsequent pregnancies (see Chap. 7, p. 174). One example is tight preconceptional glucose control in diabetic women. Placental abruption, which has a 10-percent recurrence, often is associated with chronic hypertension that could possibly be reduced with more stringent blood pressure control or early delivery (Pritchard and colleagues, 1991). Finally, there is some evidence that recurrent fetal loss due to antiphospholipid antibodies can be decreased with treatment (see Chap. 54, p. 1151). This is more likely if fetal death was associated with placental insufficiency, growth restriction, or placental infarction (Reddy and colleagues, 2007).

Management of Subsequent Pregnancy

Few studies address management of the woman who has suffered a prior fetal death. The few modifiable risk factors such as hypertension and diabetes control are addressed. Some first- and second-trimester screening schemes may be enlightening. According to Reddy (2007), because almost half of fetal deaths are associated with growth restriction, fetal sonographic anatomical assessment at midpregnancy is followed by serial growth studies beginning at 28 weeks.

Weeks and colleagues (1995) evaluated fetal biophysical testing in 300 women whose only indication was prior stillbirth. There was only one recurrent stillbirth, and only three fetuses had abnormal testing results before 32 weeks. There was no relationship between the gestational age of the previous stillborn and the incidence or timing of abnormal test results or fetal jeopardy in the subsequent pregnancy. They concluded that antepartum surveillance should begin at 32 weeks or later in the otherwise healthy woman with a history of stillbirth. This recommendation is supported by the American College of Obstetricians and Gynecologists (2009) with the caveat that it increases the iatrogenic preterm delivery rate.

INJURIES OF THE FETUS AND NEWBORN

There are a number of birth injuries that can potentially complicate all types of deliveries. Some are more likely associated with "traumatic" delivery by forceps or vacuum, and others follow otherwise uncomplicated spontaneous delivery. Many are now discussed, and the remainder are described elsewhere in connection with specific obstetrical complications that lead to or contribute to the injury.

Incidence and Types of Injuries

There are few population studies available. In one from Nova Scotia from 1988 through 2001 that included 119,432 singleton, nonanomalous, vertex-presenting fetuses, the overall risk of trauma was 2 percent (Baskett and associates, 2007). But only

TABLE 29-10. Incidence of Major and Minor Trauma at Delivery—Nova Scotia, 1988–2001

		Trauma at Delivery	
Type of Delivery (Rate of Trauma)	**Number**	**Major[a]**	**Minor[b]**
Spontaneous (14 per 1000)	88,324	1:835	1:77
Assisted			
Vacuum (71 per 1000)	3175	1:265	1:15
Forceps (58 per 1000)	10,478	1:194	1:19
Failed assisted			
Vacuum (105 per 1000)	609	1:120	1:10
Forceps (56 per 1000)	714	1:143	1:20
Cesarean (8.6 per 1000)	16,132	1:3226	1:120
Labor (12 per 1000)	10,731	1:2682	1:84
No labor (1.2 per 1000)	5401	1:5401	1:900
All (19.5 per 1000)	119,432	1:639 (1.6 per 1000)	1:56 (18 per 1000)

[a]Major trauma = depressed skull fracture, intracranial hemorrhage, brachial plexopathy, or combination.
[b]Minor trauma = linear skull fracture, other fractures, facial palsy, cephalohematoma, or combination.
Data from Baskett and co-workers (2007).

0.16 percent of this was major trauma. As shown in Table 29-10, major trauma was most frequently associated with failed instrumented delivery, and the lowest incidence was with cesarean delivery without labor. Minor traumatic injuries followed a comparable pattern. Simonson and co-workers (2007) provided similar observations for 913 vacuum-assisted deliveries. Alexander and colleagues (2006), in the NICHD Maternal-Fetal Medicine Units Network study of 37,110 cesarean deliveries, reported 400 injuries for a 1.1-percent fetal injury rate. Most of these—260 or 0.7 percent—were skin lacerations, and there also were 88 cephalohematomas, 11 clavicular fractures, 11 facial nerve palsies, nine brachial plexopathies, and six skull fractures.

Head Injury

The fetus or infant can sustain a number of traumatic head injuries during labor or at delivery. They can be external and obvious or intracranial and even covert. Some are spontaneous, whereas others are associated with instrumented deliveries. These were reviewed recently by Doumouchtsis and Arulkumaran (2008).

Spontaneous Intracranial Hemorrhage

Fetal or neonatal intracranial hemorrhage can occur at any of several sites (Table 29-11). Isolated intraventricular hemorrhage into the germinal matrix, without associated subarach-

TABLE 29-11. Major Types of Intracranial Hemorrhage in the Newborn

Type	Gestational Age	Incidence and Severity	Cause(s) and Pathogenesis
Subdural	Term > preterm	Uncommon, Serious	Venous tears Trauma common
Subarachnoid	Preterm > term	Common, Benign	Trauma—term "Hypoxia"—preterm
Intracerebellar	Preterm > term	Uncommon, Serious	Multifactorial
Intraventricular	Preterm	Common, Serious	Germinal matrix Multifactorial
Miscellaneous	Term > preterm	Uncommon, Variable	Trauma, hemorrhagic infarction, coagulopathy, vascular defect, ECMO

ECMO = extracorporeal membrane oxygenation.
Data from Volpe (1995).

noid or subdural bleeding, is the most common type of intracranial hemorrhage. As discussed on page 607, it usually occurs spontaneously as the result of immaturity and generally does not result from traumatic delivery or obstetrical factors (Hayden and colleagues, 1985). Infants weighing less than 1500 g are most susceptible.

Spontaneous intracranial hemorrhage also has been documented in healthy term neonates (Huang and Robertson, 2004). In a prospective study, Whitby and associates (2004) used MR imaging in such infants and found that 6 percent of those delivered spontaneously and 28 percent of those delivered by forceps had a subdural hemorrhage. None of these infants had clinical findings, and hematomas resolved in all by 4 weeks.

The fetal head has considerable plasticity and may undergo appreciable molding during passage through the birth canal. The dimensions of the head actually change during the second stage, with lengthening of the occipitofrontal diameter of the skull. Rarely, severe molding can result in tearing of the bridging veins from the cerebral cortex to the sagittal sinus or in rupture of the internal cerebral veins, of the vein of Galen at its junctions with the straight sinus, or of the tentorium itself. Compression of the skull can stretch the tentorium cerebelli and can tear the vein of Galen or its tributaries. As a result, intracranial hemorrhage and/or subdural subarachnoid hemorrhage may occur even after an apparently uneventful vaginal delivery. With vacuum-assisted deliveries, Simonson and colleagues (2007) reported an incidence of 0.87 percent of asymptomatic intracranial hemorrhage. Subgaleal hemorrhages associated with instrumented delivery can have a poor prognosis (Chang and co-workers, 2007).

Traumatic Intraventricular Hemorrhage

Birth trauma is not a common cause of intracranial hemorrhage. The elimination of difficult forceps operations and appropriate management of breech delivery have contributed significantly to a reduction in the incidence of all birth injuries. For example, in more than 190,000 singleton infants greater than 2500 g born in the United Kingdom in 1994 and 1995, O'Mahony and colleagues (2005) reported an incidence of death from mechanical birth injury to be 3.1 per 100,000 births. As detailed in Chapter 23 (p. 520), appropriate use of forceps or vacuum delivery does not lead to increased intracranial hemorrhage or other neonatal injury (American College of Obstetricians and Gynecologists, 2000).

Infants suffering intracranial hemorrhage from mechanical injury, such as subdural hemorrhage from tentorial tears or massive infratentorial hemorrhage, have neurological abnormalities from the time of birth (Volpe, 1995). Severely affected infants have stupor or coma, nuchal rigidity, and opisthotonus that worsen over minutes to hours. Some infants who are born depressed appear to improve until approximately 12 hours of age, but then drowsiness, apathy, feeble cry, pallor, failure to nurse, dyspnea, cyanosis, vomiting, and convulsions become evident.

Subarachnoid hemorrhage is usually minor with no symptoms, but seizures with an interictal period may manifest. In some infants, there is catastrophic deterioration. Sonography, CT, or MR imaging of the head are useful for diagnosis and also have contributed appreciably to an understanding of the etiology and frequency of some forms of intracranial hemorrhage (Perlman and Cunningham, 1993).

Cephalohematoma

In the study from Nova Scotia, cephalohematomas were identified in 1.6 percent of all births (Baskett and co-workers, 2007). They are usually caused by injury to the periosteum of the skull during labor and delivery and rarely develop in the absence of birth trauma. For example, Simonson and colleagues (2007) reported an 11-percent incidence in 913 term infants successfully delivered by vacuum extraction. In the network study cited above of cesarean delivery outcomes, Alexander and associates (2006) found a 0.3-percent incidence of cephalohematoma. The hemorrhage may develop over one or both parietal bones, and palpable edges can be appreciated as the blood reaches the limits of the periosteum (Fig. 29-12).

A cephalohematoma may not be apparent until hours after delivery, when bleeding sufficient to raise the periosteum has occurred. It often grows larger, disappearing only after weeks or

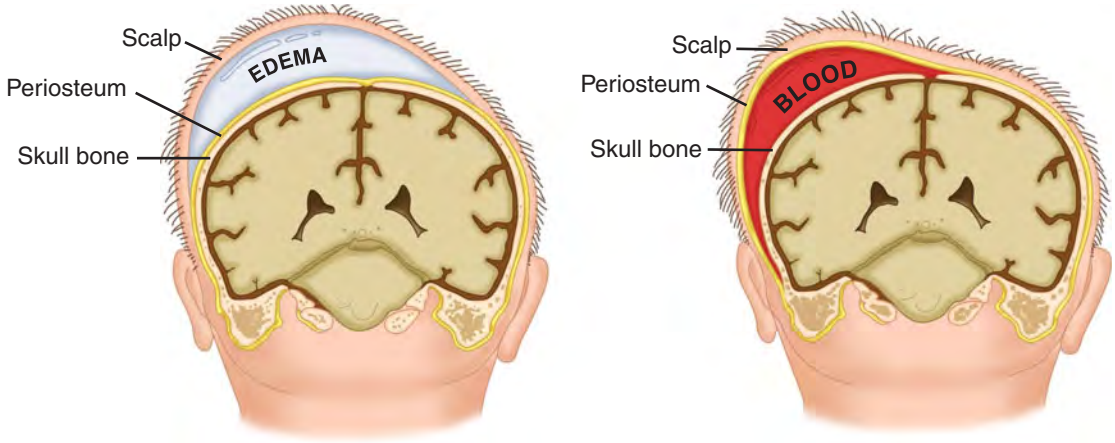

FIGURE 29-12 Difference between a large caput succedaneum (*left*) and cephalohematoma (*right*). In a caput succedaneum, the effusion overlies the periosteum and consists of edema fluid. In a cephalohematoma, it lies under the periosteum and consists of blood.

even months. The infant may become anemic. In contrast, caput succedaneum, also shown in Figure 29-12, consists of a focal swelling of the scalp from edema that overlies the periosteum. Swelling from caput succedaneum is maximal at birth, rapidly grows smaller, and usually disappears within hours or a few days. Occasionally, it becomes infected and an abscess may form (Kersten and co-workers, 2008).

Nerve Injuries

Spinal Injury

Overstretching of the spinal cord and associated hemorrhage may follow excessive traction during delivery, and there may be actual fracture or dislocation of the vertebrae. Menticoglou and associates (1995) described 15 neonates with this type of high cervical spinal cord injury and found that all of the injuries were associated with forceps rotations during delivery. Spinal cord injury also can occur during breech delivery.

Brachial Plexopathy

These injuries are relatively common and are identified between 1 in 500 to 1 in 1000 term births (Baskett and associates, 2007; Joyner and colleagues, 2006). Three types of brachial plexus damage have been described. Damage to the upper plexus is called *Erb* or *Duchenne paralysis* and involves C5 and C6 and occasionally C7. Injury leads to paralysis of the deltoid and infraspinatus muscles and the flexor muscles of the forearm. The affected arm is held straight and internally rotated, the elbow is extended, and the wrist and fingers flexed. Function of the fingers usually is retained. Because lateral head traction is frequently employed to effect delivery of the shoulders in normal vertex presentations, Erb paralysis can follow even deliveries that do not appear difficult.

Damage to the lower plexus—C8 and T1—results in *Klumpke paralysis*, in which the hand is flaccid. Total involvement of all brachial plexus nerve roots results in flaccidity of both arm and hand. With this kind of severe damage, there may also be *Horner syndrome* on the affected side—ptosis and pupillary meiosis resulting from interruption of nerve fibers in the cervical sympathetic chain.

With brachial plexus injury, increasing birthweight and breech delivery are significant risk factors. In a study of 130 infants with brachial plexus injuries, Ubachs and colleagues (1995) found that cases involving C5 to C6 nerve roots were frequently associated with breech delivery. More extensive damage involving C5 to C7 or C5 to T1 often followed difficult cephalic deliveries. Unfortunately, and as discussed in Chapter 20 (p. 481), shoulder dystocia cannot be predicted reliably. Thus, it is fortunate that most nerve injuries resolve with conservative therapy. Surgical repair is reserved for persistent cases due to nerve root avulsion (Malessy and Pondaag, 2009).

Facial Paralysis

Pressure on the facial nerve as it emerges from the stylomastoid foramen can cause damage resulting in facial paralysis. The incidence ranges from less than 1 to 7.5 per 1000 term births and is likely influenced by the vigor with which the diagnosis is sought (Levine and colleagues, 1984; White and associates, 1996). Facial paralysis may be apparent at delivery or may develop shortly after birth (**Fig. 29-13**). It most commonly is associated with normal spontaneous or cesarean delivery (Levine and co-workers, 1984). Only approximately 20 percent are associated with forceps deliveries (White and associates, 1996). In these deliveries, facial nerve damage can be caused by pressure exerted by the posterior blade when forceps have been placed obliquely on the fetal head. In these cases, forceps marks

FIGURE 29-13 A. Paralysis of the right side of the face 15 minutes after forceps delivery. The grimace is limited to the left face because the right side is flaccid. **B.** Same infant 24 hours later. Recovery was complete in another 24 hours.

indicate the cause of injury. Spontaneous recovery within a few days is the rule. Injuries to the sixth cranial nerve, with resultant lateral rectus ocular muscle paralysis, following operative vaginal delivery have also been reported (Galbraith, 1994).

Skeletal and Muscle Injuries

Fractures

Clavicular fractures are common, unpredictable, and unavoidable complications of normal birth. Their incidence is 3 to 18 per 1000 live births (Roberts and associates, 1995; Turpenny and Nimmo, 1993). In a cohort of newborns with such fractures, Chez and colleagues (1994) were unable to identify a specific factor that could be changed to avoid these fractures.

Humeral fractures are not common. Difficulty encountered in the delivery of the shoulders in cephalic deliveries and of extended arms in breech deliveries often produces such fractures. Up to 70 percent of cases, however, follow uneventful delivery (Turpenny and Nimmo, 1993). Humeral fractures are often of the greenstick type, although complete fracture with overriding bones may occur. Palpation of the clavicles and long bones should be performed on all newborns when a fracture is suspected. Crepitation or unusual irregularity should prompt radiographic examination.

Femoral fractures are relatively rare and usually associated with breech delivery.

Mandibular fractures have been reported and were recently reviewed by Vasconcelos and associates (2009). *Skull fracture* was identified in 3.7 per 100,000 births in nearly 2 million deliveries in two areas of France between 1990 and 2000 (Dupuis and co-workers, 2005). Almost 75 percent were associated with instrumented deliveries, and the others with spontaneous or cesarean delivery. In the radiograph shown in **Figure 29-14**, a focal but markedly depressed skull fracture is apparent. Labor was characterized by vigorous contractions, full dilatation of the cervix, and arrest of descent of the head, which was tightly wedged in the pelvis. The fracture likely resulted from compression of the skull against the sacral promontory, from lifting hand pressure by the surgeon, or from upward hand pressure by an assistant who helped to push the head out of the birth canal at cesarean delivery. Surgical decompression of the fracture was successful.

Muscular Injuries

The sternocleidomastoid muscle may be injured, particularly during breech delivery. There may be a tear of the muscle or the fascial sheath, leading to a hematoma and gradual cicatricial contraction. As the neck lengthens in the process of normal growth, the head is gradually turned toward the side of the injury—a condition known as *torticollis.* The damaged muscle is less elastic and does not elongate at the same rate as its normal contralateral counterpart. Roemer (1954) reported that 27 of 44 infants showing this deformity had been delivered by breech or internal podalic version. He postulated that lateral hyperextension sufficient to rupture the sternocleidomastoid may occur as the aftercoming head passes over the sacral promontory.

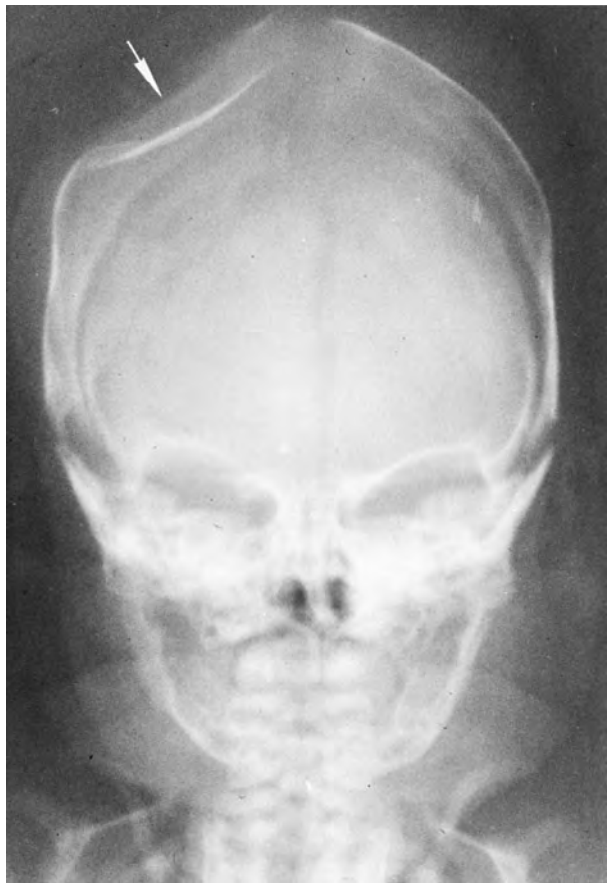

FIGURE 29-14 Depressed skull fracture (*arrow*) evident immediately after cesarean delivery. Labor had progressed, and the head was deep in the pelvis. Dislodgment of the head from the birth canal was performed by an assistant using manual pressure upward through the vagina.

Congenital Injuries

Amnionic Band Syndrome

A free strip of amnion can form a focal ring around an extremity or digit, eventually producing enough constriction to cause damage or even amputation of the encircled structure. Occasionally, the amputated part may be found within the uterus. The genesis of such bands is debated. Streeter (1930) and others proposed that a localized failure of germ plasm or an inherent developmental abnormality of the involved structures is responsible for the abnormalities. Torpin (1968) and others contend that the lesions are the consequence of early rupture of the amnion. Soldado and colleagues (2006) have developed an animal model to study this further. These lesions must be differentiated from limb-reduction defects associated with chorionic villus sampling done before 9 weeks as discussed in Chapter 13 (p. 300).

Congenital Postural Deformities

An otherwise normal fetal structure may be deformed by mechanical factors arising from chronically low volumes of amnionic fluid, by restriction of movement imposed by the small size and inappropriate shape of an abnormal uterine cavity, or

by the presence of additional fetuses. Such mechanical deformations include talipes equinovarus, that is, clubfoot; scoliosis; and hip dislocation (Miller and co-workers, 1981). Talipes equinovarus and other positional foot abnormalities are associated with membrane rupture from early amniocentesis between 11 and 13 weeks (see Chap. 13, p. 299). Finally, hypoplastic lungs also can result from oligohydramnios (see Chap. 21, p. 496).

SECTION 6

PUERPERIUM

CHAPTER 30

The Puerperium

ANATOMICAL, PHYSIOLOGICAL, AND CLINICAL ASPECTS 646
BREASTS AND LACTATION 649
CARE OF THE MOTHER DURING THE PUERPERIUM 654
HOME CARE 658

The puerperium is the period of time encompassing the first few weeks following birth. The duration of this "period" is understandably inexact, and it is considered by most to be between 4 and 6 weeks. Although a relatively uncomplex time compared with pregnancy, the puerperium is characterized by many physiological changes. Some of these changes may be simply bothersome for the new mother, although serious complications can also arise.

Some mothers have feelings of abandonment following delivery because of a newly aimed focus upon the infant. Thus, the puerperium may be a time of intense anxiety for many women. To illustrate this, data gathered by the Pregnancy Risk Assessment Monitoring System—*PRAMS*—is informative. This ongoing population based surveillance system was initiated in 1987 by the Centers for Disease Control and Prevention (2007a) to better understand why infant mortality rates had plateaued. The system collects data concerning maternal attitudes and experiences before, during, and shortly after pregnancy. Kanotra and colleagues (2007) analyzed data in a 10-state area in 2000 to assess challenges that women faced from 2 to 9 months following delivery. Their main findings are listed in Table 30-1.

ANATOMICAL, PHYSIOLOGICAL, AND CLINICAL ASPECTS

Vagina and Vaginal Outlet

Early in the puerperium, the vagina and its outlet form a capacious, smooth-walled passage that gradually diminishes in size but rarely returns to nulliparous dimensions. Rugae begin to reappear by the third week but are not as prominent as before. The hymen is represented by several small tags of tissue, which scar to form the *myrtiform caruncles.* Vaginal epithelium begins to proliferate by 4 to 6 weeks, usually coincidental with resumed ovarian estrogen production. Lacerations or stretching of the perineum during delivery may result in relaxation of the vaginal outlet. Some damage to the pelvic floor may be inevitable, and parturition predisposes to uterine prolapse as well as urinary and anal incontinence. This is a matter of great contemporaneous concern and is discussed in detail in Chapter 17 (p. 401).

Uterus

Vessels

The massively increased uterine blood flow necessary to maintain pregnancy is made possible by significant hypertrophy and remodeling of all pelvic vessels. After delivery, their caliber diminishes to approximately the size of the prepregnant state. Within the puerperal uterus, larger blood vessels become obliterated by hyaline changes, gradually resorbed, and replaced by smaller ones. Minor vestiges of the larger vessels, however, may persist for years.

Cervix and Lower Uterine Segment

During labor, the outer cervical margin, which corresponds to the external os, is usually lacerated, especially laterally. The cervical opening contracts slowly and for a few days immediately after labor readily admits two fingers. By the end of the first week, this opening narrows, the cervix thickens, and the endocervical canal reforms. The external os does not completely resume its pregravid appearance. It remains somewhat wider, and typically, bilateral depressions at the site of lacerations become permanent. These changes are characteristic of a parous cervix. The markedly thinned-out lower uterine segment contracts and retracts, but not as forcefully as the uterine corpus. During the next few weeks, the lower segment is converted from a clearly distinct substructure large enough to accommodate the fetal

TABLE 30-1. Pregnancy Risk Assessment Surveillance System—PRAMS[a]. Concerns Raised by Women in the First 2–9 Months Postpartum

Concerns	Percent
1. Need for social support	32
2. Breast feeding issues	24
3. Inadequate education about newborn care	21
4. Help with postpartum depression	10
5. Perceived need for extended hospital stay	8
6. Need for maternal insurance coverage postpartum	6

[a]Centers for Disease Control and Prevention (2007a). Data from Kanotra and associates (2007).

head, to a barely discernible uterine isthmus located between the corpus and internal os.

Cervical epithelium also undergoes considerable remodeling, and this actually may be salutary. For example, Ahdoot and colleagues (1998) found that about half of women showed regression of high-grade dysplasia following vaginal delivery.

Uterine Involution

Immediately after placental expulsion, the fundus of the contracted uterus lies slightly below the umbilicus. It consists mostly of myometrium covered by serosa and lined by basal decidua. The anterior and posterior walls, in close apposition, each measure 4 to 5 cm thick (Buhimschi and colleagues, 2003). Immediately postpartum, the uterus weighs approximately 1000 g. Because the blood vessels are compressed by the contracted myometrium, the uterus on section appears ischemic compared with the reddish-purple hyperemic pregnant organ.

During the puerperium, a truly remarkable *tour de force* of destruction or deconstruction begins. Two days after delivery, the uterus begins to involute, as shown in **Figure 30-1**, and at 1 week, it weighs about 500 g. By 2 weeks, it weighs about 300 g and has descended into the true pelvis. Around 4 weeks after delivery, it regains its previous nonpregnant size of 100 g or less. The total number of muscle cells probably does not decrease appreciably. Instead, the individual cells decrease markedly in size—from 500-800 μm by 5 to 10 μm at term to 50-90 μm by 2.5-5 μm postpartum. Involution of the connective tissue framework occurs equally rapidly.

Because separation of the placenta and membranes involves the spongy layer, the decidua basalis is not sloughed. The decidua that remains has striking variations in thickness, has an irregular jagged appearance, and is infiltrated with blood, especially at the placental site (see Fig. 30-1).

Sonographic Findings. It takes up to 5 weeks for the uterine cavity to regress to its nonpregnant state of a potential space. Tekay and Jouppila (1993) studied 42 normal women postpartum and identified fluid in the endometrial cavity in 78 percent at 2 weeks, 52 percent at 3 weeks, 30 percent at 4 weeks, and 10 percent at 5 weeks. Wachsberg and Kurtz (1992) followed 72 women and identified gas in the endometrial cavity in 19 percent within 3 days after delivery. In 7 percent, it was seen at 3 weeks. Finally, using Doppler ultrasound, Sohn and colleagues (1988) described continuously increasing uterine artery vascular resistance during the first 5 postpartum days.

Afterpains

In primiparas, the uterus tends to remain tonically contracted following delivery. However, in multiparas, it often contracts vigorously at intervals and gives rise to *afterpains,* which are similar to but milder than the pain of labor contractions. They are

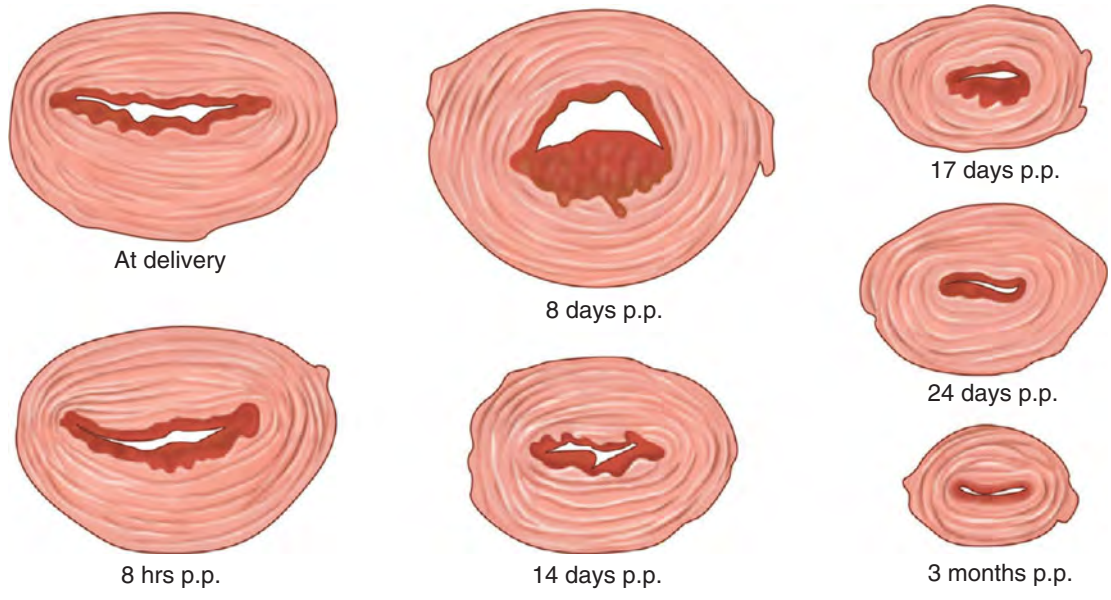

FIGURE 30-1 Cross sections of uteri made at the level of the involuting placental site at varying times after delivery. p.p. = postpartum. (Redrawn from Williams, 1931.)

more pronounced as parity increases and worsen when the infant suckles, likely because of oxytocin release (Holdcroft and colleagues, 2003). Usually, afterpains decrease in intensity and become mild by the third day.

Lochia

Early in the puerperium, sloughing of decidual tissue results in a vaginal discharge of variable quantity. The discharge is termed *lochia* and consists of erythrocytes, shredded decidua, epithelial cells, and bacteria. For the first few days after delivery, there is blood sufficient to color it red—*lochia rubra.* After 3 or 4 days, lochia becomes progressively pale in color—*lochia serosa.* After about the 10th day, because of an admixture of leukocytes and reduced fluid content, lochia assumes a white or yellowish-white color—*lochia alba.* Lochia persists for up to 4 to 8 weeks after delivery (Visness and co-workers, 1997).

Endometrial Regeneration

Within 2 or 3 days after delivery, the remaining decidua becomes differentiated into two layers. The superficial layer becomes necrotic and is sloughed in the lochia. The basal layer adjacent to the myometrium remains intact and is the source of new endometrium. The endometrium arises from proliferation of the endometrial glandular remnants and the stroma of the interglandular connective tissue.

Endometrial regeneration is rapid, except at the placental site. Within a week or so, the free surface becomes covered by epithelium, and Sharman (1953) identified fully restored endometrium in all biopsy specimens obtained from the 16th day onward. Histological endometritis is part of the normal reparative process. Moreover, microscopic inflammatory changes characteristic of acute salpingitis are seen in almost half of postpartum women between 5 and 15 days. However, these do not reflect infection (Andrews, 1951).

Subinvolution

This term describes an arrest or a retardation of involution. It is accompanied by prolongation of lochial discharge and irregular or excessive uterine bleeding, which sometimes may be profuse. On bimanual examination, the uterus is larger and softer than would be expected. Both retention of placental fragments and pelvic infection may cause subinvolution. Ergonovine or methylergonovine (Methergine), 0.2 mg every 3 to 4 hours for 24 to 48 hours, is recommended by some for subinvolution, but its efficacy is questionable. On the other hand, bacterial metritis responds to oral antimicrobial therapy. Wager and colleagues (1980) reported that almost a third of cases of late postpartum uterine infection are caused by *Chlamydia trachomatis.* Thus, azithromycin or doxycycline therapy is appropriate empirical therapy.

Andrew and colleagues (1989) described 25 cases of hemorrhage between 7 and 40 days postpartum associated with noninvoluted uteroplacental arteries. These abnormal arteries were filled with thrombi and lacked an endothelial lining. Perivascular trophoblasts were also identified in the vessel walls. They postulated that subinvolution, at least with regard to placental vessels, may represent an aberrant interaction between uterine cells and trophoblast.

Placental Site Involution

Complete extrusion of the placental site takes up to 6 weeks (Williams, 1931). When this process is defective, late-onset puerperal hemorrhage may ensue. Immediately after delivery, the placental site is approximately the size of the palm, but it rapidly decreases thereafter. Within hours of delivery, the placental site normally consists of many thrombosed vessels that ultimately undergo organization (see Fig. 30-1). By the end of the second week, it is 3 to 4 cm in diameter.

Williams (1931) described placental site involution as a process of exfoliation, which is in great part brought about by the undermining of the implantation site by growth of endometrial tissue. Thus, involution is not simply absorption in situ. Exfoliation consists of both extension and "downgrowth" of endometrium from the margins of the placental site, as well as development of endometrial tissue from the glands and stroma left deep in the decidua basalis after placental separation. Anderson and Davis (1968) concluded that placental site exfoliation results from sloughing of infarcted and necrotic superficial tissues followed by a remodeling process.

Late Postpartum Hemorrhage

The American College of Obstetricians and Gynecologists (2006) defines *secondary postpartum hemorrhage* as bleeding 24 hours to 12 weeks after delivery. Clinically worrisome uterine hemorrhage develops within 1 to 2 weeks in perhaps 1 percent of women. Such bleeding most often is the result of abnormal involution of the placental site. It occasionally is caused by retention of a placental fragment. Usually the retained piece undergoes necrosis with deposition of fibrin and may eventually form a so-called *placental polyp.* As the eschar of the polyp detaches from the myometrium, hemorrhage may be brisk. Demers (2005) and Salman (2008) and their associates have described delayed postpartum hemorrhage caused by von Willebrand disease (see Chap. 51, p. 1097).

Management. Because few women with delayed hemorrhage have retained placental fragments, we do not routinely perform curettage. Lee and associates (1981) studied 27 women with significant bleeding after the first postpartum day. In 20, sonographic evaluation revealed an empty uterus, and only one woman of the 27 had retained placental tissue. Importantly, in some with delayed hemorrhage, curettage will worsen bleeding by avulsing part of the implantation site. Thus, in a stable patient, if sonographic examination shows an empty cavity, then oxytocin, ergonovine, methylergonovine, or a prostaglandin analog is given. Antimicrobials are added if uterine infection is suspected. If large clots are seen in the uterine cavity with sonography, then *gentle* suction curettage is considered. Otherwise curettage is carried out only if appreciable bleeding persists or recurs after medical management.

Urinary Tract

Bladder trauma is associated most closely with the length of labor and thus to some degree is a normal accompaniment of vaginal delivery. Funnell and associates (1954) used cystoscopy immediately postpartum and described varying degrees of submucosal hemorrhage and edema. Postpartum, the bladder has an increased

capacity and a relative insensitivity to intravesical pressure. Thus, overdistension, incomplete emptying, and excessive residual urine are common. Their management is discussed on page 655.

The dilated ureters and renal pelves return to their prepregnant state over the course of 2 to 8 weeks after delivery (see Chap. 5, p. 123). Urinary tract infection is of concern because residual urine and bacteriuria in a traumatized bladder, coupled with a dilated collecting system, are conducive to infection.

Incontinence

Urinary incontinence in the first few days postpartum is uncommon. That said, there is increasing attention to the potential for the development of urinary incontinence subsequent to pregnancy. Recent and ongoing evaluations have focused on the effect of delivery on urinary and anal incontinence as well as pelvic organ prolapse. These long-term effects are complex in origin and are related to numerous factors that may cause neuromuscular damage. For example, MacArthur and colleagues (2006) found that 14 percent of parous women who had delivered exclusively by cesarean reported incontinence when monitored long-term. Risks of incontinence from vaginal, perineal, and anal sphincter lacerations and from episiotomy are considered in detail in Chapter 17 (p. 401). Importantly, the debate concerning avoidance of such injuries by *elective primary cesarean delivery* was addressed in detail by a National Institutes of Health (NIH) sponsored State-of-the-Science Conference in March 2006 (see Chap. 25, p. 548). Chiarelli and Cockburn (2002) reported on a randomized trial to reduce the prevalence and severity of urinary incontinence. They found that multifaceted intervention that included pelvic floor exercises was effective.

Peritoneum and Abdominal Wall

The broad and round ligaments require considerable time to recover from the stretching and loosening that occur during pregnancy. As a result of ruptured elastic fibers in the skin and prolonged distension caused by the pregnant uterus, the abdominal wall remains soft and flaccid. Several weeks are required for these structures to return to normal. Recovery is aided by exercise. Except for silvery striae, the abdominal wall usually resumes its prepregnancy appearance. When muscles remain atonic, however, the abdominal wall also remains lax. Marked separation of the rectus muscles—*diastasis recti*—may result.

Blood and Fluid Changes

Marked leukocytosis and thrombocytosis may occur during and after labor. The white blood cell count sometimes reaches 30,000/μL, with the increase predominantly due to granulocytes. There is a relative lymphopenia and an absolute eosinopenia. Normally, during the first few postpartum days, hemoglobin concentration and hematocrit fluctuate moderately. If they fall much below the levels present just prior to labor, a considerable amount of blood has been lost (see Chap. 35, p. 761).

Although not extensively studied, in most women, blood volume has nearly returned to its nonpregnant level by 1 week after delivery. Cardiac output usually remains elevated for 24 to 48 hours postpartum and declines to nonpregnant values by 10 days (Robson and colleagues, 1987). Heart rate changes follow this pattern. Systemic vascular resistance follows inversely. It remains in the lower range characteristic of pregnancy for 2 days postpartum and then begins to steadily increase to normal nonpregnant values.

Pregnancy-induced changes in blood coagulation factors persist for variable periods during the puerperium. Elevation of plasma fibrinogen is maintained at least through the first week, and hence, so is the sedimentation rate.

Normal pregnancy is associated with an appreciable increase in extracellular water, and postpartum diuresis is a physiological reversal of this process. This regularly occurs between the second and fifth days and corresponds with loss of residual pregnancy hypervolemia. In preeclampsia, both retention of fluid antepartum and diuresis postpartum may be greatly increased (see Chap. 34, p. 718).

Weight Loss

In addition to the loss of 5 to 6 kg due to uterine evacuation and normal blood loss, there is usually a further decrease of 2 to 3 kg through diuresis. Chesley and co-workers (1959) demonstrated a decrease in sodium space of about 2 L during the first week postpartum. According to Schauberger and co-investigators (1992), women approach their self-reported prepregnancy weight 6 months after delivery but still retain an average surplus of 1.4 kg (3 lb). Indigent women are more likely to retain weight gained during pregnancy (Olson and associates, 2003).

BREASTS AND LACTATION

Anatomically, each mature mammary gland or breast is composed of 15 to 25 lobes. They are arranged radially and are separated from one another by varying amounts of fat. Each lobe consists of several lobules, which in turn are composed of large numbers of alveoli. Each alveolus is provided with a small duct that joins others to form a single larger duct for each lobe as shown in **Figure 30-2**. These *lactiferous ducts* open separately on the nipple, where they may be distinguished as minute but distinct orifices. The alveolar secretory epithelium synthesizes the various milk constituents.

Colostrum

After delivery, the breasts begin to secrete colostrum, which is a deep lemon-yellow liquid. It usually can be expressed from the nipples by the second postpartum day. Compared with mature milk, colostrum contains more minerals and amino acids (Chuang and associates, 2005). It also has more protein, much of which is globulin, but less sugar and fat. Secretion persists for approximately 5 days, with gradual conversion to mature milk during the ensuing 4 weeks. Colostrum contains antibodies, and its content of immunoglobulin A (IgA) offers the newborn protection against enteric pathogens. Other host resistance factors found in colostrum and milk include complement, macrophages, lymphocytes, lactoferrin, lactoperoxidase, and lysozymes.

Milk

Human milk is a suspension of fat and protein in a carbohydrate-mineral solution. A nursing mother easily produces 600 mL of

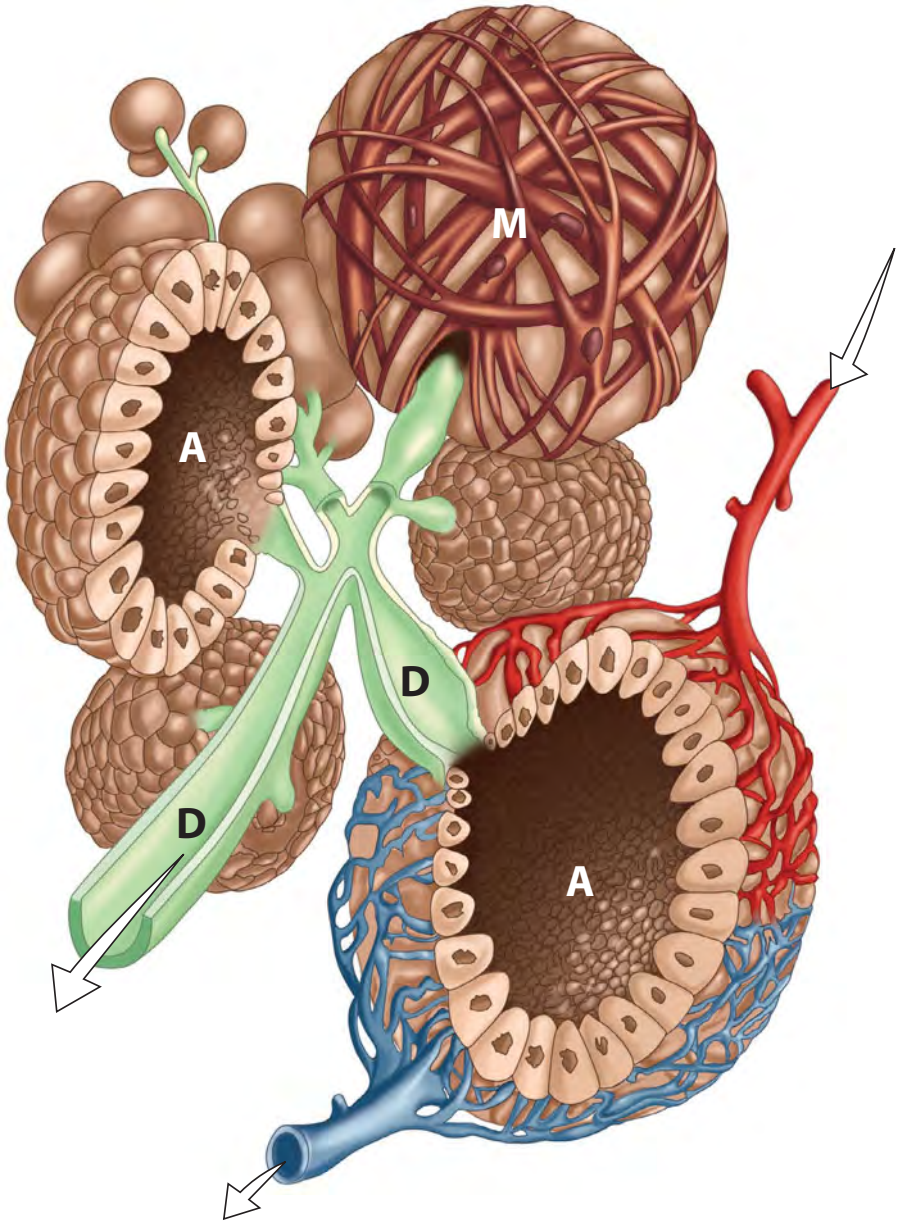

FIGURE 30-2 Graphic demonstration of the alveolar and ductal system. Note the myoepithelial fibers (*M*) that surround the outside of the uppermost alveolus. The secretions from the glandular elements are extruded into the lumen of the alveoli (*A*) and ejected by the myoepithelial cells into the ductal system (*D*), which empties through the nipple. Arterial blood supply to the alveolus is identified by the upper right arrow and venous drainage by the arrow beneath. (Redrawn from Dr. John C. Porter.)

milk daily, and maternal gestational weight gain has little impact on its quantity or quality (Institute of Medicine, 1990). Milk is isotonic with plasma, and lactose accounts for half of the osmotic pressure. Essential amino acids are derived from blood, and nonessential amino acids are derived in part from blood or synthesized in the mammary gland. Most milk proteins are unique and include α-lactalbumin, β-lactoglobulin, and casein. Fatty acids are synthesized in the alveoli from glucose and are secreted by an apocrine-like process. All vitamins except K are found in human milk, but in variable amounts. Vitamin D content is low—22 IU/mL, and newborn supplementation is recommended by the American Academy of Pediatrics (Wagner and colleagues, 2008).

Whey is milk serum and has been shown to contain large amounts of interleukin-6 (Saito and co-workers, 1991). It is associated closely with local IgA production by the breast. *Prolactin* appears to be actively secreted into breast milk (Yuen, 1988). *Epidermal growth factor (EGF)* has been identified in human milk, and because it is not destroyed by gastric proteolytic enzymes, it may be absorbed to promote growth and maturation of newborn intestinal mucosa (McCleary, 1991).

Endocrinology of Lactation

The precise humoral and neural mechanisms involved in lactation are complex. Progesterone, estrogen, and placental lactogen, as well as prolactin, cortisol, and insulin, appear to act in concert to stimulate the growth and development of the milk-secreting apparatus (Porter, 1974). With delivery, there is an abrupt and profound decrease in the levels of progesterone and estrogen. This decrease removes the inhibitory influence of progesterone on α-lactalbumin production by the rough endoplasmic reticulum. Increased α-lactalbumin stimulates lactose synthase to increase milk lactose. Progesterone withdrawal also allows prolactin to act unopposed in its stimulation of α-lactalbumin production.

The intensity and duration of subsequent lactation are controlled, in large part, by the repetitive stimulus of nursing. Prolactin is essential for lactation, and women with extensive pituitary necrosis—*Sheehan syndrome*—do not lactate (see Chap. 53, p. 1140). Although plasma prolactin levels fall after delivery to levels lower than during pregnancy, each act of suckling triggers a rise in levels (McNeilly and associates, 1983). Presumably a stimulus from the breast curtails the release of dopamine (prolactin-inhibiting factor) from the hypothalamus, and this in turn transiently induces increased prolactin secretion.

The neurohypophysis secretes oxytocin in pulsatile fashion. This stimulates milk expression from a lactating breast by causing contraction of myoepithelial cells in the alveoli and small milk ducts (see Fig. 30-2). Milk ejection, or *letting down*, is a reflex initiated especially by suckling, which stimulates the neurohypophysis to liberate oxytocin. The reflex may even be provoked by an infant cry and can be inhibited by maternal fright or stress.

TABLE 30-2. Established and Potential Protective Effects on Infants of Human Milk and Breast Feeding

Decreased Incidence/Severity	Possible Protective Effects
Diarrhea	Sudden infant death syndrome
Lower respiratory infection	Type 1 diabetes
Otitis media	Inflammatory bowel disease
Bacteremia	Lymphoma
Bacterial meningitis	Allergies
Botulism	Chronic digestive diseases
Necrotizing enterocolitis	
Urinary infections	

From the American Academy of Pediatrics (1997).

Immunological Consequences of Breast Feeding

Antibodies in human colostrum and milk are poorly absorbed by infants. This does not lessen their importance because the predominant immunoglobulin is secretory IgA. This macromolecule is secreted across mucous membranes and has important antimicrobial functions. Milk contains secretory IgA antibodies against *Escherichia coli,* and breast-fed infants are less prone to enteric infections than bottle-fed infants (Cravioto and associates, 1991). Human milk also provides protection against rotavirus infections, which cause up to half of cases of infant gastroenteritis in this country (Newburg and associates, 1998). Breast feeding also likely reduces the risk of atopic dermatitis and wheezing illnesses in early childhood (Friedman and Zeiger, 2005).

Much attention has been directed to the role of maternal breast-milk lymphocytes in the immunological processes of the newborn. Milk contains both T and B lymphocytes, but the T lymphocytes appear to differ from those found in blood. Specifically, milk T lymphocytes are almost exclusively composed of cells that exhibit specific membrane antigens, including the LFA-1 high-memory T-cell phenotype. These memory T cells appear to be another avenue for the neonate to benefit from the maternal immunological experience (Bertotto and associates, 1990). Lymphocytes in colostrum undergo blastoid transformation in vitro following exposure to specific antigens.

Nursing

Human milk is ideal food for neonates. It provides age-specific nutrients as well as immunological factors and antibacterial substances (American College of Obstetricians and Gynecologists, 2007). Milk also contains factors that act as biological signals for promoting cellular growth and differentiation. The American Academy of Pediatrics (1997) has provided a list of benefits of nursing as outlined in Table 30-2. For both mother and infant, the benefits of breast feeding are likely long-term. For example, women who breast feed have a lower risk of breast cancer, and their children have increased adult intelligence independent of a wide range of possible confounding factors (Collaborative Group on Hormonal Factors in Breast Cancer, 2002; Kramer and associates, 2008). Breast feeding is associated with decreased postpartum weight retention (Baker and co-workers, 2008). Moveover, women in the Nurses' Health Study who reported breast feeding for at least two cumulative years had a 23-percent lower risk of coronary heart disease (Stuebe and colleagues, 2009).

Because of associated health benefits, one of the goals of the United States Public Health Service for year 2010 is to increase breast-feeding rates (Centers for Disease Control and Prevention, 2007b). Educational initiatives to include the father and peer counseling may improve these rates (Bonuck, 2005; Merewood, 2005; Pisacane, 2005; Wolfberg, 2004, and all their colleagues). Moreover, The Baby Friendly Hospital Initiative is an international program developed to increase rates of exclusive breast feeding and to extend its duration. It is based on the World Health Organization (1998) *Ten Steps to Successful Breastfeeding*, which are shown in Table 30-3. Worldwide, almost

TABLE 30-3. Ten Steps to Successful Breast Feeding

1. Have a written breast feeding policy that is regularly communicated to all healthcare staff
2. Train all staff in skills necessary to implement this policy
3. Inform all pregnant women about the benefits and management of breast feeding
4. Help mothers initiate breast feeding within an hour of birth
5. Show mothers how to breast feed and how to sustain lactation, even if they should be separated from their infants
6. Feed newborn infants nothing but breast milk, unless medically indicated, and under no circumstances provide breast milk substitutes, feeding bottles, or pacifiers free of charge or at low cost
7. Practice rooming-in, which allows mothers and infants to remain together 24 hours a day
8. Encourage breast feeding on demand
9. Give no artificial pacifiers to breast feeding infants
10. Help start breast feeding support groups and refer mothers to them

Adapted from the World Health Organization (1998).

20,000 hospitals are designated as "baby-friendly." There are also a variety of individual resources available for breast-feeding mothers that include online information from the American Academy of Pediatrics (http://www.aap.org) and La Leche League International (http://www.lalecheleague.org).

Breast Engorgement

Women who do not breast feed may experience engorgement, milk leakage, and breast pain, which peaks at 3 to 5 days after delivery (Spitz and associates, 1998). As many as half require analgesia for breast-pain relief. Up to 10 percent of women report severe pain up to 14 days.

Breasts should be supported with a well-fitting brassiere. Pharmacological or hormonal agents are not recommended to suppress lactation. Instead, ice packs and oral analgesics for 12 to 24 hours can be used to relieve discomfort. A breast binder is used at Parkland Hospital for these women, and a "sports bra" is used at the University of Alabama Hospital.

Milk Fever

Puerperal fever from breast engorgement is common. Before breast feeding was commonplace, Almeida and Kitay (1986) reported that 13 percent of postpartum women had fever that ranged from 37.8 to 39°C from engorgement. Fever seldom persisted for longer than 4 to 16 hours. The incidence and severity of engorgement, and fever associated with it, are much lower if women breast feed. Other causes of fever, especially those due to infection, must be excluded.

Contraception for Breast-Feeding Women

Ovulation may resume as early as 3 weeks after delivery, even in lactating women. Its timing depends on individual biological variation as well as the intensity of breast feeding. Progestin-only contraceptives—"mini-pills," depot medroxyprogesterone, or progestin implants—do not affect the quality or quantity of milk. Estrogen-progestin contraceptives likely reduce the quantity of breast milk, but under the proper circumstances, they too can be used by breast-feeding women. These hormonal methods are summarized in Table 30-4 and are discussed in Chapter 32 (p. 673).

TABLE 30-4. Recommendations for Hormonal Contraception If Used by Breast-Feeding Women

- Progestin-only oral contraceptives prescribed or dispensed at discharge from the hospital to be started 2–3 weeks postpartum—for example, the first Sunday after the newborn is 2 weeks old
- Depot medroxyprogesterone acetate initiated at 6 weeks postpartum[a]
- Hormonal implants inserted at 6 weeks postpartum
- The levonorgestrel intrauterine system can be inserted at 6 weeks postpartum
- Combined estrogen-progestin contraceptives, if prescribed, should not be started before 6 weeks postpartum, and only when lactation is well established and the infant's nutritional status appropriate.

[a]There are certain clinical situations in which earlier initiation might be considered.
Reprinted, with permission, from American College of Obstetricians and Gynecologists. Breastfeeding: Maternal and infant aspects. ACOG Clin Rev 2007; 12 (1 suppl): 1-16.

Contraindications to Breast Feeding

Nursing is contraindicated in women who take street drugs or do not control their alcohol use; have an infant with galactosemia; have human immunodeficiency virus (HIV) infection; have active, untreated tuberculosis; take certain medications; or are undergoing treatment for breast cancer (American College of Obstetricians and Gynecologists, 2007). Breast feeding has been recognized for some time as a mode of HIV transmission. Nduati and colleagues (2000) randomly assigned 401 HIV-seropositive mother–infant pairs in Kenya to formula or breast feeding. At age 2 years, the rate of viral infection in breast-fed children was 37 percent—compared with 21 percent in formula-fed children.

Other viral infections do not contraindicate breast feeding. For example, with maternal cytomegalovirus infection, both virus and antibodies are present in breast milk. And although hepatitis B virus is excreted in milk, breast feeding is not contraindicated if hepatitis B immune globulin is given to these infants (American College of Obstetricians and Gynecologists, 2007). Maternal hepatitis C infection is not a contraindication because the 4-percent risk of infant transmission is the same for breast- and bottle-fed infants (Centers for Disease Control and Prevention, 1998). Women with active herpes simplex virus may suckle their infants if there are no breast lesions and if particular care is directed to hand washing before nursing.

Care of Breasts

The nipples require little attention other than cleanliness and attention to skin fissures. Fissured nipples render nursing painful, and they may have a deleterious influence on milk production. These cracks also provide a portal of entry for pyogenic bacteria. Because dried milk is likely to accumulate and irritate the nipples, washing the areola with water and mild soap is helpful before and after nursing. When the nipples are irritated or fissured, it may be necessary to use topical lanolin and a nipple shield for 24 hours or longer. If fissuring is severe, the infant should not be permitted to nurse on the affected side. Instead, the breast should be emptied regularly with a pump until the lesions are healed.

Proper technique for positioning the mother and infant during nursing has been reviewed by the American College of Obstetricians and Gynecologists (2007). This includes proper techniques for *latch-on* of the infant during suckling.

Drugs Secreted in Milk

Most drugs given to the mother are secreted in breast milk. However, the amount of drug ingested by the infant typically is small. Many factors influence drug excretion, including plasma

TABLE 30-5. Drugs That Have Been Associated with Significant Effects on Some Nursing Infants

Drug	Reported Effect[a]
Acebutolol	Hypotension, bradycardia, tachypnea
5-Aminosalicylic acid	Diarrhea (one case)
Atenolol	Cyanosis, bradycardia
Bromocriptine	Suppresses lactation, may be hazardous to the mother
Aspirin (salicylates)	Metabolic acidosis (one case)
Clemastine	Drowsiness, irritability, refusal to feed, high-pitched cry, neck stiffness (one case)
Ergotamine	Vomiting, diarrhea, convulsions—doses used in migraine medications
Lithium	A third to half therapeutic blood concentration in infants
Phenindione	Anticoagulant—increased prothrombin and partial thromboplastin time in one infant—not used in United States
Phenobarbital	Sedation; infantile spasms after weaning from milk containing phenobarbital; methemoglobinemia (one case)
Primidone	Sedation, feeding problems
Sulfasalazine	Bloody diarrhea (one case)

[a]Blood concentration in the infant may be of clinical importance.

concentration, degree of protein binding, plasma and milk pH, degree of ionization, lipid solubility, and molecular weight. The ratio of drug concentrations in breast milk to those in maternal plasma is the *milk-to-plasma drug-concentration ratio*. Most drugs have a milk-to-plasma ratio of 1 or less, about 25 percent have a ratio of more than 1, and about 15 percent have a ratio greater than 2 (Ito, 2000). Ideally, to minimize infant exposure, medication selection for the mother should favor drugs with a shorter half-life, poorer oral absorption, and lower lipid solubility. If multiple, daily drug doses are required, then each is taken by the mother *after* the closest feed. Single daily-dosed drugs may be taken just prior to the longest infant sleep interval—usually at bedtime (Spencer and co-workers, 2002).

There are only a few drugs that need to be avoided while breast feeding (Table 30-5). Cytotoxic drugs may interfere with cellular metabolism and potentially cause immune suppression or neutropenia, affect growth, or at least theoretically, increase the risk of childhood cancer. Examples include cyclophosphamide, cyclosporine, doxorubicin, and methotrexate. If a medication presents a concern, then the importance of therapy should be ascertained, as well as whether a safer alternative is available and whether neonatal exposure can be minimized if the medication dose is taken immediately after each breast feeding (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2007).

Radioactive isotopes of copper, gallium, indium, iodine, sodium, and technetium rapidly appear in breast milk. Consultation with a nuclear medicine specialist is recommended before performing a diagnostic study with these isotopes. The goal is to use a radionuclide with the shortest excretion time in breast milk. The mother should pump her breasts before the study and store enough milk in a freezer for feeding the infant. After the study, she should pump her breasts to maintain milk production but discard all milk produced during the time that radioactivity is present. This ranges from 15 hours up to 2 weeks, depending on the isotope used.

Mastitis

Parenchymatous infection of the mammary glands is a rare complication antepartum but is estimated to develop in up to a third of breast-feeding women (Barbosa-Cesnik and associates, 2003). In our experiences, its incidence is much lower and probably less than 1 percent. Symptoms of suppurative mastitis seldom appear before the end of the first week postpartum and as a rule, not until the third or fourth week. Infection almost invariably is unilateral, and marked engorgement usually precedes inflammation. Symptoms include chills or actual rigor, which are soon followed by fever and tachycardia. The breast becomes hard and reddened, and there is severe pain. About 10 percent of women with mastitis develop an abscess. Detection of fluctuation may be difficult, and sonography may be helpful to detect an abscess.

Etiology

In earlier studies, *Staphylococcus aureus* was the most commonly isolated organism. Matheson and colleagues (1988) reported it in 40 percent of women with mastitis. Other commonly isolated organisms are coagulase-negative staphylococci and viridans streptococci. The immediate source of organisms that cause mastitis is almost always the infant's nose and throat. Bacteria enter the breast through the nipple at the site of a fissure or small abrasion.

The infecting organism can usually be cultured from milk. Toxic shock syndrome from mastitis caused by *S. aureus* has been reported (Demey and associates, 1989; Fujiwara and Endo, 2001).

At times, suppurative mastitis reaches epidemic levels among nursing mothers. Such outbreaks most often coincide with the appearance of a new strain of antibiotic-resistant staphylococcus. A contemporaneous example is community-acquired methicillin-resistant *S. aureus* (CA-MRSA), which has rapidly become the most commonly isolated staphylococcal species in some areas (Klevens and co-workers, 2007; Pallin and colleagues, 2008). At Parkland Hospital from 2000 to 2004, Laibl and associates (2005) reported that a fourth of CA-MRSA isolates were from women with puerperal mastitis. Hospital-acquired MRSA may cause mastitis when the infant becomes colonized after hand contact with nursery personnel who are colonized. In turn, these infants may spread CA-MRSA (Centers for Disease Control and Prevention, 2006). Stafford and colleagues (2008) noted a higher incidence of subsequent abscess in those with CA-MRSA-associated mastitis.

Treatment

Provided that appropriate therapy for mastitis is started before suppuration begins, the infection usually resolves within 48 hours. Abscess formation is more common with *S. aureus* infection (Matheson and associates, 1988). Most recommend that milk be expressed from the affected breast onto a swab and cultured before beginning therapy. Bacterial identification and antimicrobial sensitivities provide information mandatory for a successful surveillance program of nosocomial infections.

The initial antimicrobial choice is influenced by the current experience with staphylococcal infections at the institution. Although most are community-acquired organisms, as discussed above, these frequently include CA-MRSA. Dicloxacillin, 500 mg orally four times daily, may be started empirically. Erythromycin is given to women who are penicillin sensitive. If the infection is caused by resistant, penicillinase-producing staphylococci, or if resistant organisms are suspected while awaiting the results of culture, then vancomycin or another anti-MRSA antimicrobial should be given. Even though clinical response may be prompt, treatment should be continued for 10 to 14 days.

Marshall and colleagues (1975) demonstrated the importance of continued breast feeding. They reported that the only three abscesses that developed in 65 women with mastitis were in 15 women who quit breast feeding. Thomsen and co-workers (1984) observed that vigorous milk expression was sufficient treatment alone. Sometimes the infant will not nurse on the inflamed breast. This probably is not related to any changes in the milk taste but is secondary to engorgement and edema, which can make the areola harder to grip. Pumping can alleviate this. When nursing bilaterally, it is best to begin suckling on the uninvolved breast. This allows let-down to commence before moving to the tender breast.

Breast Abscess

In a population-based study of nearly 1.5 million Swedish women, the incidence of breast abscess was 0.1 percent (Kvist and Rydhstroem, 2005). An abscess should be suspected when defervescence does not follow within 48 to 72 hours of mastitis treatment, or when a mass is palpable. Traditional therapy is surgical drainage, which usually requires general anesthesia. The incision should be made corresponding to Langer skin lines for a cosmetic result (Stehman, 1990). In early cases, a single incision over the most dependent portion of fluctuation is usually sufficient, but multiple abscesses require several incisions and disruption of loculations. The resulting cavity is loosely packed with gauze, which should be replaced at the end of 24 hours by a smaller pack. A less invasive alternative is sonographic-guided needle aspiration using local anesthesia, which has success rates of 80 to 90 percent (O'Hara and colleagues, 1996; Schwarz and Shrestha, 2001).

Galactocele

Occasionally a milk duct becomes obstructed by inspissated secretions, and milk may accumulate in one or more mammary lobes. The amount is ordinarily limited, but an excess may form a fluctuant mass—a galactocele—that may cause pressure symptoms and have the appearance of an abscess. It may resolve spontaneously or require aspiration.

Accessory Breast Tissue

Extra breasts—*polymastia*, or extra nipples—*polythelia*, may develop along the former embryonic mammary ridge. Also termed the *milk line*, this line extends from the axilla to the groin bilaterally. The incidence of accessory breast tissue ranges from 0.22 to 6 percent in the general population (Loukas and colleagues, 2007). Breasts may be so small as to be mistaken for pigmented moles, or when without a nipple, for lymphadenopathy or a lipoma. Polymastia has no obstetrical significance, although occasionally their enlargement during pregnancy or engorgement postpartum may result in discomfort and anxiety.

Nipples

Occasionally lactiferous ducts open directly into a depression at the center of the areola. With these depressed nipples, nursing is difficult. If the depression is not deep, milk sometimes can be made available by use of a breast pump. If instead the nipple is greatly inverted, daily attempts should be made during the last few months of pregnancy to draw the nipple out with the fingers.

Abnormalities of Secretion

There are marked individual variations in the amount of milk secreted. Many of these are dependent not on general maternal health but on breast glandular development. Rarely, there is complete lack of mammary secretion—*agalactia*. Occasionally, mammary secretion is excessive—*polygalactia*.

CARE OF THE MOTHER DURING THE PUERPERIUM

Hospital Care

For the first hour after delivery, blood pressure and pulse should be taken every 15 minutes, or more frequently if indicated. The amount of vaginal bleeding is monitored, and the fundus palpated to ensure that it is well contracted. If relaxation is detected, the uterus should be massaged through the abdominal

wall until it remains contracted. The addition of uterotonins is sometimes required. Blood may accumulate within the uterus without external bleeding. This may be detected early by detecting uterine enlargement during fundal palpation in the first postdelivery hours. Because the likelihood of significant hemorrhage is greatest immediately postpartum, even in normal cases, the uterus is closely monitored for at least 1 hour after delivery. Postpartum hemorrhage is discussed in Chapter 35 (p. 773).

If regional analgesia or general anesthesia is used for labor or delivery, the mother should be observed in an appropriately equipped and staffed recovery area.

Early Ambulation

Women are out of bed within a few hours after delivery. An attendant should be present for at least the first time, in case the woman becomes syncopal. The many confirmed advantages of early ambulation include fewer bladder complications and less frequent constipation. Early ambulation has reduced the frequency of puerperal venous thrombosis and pulmonary embolism (see Chap. 47, p. 1019).

Perineal Care

The woman is instructed to cleanse the vulva from anterior to posterior—the vulva toward the anus. An ice bag applied to the perineum may help reduce edema and discomfort during the first several hours if there is a laceration or an episiotomy. Most women also appear to obtain a measure of relief from the periodic application of a local anesthetic spray. Severe discomfort usually indicates a problem, such as a hematoma within the first day or so, and infection after the third or fourth day (see Chap. 35, p. 783). **Severe perineal, vaginal, or rectal pain always warrants careful inspection and palpation.** Beginning approximately 24 hours after delivery, moist heat as provided with warm sitz baths can be used to reduce local discomfort. Tub bathing after uncomplicated delivery is allowed. The episiotomy incision normally is firmly healed and nearly asymptomatic by the third week.

Bladder Function

Bladder filling after delivery may be variable. In most units, intravenous fluids are infused during labor and for an hour after delivery. Oxytocin, in doses that have an antidiuretic effect, is commonly infused postpartum, and rapid bladder filling is common. Moreover, both bladder sensation and capability to empty spontaneously may be diminished by local or conduction analgesia, by episiotomy or lacerations, and by instrumented delivery. Thus, urinary retention with bladder overdistension is common in the early puerperium. Ching-Chung and colleagues (2002) reported retention in 4 percent of women delivered vaginally. Musselwhite and associates (2007) reported retention in 4.7 percent of women who had labor epidural analgesia. Risk factors that increased likelihood of retention were primiparity, oxytocin-induced or -augmented labor, perineal lacerations, instrumented delivery, catheterization during labor, and labor with duration over 10 hours.

Prevention of bladder overdistension demands observation after delivery to ensure that the bladder does not overfill and that with each voiding, it empties adequately. The enlarged bladder can be palpated suprapubically, or it is evident abdominally indirectly as it elevates the fundus above the umbilicus. Van Os and Van der Linden (2006) have investigated the use of an automated sonography system to detect high bladder volumes and thus postpartum urinary retention.

Management

If a woman has not voided within 4 hours after delivery, it is likely that she cannot. If she has trouble voiding initially, she also is likely to have further trouble. An examination for perineal and genital-tract hematomas is made. With an overdistended bladder, an indwelling catheter should be left in place until the factors causing retention have abated. Even without a demonstrable cause, it usually is best to leave the catheter in place for at least 24 hours. This prevents recurrence and allows recovery of normal bladder tone and sensation.

When the catheter is removed, it is necessary subsequently to demonstrate ability to void appropriately. If a woman cannot void after 4 hours, she should be catheterized and the urine volume measured. If more than 200 mL, the bladder is not functioning appropriately, and the catheter is left for another day. If less than 200 mL of urine is obtained, the catheter can be removed and the bladder rechecked subsequently as described. Harris and colleagues (1977) reported that 40 percent of such women develop bacteriuria, and thus, a single-dose or short course of antimicrobial therapy is reasonable after the catheter is removed.

Subsequent Discomfort

Discomfort and its causes following cesarean delivery are considered in Chapter 25 (p. 561). During the first few days after vaginal delivery, the mother may be uncomfortable for a variety of reasons, including afterpains, episiotomy and lacerations, breast engorgement, and at times, postdural puncture headache. Mild analgesics containing codeine, aspirin, or acetaminophen, preferably in combinations, are given as frequently as every 3 hours during the first few days.

Depression

It is fairly common for a mother to exhibit some degree of depressed mood a few days after delivery. Termed *postpartum blues,* this likely is the consequence of a number of factors that include emotional letdown that follows the excitement and fears experienced during pregnancy and delivery, discomforts of the early puerperium, fatigue from sleep deprivation, anxiety over the ability to provide appropriate infant care, and body image concerns.

In most women, effective treatment includes anticipation, recognition, and reassurance. This disorder is usually mild and self-limited to 2 to 3 days, although it sometimes lasts for up to 10 days. Should these moods persist or worsen, evaluation is done for symptoms of major depression. Gavin and associates (2005) in a systematic review found depression in almost 20 percent of postpartum women. A recent analysis of the PRAMS database reported its prevalence to range from 12 to 20 percent in 17 states (Centers for Disease Control and Prevention, 2008). In a state-wide study from New Jersey, low-income women with pregestational or gestational diabetes had a twofold risk of perinatal or postpartum depression (Kozhimannil and colleagues,

2009). In women with preexisting psychiatric disorders, the first month after childbirth is associated with increased risk of psychiatric readmission (Munk-Olsen and co-workers, 2009). Further evaluation and management is discussed in Chapter 55 (p. 1176). Suicidal or infanticidal ideation is dealt with emergently. Because major postpartum depression recurs in at least a fourth of women in subsequent pregnancies, some recommend pharmacological prophylaxis beginning in late pregnancy or immediately postpartum (Wisner and co-workers, 2004).

Abdominal Wall Relaxation

If the abdomen is unusually flabby or pendulous, an ordinary girdle is often satisfactory. An abdominal binder is at best a temporary measure. Exercises to restore abdominal wall tone may be started anytime after vaginal delivery and as soon as abdominal soreness diminishes after cesarean delivery.

Diet

There are no dietary restrictions for women who have been delivered vaginally. Two hours after a normal vaginal delivery, if there are no complications, a woman should be allowed to eat. With breast feeding, the number of calories and protein consumed during pregnancy should be increased slightly as recommended by the Food and Nutrition Board of the National Research Council (see Chap. 8, p. 202). If the mother does not breast feed, dietary requirements are the same as for a nonpregnant woman.

It is standard practice in our hospitals to continue iron supplementation for at least 3 months after delivery and to check the hematocrit at the first postpartum visit.

Thromboembolic Disease

The frequency of deep-venous thrombosis and pulmonary embolism complicating pregnancy and the puerperium has decreased in recent years (see Chap. 47, p. 1019). Almost half of thromboembolic events associated with pregnancy develop in the puerperium. Jacobsen and colleagues (2008) recently reported that pulmonary embolism is most common in the first 6 weeks postpartum.

Neuromuscular and Joint Problems

Pain in the pelvic girdle, hips, or lower extremities may be due to stretching or tearing injuries sustained at normal or difficult delivery.

Obstetrical Neuropathies

Pressure on branches of the lumbosacral nerve plexus during labor may be manifest by complaints of intense neuralgia or cramplike pains extending down one or both legs as soon as the head descends into the pelvis. If the nerve is injured, pain may continue after delivery, and there also may be variable degrees of sensory loss or muscle paralysis. In some cases, there is footdrop, which can be secondary to injury at the level of the lumbosacral root, lumbosacral plexus, sciatic nerve, or common fibular (peroneal) nerve. Components of the lumbosacral plexus cross the pelvic brim and can be compressed by the fetal head or by forceps. The common fibular nerves may be externally compressed when the legs are positioned in stirrups, especially during a prolonged second stage of labor.

The incidence of obstetrical neuropathy is relatively common. Wong and colleagues (2003) evaluated more than 6000 consecutively delivered women at Northwestern University and found that approximately 1 percent had a confirmed nerve injury. Lateral femoral cutaneous neuropathies were the most common (24), followed by femoral neuropathies (14). A motor deficit accompanied a third of injuries. Nulliparity, prolonged second-stage labor, and pushing for a long duration in the semi-Fowler position were risk factors. The median duration of symptoms was 2 months, and the range was 2 weeks to 18 months.

Muscle Injuries

Pelvic or hip muscles and tendons can be stretched, torn, or separated during even normal labor. If nerve injury is excluded, we have found that magnetic resonance (MR) imaging is informative. An example is shown in **Figure 30-3**. Most of these resolve with anti-inflammatory agents and physical therapy. Rarely, there may be septic pyomyositis as described by Sokolov and colleagues (2007).

Pelvic Bone and Joint Problems

Separation of the symphysis pubis or one of the sacroiliac synchondroses during labor may be followed by pain and marked

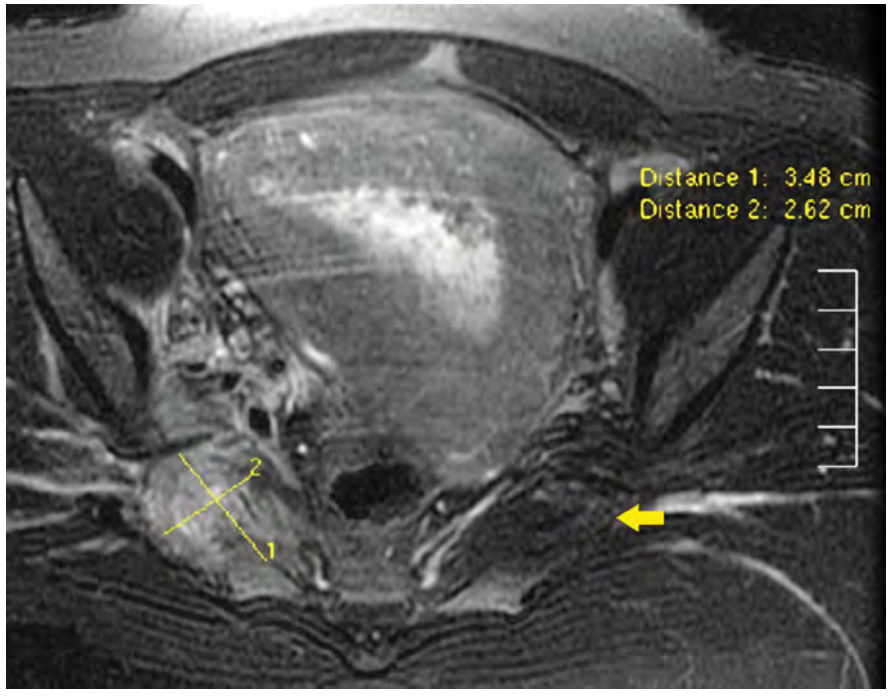

FIGURE 30-3 Magnetic resonance image of a piriformis hematoma. A large inhomogeneous mass of the right piriformis muscle consistent with a hematoma (*yellow cursor measurements*) is compared with the normal appearing left piriformis muscle (*yellow arrow*).

FIGURE 30-4 Radiograph demonstrating a 5-cm pubic diastasis immediately after vaginal delivery. Pain diminished over several weeks. Six months later, a repeat radiograph showed a 1-cm symphyseal gap. (Reprinted from Chang D and Markman BS: Spontaneous resolution of a pubic-symphysis diastasis. *N Engl J Med* 346:39, with permission. Copyright © 2002 Massachusetts Medical Society. All rights reserved.)

interference with locomotion (Fig. 30-4). Estimates of their frequency vary widely from 1 in 600 to 1 in 30,000 deliveries (Reis and colleagues, 1932; Taylor and Sonson, 1986). In our experiences, symptomatic separations are uncommon. When they are symptomatic, the onset of pain is often acute during delivery, but symptoms may manifest either antepartum or up to 48 hours postpartum (Snow and Neubert, 1997). Treatment is generally conservative, with rest in a lateral decubitus position and an appropriately fitted pelvic binder. Surgery is occasionally necessary in some symphyseal separations of more than 4 cm (Kharrazi and colleagues, 1997). Recurrence is more than 50 percent in subsequent pregnancy, and Culligan and associates (2002) recommend consideration of cesarean delivery. In some cases, fractures of the sacrum or pubic ramus are caused by even uncomplicated deliveries (Alonso-Burgos and colleagues, 2007). The latter are more likely with osteoporosis associated with heparin or corticosteroid therapy (Cunningham, 2005). This is discussed further in Chapter 53.

Immunizations

The D-negative woman who is not isoimmunized and whose infant is D-positive is given 300 μg of anti-D immune globulin shortly after delivery (see Chap. 29, p. 624). Women who are not already immune to rubella or rubeola measles are excellent candidates for combined measles-mumps-rubella vaccination before discharge (see Chap. 8, p. 208). Unless contraindicated, a diphtheria-tetanus toxoid booster injection is also given to postpartum women prior to discharge at Parkland Hospital.

Time of Discharge

Following uncomplicated vaginal delivery, hospitalization is seldom warranted for more than 48 hours. A woman should receive instructions concerning anticipated normal physiological changes of the puerperium, including lochia patterns, weight loss from diuresis, and milk let-down. She also should receive instructions concerning fever, excessive vaginal bleeding, or leg pain, swelling, or tenderness. Shortness of breath or chest pain warrants immediate concern.

Early Discharge

The length of hospital stays following labor and delivery is now regulated by federal law. Currently, the norms are hospital stays of up to 48 hours following uncomplicated vaginal delivery and up to 96 hours following uncomplicated cesarean delivery (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2007). Earlier hospital discharge is acceptable for appropriately selected women if they desire it.

Contraception

During the hospital stay, a concerted effort should be made to provide family planning education. Steroidal contraception and its effects on lactation are discussed in Chapter 32 (p. 694). Other forms of contraception are discussed throughout Chapter 32 and sterilization procedures in Chapter 33.

If a woman is not breast feeding, menses usually return within 6 to 8 weeks. At times, however, it is difficult clinically to assign a specific date to the first menstrual period after delivery. Only about 20 percent of women ovulate preceding the first menses (Hytten, 1995). A minority of women bleed small to moderate amounts intermittently, starting soon after delivery. Ovulation occurs at a mean of 7 weeks, but ranges from 5 to 11 weeks (Perez and associates, 1972). That said, ovulation before 28 days has been described (Hytten, 1995). Thus, conception is possible during the artificially defined 6-week puerperium. **Women who become sexually active during the puerperium, and who do not desire to conceive should initiate contraception.** This message is not universally delivered to women, nor is it always heeded. For example, Kelly and associates (2005) reported that by the third month postpartum, 58 percent of adolescents had resumed sexual intercourse, but only 80 percent of these were using contraception.

Breast Feeding and Ovulation

Women who breast feed ovulate much less frequently compared with those who do not, and there are great variations. Lactating women may first menstruate as early as the second or as late as the 18th month after delivery. Campbell and Gray (1993) analyzed daily urine specimens to determine the time of ovulation in 92 women. As shown in Figure 30-5, breast feeding in general delays resumption of ovulation, although as already emphasized, it does not invariably forestall it. Other findings in their study included the following:

1. Resumption of ovulation was frequently marked by return of normal menstrual bleeding
2. Breast-feeding episodes lasting 15 minutes seven times each day delayed resumption of ovulation
3. Ovulation can occur without bleeding
4. Bleeding can be anovulatory
5. The risk of pregnancy in breast-feeding women was approximately 4 percent per year

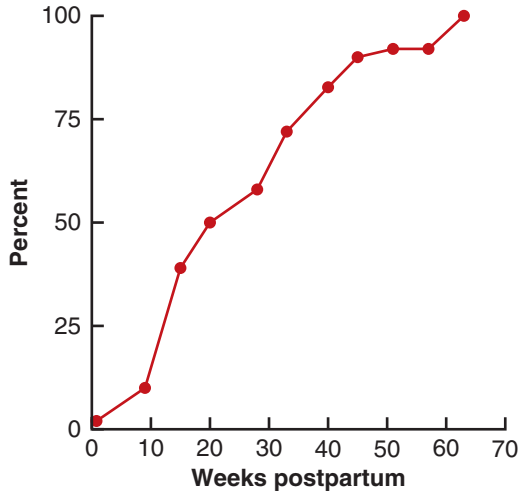

FIGURE 30-5 Cumulative proportion of breast-feeding women who ovulated during the first 70 weeks following delivery. (Data from Campbell and Gray, 1993.)

HOME CARE

Coitus

There are no evidence-based rules concerning resumption of coitus after delivery. It seems best to use common sense. After 2 weeks, coitus may be resumed *based on desire and comfort.* Barrett and colleagues (2000) reported that almost 90 percent of 484 primiparous women resumed sexual activity by 6 months. And although 65 percent of these reported problems, only 15 percent discussed them with a healthcare provider.

Intercourse *too soon* may be unpleasant, if not frankly painful, due to incomplete healing of the episiotomy or lacerations. Moreover, the vaginal epithelium is thin and very little lubrication follows sexual stimulation. This likely is due to the hypoestrogenic state following delivery and lasting until ovulation resumes. It may be particularly problematic in breast-feeding women who are hypoestrogenic for many months postpartum (Palmer and Likis, 2003; Wisniewski and Wilkinson, 1991). For treatment, small amounts of topical estrogen cream can be applied daily for several weeks to vaginal and vulvar tissues. Additionally, vaginal lubricants may be used with coitus.

Late Maternal Morbidity

Taken together, major and minor maternal morbidity are surprisingly common in the months following childbirth (MacArthur and colleagues, 1991). In a survey of 1249 British mothers followed for up to 18 months, 3 percent required hospital readmission within 8 weeks (Glazener and co-workers, 1995). Milder health problems during the first 8 weeks were reported by 87 percent. And as shown in Table 30-6, almost three fourths continued to have a variety of problems for up to 18 months. Thus, although reported problems declined with time, they did so more slowly than generally assumed. Further reports by Lydon-Rochelle (2001), McGovern (2006), Thompson (2002), and all their colleagues described similar findings. From the foregoing, maternal morbidity following delivery is common, and at least historically, it was underappreciated. These studies called for a greater awareness of the needs of women as they convalesce from birthing.

Postpartum Follow-Up Care

By discharge, women who had an uncomplicated course can resume most activities, including bathing, driving, and household functions. Jimenez and Newton (1979) tabulated cross-cultural

TABLE 30-6. Puerperal Morbidity in Percent Reported by Women after Hospital Discharge

Morbidity	By 8 Weeks Postpartum	2 to 18 Months Postpartum
Feeling tired	59	54
Breast problems	36	20
Anemia	25	7
Backache	24	20
Hemorrhoids	23	15
Headache	22	15
Tearfulness/depression	21	17
Constipation	20	7
Suture breakdown	16	—
Vaginal discharge	15	8
Others[a]	2–7	1–8
At least one of the above	87	76

[a]Includes abnormal bleeding, urinary incontinence or infection, difficulty voiding, and hypertension.

Reproduced from *BJOG*, Vol. 102, Issue 4, CMA Glazener, M Abdalla, P Stroud, A Templeton, IT Russell, and S Naji, Postnatal maternal morbidity: Extent, causes, prevention and treatment, 282–287, 1995, with the permission of the Royal College of Obstetricians and Gynaecologists.

information on 202 societies from different international geographic regions. Following childbirth, most societies did not restrict work activity, and approximately half expected a return to full duties within 2 weeks. Tulman and Fawcett (1988) later reported that only half of mothers regained their usual level of energy by 6 weeks postpartum. Women who delivered vaginally were twice as likely to have normal energy levels at this time compared with those with a cesarean delivery. Ideally, the care and nurturing of the infant should be provided by the mother with ample help from the father.

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007) recommend a postpartum visit between 4 and 6 weeks. This has proven quite satisfactory to identify abnormalities beyond the immediate puerperium as well as to initiate contraceptive practices. The Centers for Disease Control and Prevention (2007c) recently reported follow-up data from the Pregnancy Risk Assessment Monitoring System (PRAMS) database. Although overall compliance with postpartum visits was 90 percent, it ranged from 65 to 80 percent in adolescents, poorly educated or indigent women, and those with no prenatal care.

CHAPTER 31

Puerperal Infection

PUERPERAL FEVER 661
UTERINE INFECTION 661
PATHOGENESIS 663
CLINICAL COURSE 663
TOXIC SHOCK SYNDROME 670

Puerperal infection is a general term used to describe any bacterial infection of the genital tract after delivery. The earliest reference to puerperal infection is found in the works of Hippocrates from the 5th century BC, *De Mulierum Morbis.* He attributed the condition to retention of bowel contents. The history of puerperal infection is discussed in greater detail in previous editions of *Williams Obstetrics.*

Along with preeclampsia and obstetrical hemorrhage, puerperal infection formed the lethal triad of causes of maternal deaths for many decades of the 20th century. Fortunately, because of effective antimicrobials, maternal deaths from infection have become uncommon. Berg and associates (2003) reported results from the Pregnancy Mortality Surveillance System, which contained 3201 maternal deaths in the United States from 1991 through 1997. Infection caused 13 percent of pregnancy-related deaths and was the fifth leading cause of death. In a similar analysis of the North Carolina population from 1991 through 1999, Berg and colleagues (2005) reported that 40 percent of infection-related maternal deaths were preventable.

PUERPERAL FEVER

A number of factors can cause fever—a temperature of 38.0°C (100.4°F) or higher—in the puerperium. **Most persistent fevers after childbirth are caused by genital tract infection.** Filker and Monif (1979) reported that only about 20 percent of women febrile within the first 24 hours after giving birth vaginally were subsequently diagnosed with pelvic infection. This was in contrast to 70 percent of those undergoing cesarean delivery. It must be emphasized that spiking fevers of 39°C or higher that develop within the first 24 hours postpartum may be associated with virulent pelvic infection caused by group A streptococcus. Other common causes of puerperal fever are breast engorgement and pyelonephritis or occasionally respiratory complications after cesarean delivery (Maharaj, 2007).

About 15 percent of women who do not breast feed develop postpartum fever from breast engorgement. This figure is lower in breast-feeding women (see Chap. 30, p. 652). Attributable fever rarely exceeds 39°C in the first few postpartum days and usually lasts less than 24 hours. Acute pyelonephritis has a variable clinical picture, and postpartum, the first sign of renal infection may be fever, followed later by costovertebral angle tenderness, nausea, and vomiting. Atelectasis is caused by hypoventilation and is best prevented by coughing and deep breathing on a fixed schedule following surgery. Fever associated with atelectasis is thought to follow infection by normal flora that proliferate distal to obstructing mucous plugs. Minor temperature elevations in the puerperium may also occasionally be caused by superficial or deep-venous thrombosis of the legs.

UTERINE INFECTION

Postpartum uterine infection has been called variously *endometritis, endomyometritis,* and *endoparametritis.* Because infection involves not only the decidua but also the myometrium and parametrial tissues, we prefer the inclusive term *metritis with pelvic cellulitis.*

Predisposing Factors

The route of delivery is the single most significant risk factor for the development of uterine infection (Burrows and associates,

2004; Koroukian, 2004). In the French Confidential Enquiry on Maternal Deaths, Deneux-Tharaux and colleagues (2006) cited a nearly 25-fold increased infection-related mortality rate with cesarean versus vaginal delivery. Rehospitalization rates for wound complications and endometritis were increased significantly in women undergoing a planned primary cesarean delivery compared with those having a planned vaginal birth (Declercq, 2007).

Vaginal Delivery

Compared with cesarean delivery, metritis following vaginal delivery is relatively uncommon. Women delivered vaginally at Parkland Hospital have a 1- to 2-percent incidence of metritis. Women at high risk for infection because of membrane rupture, prolonged labor, and multiple cervical examinations have a 5- to 6-percent incidence of metritis after vaginal delivery. If there is intrapartum chorioamnionitis, the risk of persistent uterine infection increases to 13 percent (Maberry and colleagues, 1991). Finally, manual removal of the placenta, discussed in Chapter 35 (p. 774), increased the puerperal metritis rate threefold in the study by Baksu and associates (2005).

Cesarean Delivery

Single-dose perioperative antimicrobial prophylaxis is given almost universally at cesarean delivery. The American College of Obstetricians and Gynecologists (2003) recommends such prophylaxis for women at high risk for postpartum infection (see Chap. 25, p. 561). Such single-dose antimicrobial prophylaxis has done more to decrease the incidence and severity of postcesarean delivery infections than any other practice in the past 30 years.

The magnitude of the risk is exemplified from reports that predate antimicrobial prophylaxis. In 1973, Sweet and Ledger reported an overall incidence of uterine infection of 13 percent among affluent women who underwent cesarean delivery compared with 27 percent of indigent women. Cunningham and associates (1978) described an overall incidence of 50 percent in women who had cesarean delivery at Parkland Hospital. Important risk factors for infection following surgery included prolonged labor, membrane rupture, multiple cervical examinations, and internal fetal monitoring. Women with all of these factors who were not given perioperative prophylaxis had a 90-percent serious pelvic infection rate (DePalma and colleagues, 1982).

Other Risk Factors

It is generally accepted that pelvic infection is more common in women of lower socioeconomic status compared with those more advantaged (Maharaj, 2007). Except in extreme cases usually not seen in this country, it is unlikely that anemia or poor nutrition predispose to infection. *Bacterial colonization* of the lower genital tract with certain microorganisms—for example, group B streptococcus, *Chlamydia trachomatis, Mycoplasma hominis, Ureaplasma urealyticum*, and *Gardnerella vaginalis*—has been associated with an increased risk of postpartum infection (Andrews, 1995; Jacobsson, 2002; Watts, 1990, and all their colleagues). Other factors associated with an increased risk of infection include cesarean delivery for *multifetal gestation, young maternal age and nulliparity, prolonged labor induction, obesity,* and *meconium-stained amnionic fluid* (Jazayeri, 2002; Kabiru and Raynor, 2004; Myles, 2002, and all their colleagues).

Bacteriology

Most female pelvic infections are caused by bacteria indigenous to the female genital tract. Over the past decade, there have been reports of group A β-hemolytic streptococcus causing toxic shock-like syndrome and life-threatening infection (Aronoff and Mulla, 2008; Castagnola, 2008; Nathan and Leveno, 1994; Palep-Singh, 2007, and all their colleagues). Prematurely ruptured membranes is a prominent risk factor (Anteby and associates, 1999). In two reviews by Crum (2002) and Udagawa (1999) and their colleagues, women in whom group A streptococcal infection was manifested before, during, or within 12 hours of delivery had a maternal mortality rate of almost 90 percent and fetal mortality rate of greater than 50 percent. In the past 5 years, skin and soft-tissue infections due to community-acquired methicillin-resistant *Staphylococcus aureus*—CA-MRSA—have become common (see Chap. 58, p. 1223). As of 2009, these strains are not a common agent of puerperal metritis, but they are causative in incisional wound infections (Anderson and co-workers, 2007; Patel and colleagues, 2007). And Rotas and associates (2007) reported a woman with episiotomy cellulitis with CA-MRSA and hematogenously spread necrotizing pneumonia.

Common Pathogens

Bacteria commonly responsible for female genital tract infections are listed in **Table 31-1**. Generally, infections are polymicrobial, which promotes bacterial synergy. Other factors that promote virulence are hematomas and devitalized tissue. Although the cervix and vagina routinely harbor such bacteria, the uterine cavity is usually sterile before rupture of the amnionic sac. As the consequence of labor and delivery and associated manipulations, the amnionic fluid and uterus commonly become contaminated with anaerobic and aerobic bacteria (**Fig. 31-1**). In studies done before the use of antimicrobial prophylaxis, Gilstrap and Cunningham

TABLE 31-1. Bacteria Commonly Responsible for Female Genital Infections

Aerobes

Gram-positive cocci—group A, B, and D streptococci, enterococcus, *Staphylococcus aureus, Staphylococcus epidermidis*

Gram-negative bacteria—*Escherichia coli, Klebsiella, Proteus* species

Gram-variable—*Gardnerella vaginalis*

Others

Mycoplasma and *Chlamydia* species, *Neisseria gonorrhoeae*

Anaerobes

Cocci—*Peptostreptococcus* and *Peptococcus* species

Others—*Clostridium* and *Fusobacterium* species

Mobiluncus species

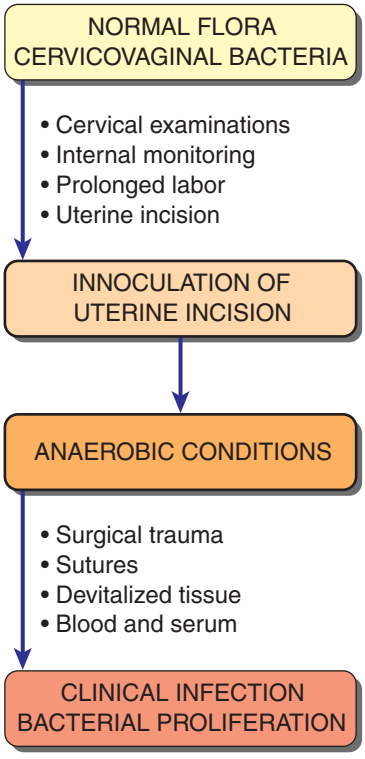

FIGURE 31-1 Pathogenesis of metritis following cesarean delivery. (Adapted from Gilstrap and Cunningham, 1979.)

(1979) cultured amnionic fluid obtained at cesarean delivery in women in labor with membranes ruptured more than 6 hours. All had bacterial growth and an average of 2.5 organisms was identified from each specimen. Anaerobic and aerobic organisms were identified in 63 percent, anaerobes alone in 30 percent, and aerobes alone in only 7 percent. Anaerobes included *Peptostreptococcus* and *Peptococcus* species in 45 percent, *Bacteroides* species in 9 percent, and *Clostridium* species in 3 percent. Aerobes included *Enterococcus* in 14 percent, group B streptococcus in 8 percent, and *Escherichia coli* in 9 percent of isolates. Sherman and coworkers (1999) later showed that bacterial isolates at cesarean delivery correlated with those taken at 3 days postpartum in those with metritis.

The role of other organisms in the etiology of these infections is unclear. Chlamydial infections have been implicated in late-onset, indolent metritis (Ismail and associates, 1985). Observations of Chaim and colleagues (2003) suggest that when cervical colonization of *U. urealyticum* is heavy, it may contribute to the development of metritis. Finally, Jacobsson and colleagues (2002) reported a threefold risk of puerperal infection in a group of Swedish women in whom bacterial vaginosis was identified in early pregnancy.

Bacterial Cultures

Routine pretreatment genital tract cultures are of little clinical use and add significant costs. Similarly, routine blood cultures seldom modify care. In two earlier studies done before perioperative prophylaxis was used, blood cultures were positive in 13 percent of women with postcesarean metritis at Parkland Hospital and 24 percent in those at Los Angeles County Hospital (Cunningham and colleagues, 1978; DiZerega and co-workers, 1979). In a more recent Finnish study, Kankuri and associates (2003) confirmed bacteremia in only 5 percent of almost 800 women with puerperal sepsis.

PATHOGENESIS

Puerperal infection following vaginal delivery primarily involves the placental implantation site, decidua and adjacent myometrium, or cervicovaginal lacerations. The pathogenesis of uterine infection following cesarean delivery is that of an infected surgical incision (see Fig. 31-1). Bacteria that colonize the cervix and vagina gain access to amnionic fluid during labor, and postpartum, they invade devitalized uterine tissue. Parametrial cellulitis next follows with infection of the pelvic retroperitoneal fibroareolar connective tissue. With early treatment, infection is contained within the paravaginal tissue but may extend deeply into the pelvis.

CLINICAL COURSE

Fever is the most important criterion for the diagnosis of postpartum metritis. Intuitively, the degree of fever is believed proportional to the extent of infection and sepsis syndrome (see Chap. 42, p. 932). Temperatures commonly are 38 to 39°C. Chills that accompany fever suggest bacteremia. Women usually complain of abdominal pain, and parametrial tenderness is elicited on abdominal and bimanual examination. Although an offensive odor may develop, many women have foul-smelling lochia without evidence for infection. Other infections, notably those due to group A β-hemolytic streptococci, are frequently associated with scanty, odorless lochia. Leukocytosis may range from 15,000 to 30,000 cells/μL, but recall that cesarean delivery itself increases the leukocyte count (Hartmann and co-workers, 2000).

Treatment

If mild metritis develops after a woman has been discharged following vaginal delivery, outpatient treatment with an oral antimicrobial agent is usually sufficient. For moderate to severe infections, however, intravenous therapy with a broad-spectrum antimicrobial regimen is indicated. Improvement follows in 48 to 72 hours in nearly 90 percent of women treated with one of several regimens. Persistent fever after this interval mandates a careful search for causes of refractory pelvic infection. These include a parametrial phlegmon—an area of intense cellulitis; an abdominal incisional or pelvic abscess or infected hematoma; and septic pelvic thrombophlebitis. In our experience, persistent fever is seldom due to antimicrobial-resistant bacteria or due to drug side effects. The woman may be discharged home after she has been afebrile for at least 24 hours. Further oral antimicrobial therapy is not needed (Dinsmoor and colleagues, 1991; French and Smaill, 2002).

Choice of Antimicrobials

Although therapy is empirical, initial treatment following cesarean delivery is directed against most of the mixed flora shown

TABLE 31-2. Antimicrobial Regimens for Pelvic Infection Following Cesarean Delivery

Regimen	Comments
Clindamycin 900 mg + gentamicin 1.5 mg/kg, q8h intravenously	"Gold standard," 90–97% efficacy, once-daily gentamicin dosing acceptable + Ampicillin added to regimen with sepsis syndrome or suspected enterococcal infection
Clindamycin + aztreonam	Gentamicin substitute with renal insufficiency
Extended-spectrum penicillins	Piperacillin, ampicillin/sulbactam
Extended-spectrum cephalosporins	Cefotetan, cefoxitin, cefotaxime
Imipenem + cilastatin	Reserved for special indications

in Table 31-1, which typically cause puerperal infections. Such broad-spectrum antimicrobial coverage is often not necessary to treat infection following vaginal delivery, and as many as 90 percent of these infections respond to regimens such as ampicillin plus gentamicin. In contrast, anaerobic coverage is included for infections following cesarean delivery (Table 31-2).

In 1979, DiZerega and colleagues compared the effectiveness of clindamycin plus gentamicin with that of penicillin G plus gentamicin for treatment of pelvic infections following cesarean delivery. Women given the *clindamycin-gentamicin* regimen had a 95-percent response rate, and this regimen is still considered by most to be the standard by which others are measured (French and Smaill, 2002). Because enterococcal infections may persist despite this standard therapy, many add ampicillin to the clindamycin-gentamicin regimen, either initially or if there is no response by 48 to 72 hours (Brumfield and associates, 2000).

Many authorities recommend that serum gentamicin levels be periodically monitored, although at the University of Alabama and Parkland Hospitals, we do not routinely do so if the woman has normal renal function. Liu and associates (1999) compared multiple-dosing versus once-daily dosing with gentamicin and found that both provided adequate serum levels. Once-daily dosing has a cure rate similar to 8-hour dosing (Livingston and colleagues, 2003).

Because of potential nephrotoxicity and ototoxicity with gentamicin in the event of diminished glomerular filtration, some have recommended a combination of clindamycin and a second-generation cephalosporin to treat such women. Others recommend a combination of clindamycin and aztreonam, a monobactam compound with activity similar to the aminoglycosides.

The spectra of β-*lactam antimicrobials* include activity against many anaerobic pathogens. Some examples include cephalosporins such as cefoxitin, cefotetan, and cefotaxime, as well as extended-spectrum penicillins such as piperacillin, ticarcillin, and mezlocillin. β Lactam antimicrobials are inherently safe and except for allergic reactions, are free of major toxicity. The β-*lactamase inhibitors*, clavulanic acid, sulbactam, and tazobactam, have been combined with ampicillin, amoxicillin, ticarcillin, and piperacillin to extend their spectra. *Metronidazole* has superior in vitro activity against most anaerobes. This agent given with ampicillin and an aminoglycoside provides coverage against most organisms encountered in serious pelvic infections.

Imipenem is a carbapenem that has broad-spectrum coverage against most organisms associated with metritis. It is used in combination with *cilastatin*, which inhibits renal metabolism of imipenem. Although this combination is effective in most cases of metritis, it seems reasonable from both a medical and an economic standpoint to reserve it for more serious infections.

Prevention of Infection

Over the years, a number of strategies have been tested to prevent or at least mitigate the severity of postpartum infections.

Perioperative Antimicrobial Prophylaxis. As noted, administration of antimicrobial prophylaxis at the time of cesarean delivery has remarkably reduced the rate of postoperative pelvic and wound infections. Numerous studies have shown that prophylactic antimicrobials reduce the rate of pelvic infection by 70 to 80 percent (Chelmow and colleagues, 2001; Smaill and Hofmeyr, 2002). The observed benefit applies to both elective and nonelective cesarean delivery and also includes a reduction in abdominal incisional infections.

Single-dose prophylaxis with ampicillin or a first-generation cephalosporin is ideal, and both are as effective as broad-spectrum agents or a multiple-dose regimen (American College of Obstetricians and Gynecologists, 2003). A recent report of extended-spectrum prophylaxis with azithromycin added to standard single-dose prophylaxis showed a significant reduction in postcesarean metritis (Tita and colleagues, 2008). These findings need to be verified. Women known to be colonized with methicillin-resistant *Staphylococcus aureus*—MRSA—are given vancomycin in addition to a cephalosporin (see Chap. 58, p. 1223). Finally, the infection rate is lowered more if the selected antimicrobial is given before the skin incision compared with cord clamping (Constantine, 2008; Kaimal, 2008; Sullivan, 2007, and all their co-workers).

A number of locally applied antimicrobials have been evaluated to prevent puerperal infection. At best, the results of these studies are mixed. Intrapartum vaginal irrigation with *chlorhexidine* did not reduce the incidence of postpartum infection in trials conducted by Rouse and colleagues (1997, 2003). Likewise, Reid and associates (2001) reported that *povidone-iodine* vaginal irrigation before cesarean delivery had no effect on the incidence of fever, metritis, or abdominal incisional infection. Conversely, Starr and colleagues (2005) reported that women who underwent preoperative vaginal cleansing with povidone-iodine had a significantly lower infection rate following cesarean delivery—7 versus 14 percent. In a placebo-controlled trial, Pitt

and colleagues (2001) applied 5 grams of *metronidazole gel* preoperatively as an adjunct to perioperative antimicrobial prophylaxis. They reported reduction in the rate of metritis from 17 to 7 percent with the gel but no significant effect on febrile morbidity or wound infections.

Treatment of Vaginitis. Prenatal treatment of asymptomatic vaginal infections has not been shown to prevent postpartum pelvic infections. Carey and associates (2000) reported no beneficial effects for women treated for asymptomatic bacterial vaginosis. Similarly, Klebanoff and colleagues (2001) reported a similar postpartum infection rate in women treated for second-trimester asymptomatic *Trichomonas vaginalis* infection compared with that of placebo-treated women.

Operative Technique. A number of technical maneuvers to alter the rate of postpartum infections in women undergoing cesarean delivery have been studied. For example, allowing the placenta to separate spontaneously compared with removing it manually lowers the risk of infection, but changing gloves by the surgical team after placental delivery does not (Atkinson and associates, 1996). Exteriorizing the uterus to close the hysterotomy may decrease febrile morbidity (Jacobs-Jokhan and Hofmeyr, 2004). No differences were found in postoperative infection rates when single- versus two-layer uterine closure was compared (Hauth and colleagues, 1992). Similarly, infection rates are not appreciatively affected by closure versus nonclosure of the peritoneum (Bamigboye and Hofmer, 2003; Tulandi and Al-Jaroudi, 2003). Importantly, although closure of subcutaneous tissue in obese women does not lower the rate of wound infection, it does decrease the incidence of wound separation (Chelmow, 2004; Magann, 2002; Naumann, 1995, and all their colleagues).

Complications of Pelvic Infections

In more than 90 percent of women, metritis responds to treatment within 48 to 72 hours. In the remainder, any of several complications may arise. As with other aspects of puerperal infections, the incidence and severity of complications are remarkably decreased by perioperative antimicrobial prophylaxis.

Wound Infections

When prophylactic antimicrobials are given as described above, the incidence of abdominal incisional infections following cesarean delivery is less than 2 percent (Andrews and colleagues, 2003). The incidence in some cases averaged 6 percent and ranged from 3 to 15 percent (Chaim and associates, 2000; Owen and Andrews, 1994). Wound infection is a common cause of persistent fever in women treated for metritis. Other risk factors for wound infections include obesity, diabetes, corticosteroid therapy, immunosuppression, anemia, hypertension, and inadequate hemostasis with hematoma formation.

Incisional abscesses that develop following cesarean delivery usually cause fever or are responsible for its persistence beginning about the fourth day. In many cases, antimicrobials had been given for uterine infection, and thus, fever is persistent. Wound erythema and drainage usually accompany it. Although organisms that cause wound infections are generally the same as those isolated from amnionic fluid at cesarean delivery, hospital-acquired pathogens occasionally are causative (Emmons and colleagues, 1988; Owen and Andrews, 1994). Treatment includes antimicrobials and surgical drainage, with careful inspection to ensure that the fascia is intact.

With local wound care given two to three times daily, secondary en bloc closure at 4 to 6 days of tissue involved in superficial wound infection can usually be accomplished (Wechter and associates, 2005). With this closure, a polypropylene or nylon suture of appropriate gauge enters 3 cm from one wound edge. It crosses the wound to incorporate the full wound thickness and emerges 3 cm from the other wound edge. These are placed in series to close the opening. In most cases, sutures may be removed on postprocedural day 10.

Wound Dehiscence. Disruption or dehiscence refers to separation of the fascial layer. This is a serious complication and requires secondary closure of the incision in the operating room. McNeeley and colleagues (1998) reported fascial dehiscence in about 1 of 300 operations in almost 9000 women undergoing cesarean delivery. Most disruptions manifested on about the fifth postoperative day and were accompanied by a serosanguineous discharge. Two thirds of 27 fascial dehiscences identified in this study were associated with concurrent fascial infection and tissue necrosis.

Necrotizing Fasciitis. This uncommon, severe wound infection is associated with high mortality. In obstetrics, necrotizing fasciitis may involve abdominal incisions, or it may complicate episiotomy or other perineal lacerations. As the name implies, there is significant tissue necrosis. Of the risk factors for fasciitis summarized by Owen and Andrews (1994), three of these—*diabetes*, *obesity*, and *hypertension*—are relatively common in pregnant women. Like pelvic infections, these usually are polymicrobial and are caused by organisms that comprise normal vaginal flora. In some cases, however, infection is caused by a single virulent bacterial species such as group A β-hemolytic streptococcus. Occasionally, necrotizing infections are caused by rarely encountered pathogens (Swartz, 2004).

Goepfert and colleagues (1997) reviewed their experiences at the University of Alabama Birmingham Hospital from 1987 through 1994. Nine cases of necrotizing fasciitis complicated over 5000 cesarean deliveries—1.8 per 1000. In two women, the infection was fatal. In a report from Brigham and Womens and Massachusetts General Hospitals, Schorge and colleagues (1998) described five women with fasciitis following cesarean delivery. None of these women had predisposing risk factors, and none died.

Treatment consists of broad-spectrum antibiotics along with prompt wide fascial debridement until healthy bleeding tissue is encountered. With extensive resection, synthetic mesh may be required to close the fascial incision (Gallup and Meguiar, 2004; McNeeley and associates, 1998).

Peritonitis

It is unusual for peritonitis to develop following cesarean delivery. It is almost invariably preceded by metritis and uterine incisional necrosis and dehiscence. Other cases may be due to

inadvertent bowel injury at cesarean delivery. Yet another cause is peritonitis following rupture of a parametrial or adnexal abscess. Finally, it may rarely be encountered after vaginal delivery.

In postpartum women, there is an important caveat to remember: **Abdominal rigidity may not be prominent with puerperal peritonitis because of abdominal wall laxity from pregnancy.** Pain may be severe, but frequently, the first symptoms of peritonitis are those of *adynamic ileus.* Marked bowel distension may develop, and these findings are unusual after uncomplicated cesarean delivery. If the infection begins in an intact uterus and extends into the peritoneum, antimicrobial treatment alone usually suffices. Conversely, peritonitis caused by uterine incisional necrosis or bowel perforation must be treated surgically.

Adnexal Infections

An *ovarian abscess* rarely develops in the puerperium. These are presumably caused by bacterial invasion through a rent in the ovarian capsule (Wetchler and Dunn, 1985). The abscess is usually unilateral, and women typically present 1 to 2 weeks after delivery. Rupture is common and peritonitis may be severe.

Parametrial Phlegmon

In some women in whom metritis develops following cesarean delivery, parametrial cellulitis is intensive and forms an area of induration, or *phlegmon,* within the leaves of the broad ligament (Fig. 31-2). These infections should be considered when fever persists longer than 72 hours despite intravenous antimicrobial therapy (DePalma and colleagues, 1982).

Phlegmons are usually unilateral, and they frequently are limited to the parametrial area at the base of the broad ligament. If the inflammatory reaction is more intense, cellulitis extends along natural lines of cleavage. The most common form of extension is laterally along the broad ligament, with a tendency to extend to the pelvic sidewall. Occasionally, posterior extension may involve the rectovaginal septum, producing a firm mass posterior to the cervix.

Severe cellulitis of the uterine incision may lead to necrosis and separation. Extrusion of purulent material commonly leads to peritonitis. Because puerperal metritis with cellulitis is typically a retroperitoneal infection, evidence of peritonitis suggests the possibility of uterine incisional necrosis, or less commonly, a bowel injury or other lesion as described above.

In most women with a phlegmon, clinical improvement follows continued treatment with a broad-spectrum antimicrobial regimen. Typically, fever resolves in 5 to 7 days, but in some cases, it is longer. Absorption of the induration may require several days to weeks. Surgery is reserved for women in whom uterine incisional necrosis is suspected. In rare cases, uterine debridement and resuturing of the incision are feasible (Rivlin and colleagues, 2004). For most, hysterectomy and surgical debridement are needed and are predictably difficult. There is often appreciable blood loss. Frequently, the cervix and lower uterine segment are involved with an intensive inflammatory process that extends to the pelvic sidewall to encompass one or both ureters. The adnexa are seldom involved, and one or both ovaries usually can be conserved.

Imaging Studies. Persistent puerperal infections can be evaluated using computed tomography (CT) or magnetic resonance (MR) imaging. Brown and colleagues (1991) used CT imaging in 74 women in whom pelvic infection was refractory to antimicrobial therapy. They found at least one abnormal radiological finding in 75 percent of these women. Maldjian and associates (1999) used MR imaging in 50 women with persistent fever and found a bladder flap hematoma in two thirds. In three women, parametrial edema was seen, and another two had a pelvic hematoma.

Uterine incisional dehiscence is sometimes suspected by CT scanning images (Figs. 31-3 and 31-4). These must be interpreted within the clinical context because apparent uterine incisional defects thought to represent edema can be seen even on images after uncomplicated cesarean delivery (Twickler and colleagues, 1991).

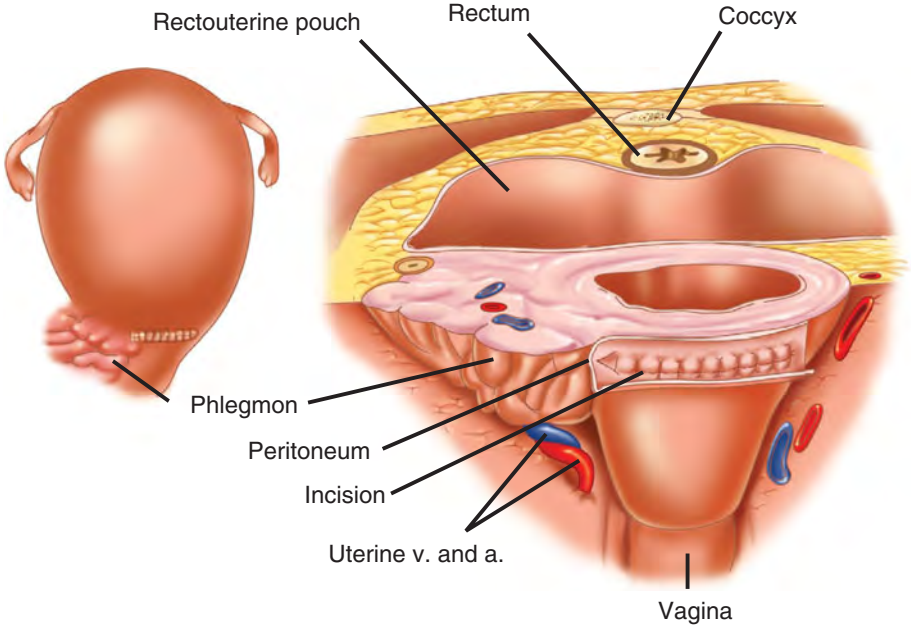

FIGURE 31-2 Parametrial phlegmon. Cellulitis causes induration in the right parametrium adjacent to the uterine cesarean incision. Induration extends to the pelvic sidewall. On bimanual pelvic examination, a phlegmon is palpable as a firm, three-dimensional mass.

Pelvic Abscess

Rarely, a parametrial phlegmon suppurates, forming a fluctuant broad ligament mass that may point above the inguinal ligament. These abscesses may dissect anteriorly as shown in Figure 31-4 and be amenable to CT-directed needle drainage. Occasionally they dissect posteriorly to the rectovaginal septum, where surgical drainage is easily effected by colpotomy incision.

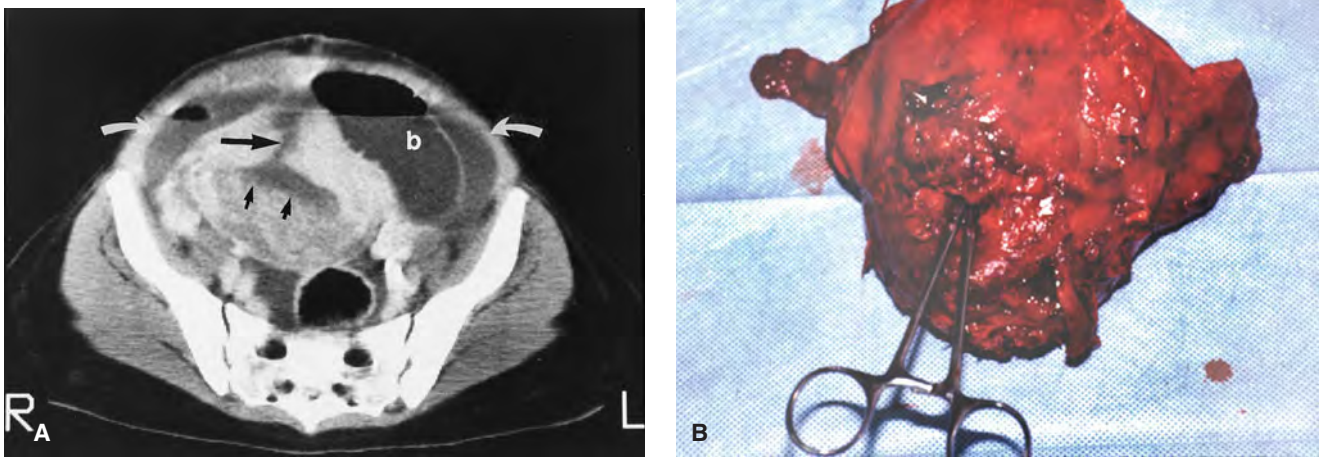

FIGURE 31-3 **A.** Pelvic computed tomography scan of dehiscence caused by infection of a vertical cesarean incision. Endometrial fluid (*small black arrows*) communicates with parametrial fluid (*curved white arrows*) through the uterine defect (*large black arrow*). A dilated bowel loop (*b*) is adjacent to the uterus on the left. **B.** Supracervical hysterectomy specimen with instrument through uterine dehiscence.

A *psoas abscess* is rare, and despite antimicrobial therapy, percutaneous drainage may be required (Shahabi and colleagues, 2002; Swanson and co-workers, 2008).

Septic Pelvic Thrombophlebitis

This was a common complication in the preantibotic era. Collins and colleagues (1951) described suppurative thrombophlebitis in 70 women cared for from 1937 through 1946 at Charity Hospital in New Orleans. Septic embolization was common and caused a third of maternal deaths during that period. With the advent of antimicrobial therapy, the mortality rate and need for surgical therapy for these infections diminished.

Pathogenesis. Puerperal infection may extend along venous routes and cause thrombosis as shown in **Figure 31-5**. Lymphangitis often coexists. The ovarian veins may then become involved because they drain the upper uterus and therefore, the placental implantation site. The experiences of Witlin and Sibai (1995) and Brown and colleagues (1999) suggest that puerperal septic thrombophlebitis is likely to involve one or both ovarian venous plexuses (**Fig. 31-6**). In a fourth of women, the clot extends into the inferior vena cava and occasionally to the renal vein.

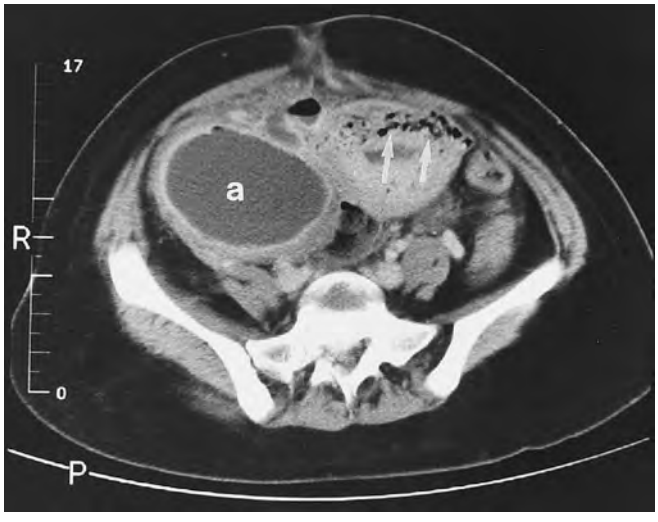

FIGURE 31-4 Pelvic computed tomography scan showing necrosis of the uterine incision with gas in the myometrium (*arrows*). There is also a large right-sided parametrial abscess (*a*).

Incidence. During a five-year survey of 45,000 women who were delivered at Parkland Hospital, Brown and associates (1999) found an incidence of septic pelvic thrombophlebitis of 1:9000 following vaginal delivery and 1:800 with cesarean delivery. The overall incidence of 1:3000 deliveries was similar to the 1:2000 reported by Dunnihoo and colleagues (1991). In a cohort of 16,650 women undergoing primary cesarean delivery, Rouse and associates (2004) reported an incidence of 1:400 with cesarean delivery—it was about 1:175 if there was antecedent chorioamnionitis, and 1:500 if there was no intrapartum infection.

Management. Women with septic thrombophlebitis usually have clinical improvement of pelvic infection with antimicrobial treatment, however, they continue to have fever. Although there occasionally is pain in one or both lower quadrants, patients are usually asymptomatic except for chills. Diagnosis can be confirmed by either pelvic CT or MR imaging (Klima and Snyder, 2008; Sheffield and Cunningham, 2001). Using both, Brown and co-workers (1999) found that 20 percent of 69 women with metritis who had fever despite 5 days of appropriate therapy had septic pelvic thrombophlebitis. Before imaging methods were available, the *heparin challenge test* was advocated. Supposedly after intravenous heparin was given, if fever abated, this was considered diagnostic of pelvic phlebitis (Josey and Staggers, 1974). This was subsequently disproved by Brown and colleagues (1986) as well as by Witlin and Sibai (1995). Although Garcia and colleagues (2006) and Klima and Snyder (2008) advocate heparin administration, we do not use or recommend anticoagulation. In a randomized study of 14 women by Brown and

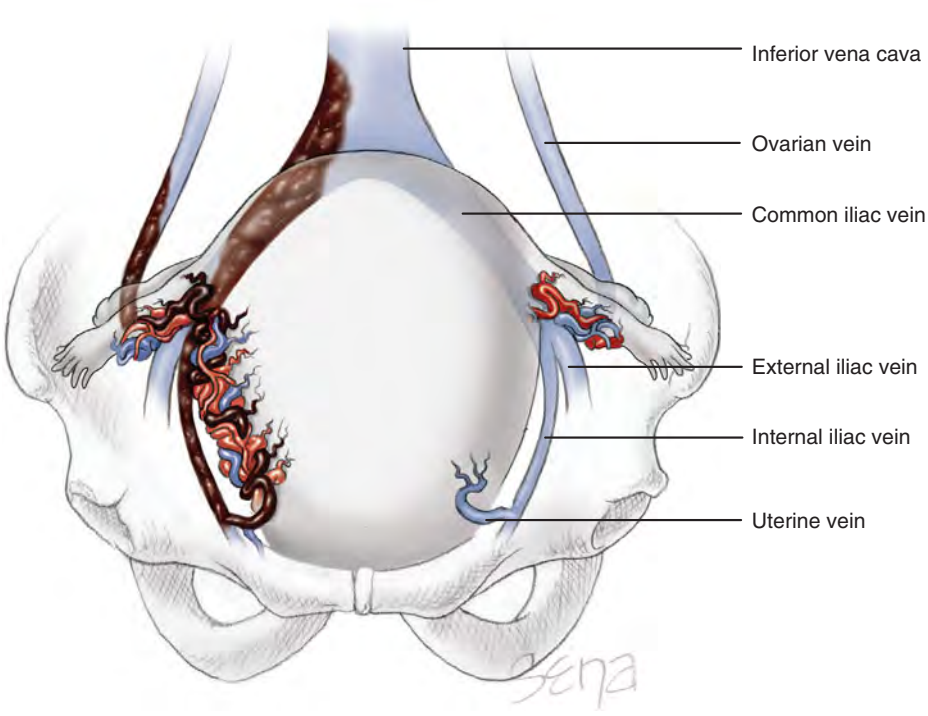

FIGURE 31-5 Routes of extension of septic pelvic thrombophlebitis. Any pelvic vessel and the inferior vena cava may be involved as shown on the left. The clot in the right common iliac vein extends from the uterine and internal iliac veins and into the inferior vena cava.

associates (1999), the addition of heparin to antimicrobial therapy for septic pelvic thrombophlebitis did not hasten recovery or improve outcome. Certainly, there is no evidence for long-term anticoagulation as given for "bland" venous thromboembolism.

Infections of the Perineum, Vagina, and Cervix

Episiotomy infections are not common because the operation is performed much less frequently now than in the past (American College of Obstetricians and Gynecologists, 2006). Reasons for this are discussed further in Chapter 17 (p. 401). Even more than 25 years ago, Owen and Hauth (1990) described only 10 episiotomy infections in 20,000 women delivered at the University of Alabama at Birmingham. With infection, dehiscence is a concern. Ramin and colleagues (1992) reported that 0.5 percent of episiotomy wounds dehisced at Parkland Hospital, and 80 percent of these were due to infection. More recently, Uygur and colleagues (2004) reported a 1-percent dehiscence rate and attributed two thirds to infection. There are no data to suggest that dehiscence is related to faulty repair.

Infection of a fourth-degree laceration is likely to be more serious. Goldaber and colleagues (1993) described 390 such women of whom 5.4 percent had morbidity—2.8 percent had infection and dehiscence, 1.8 percent had only dehiscence, and 0.8 percent only infection. Although life-threatening septic shock is rare, it may still occur as a result of an infected episiotomy (Soltesz and colleagues, 1999).

FIGURE 31-6 Pelvic computed tomography scan with contrast shows enlargement of the right ovarian venous plexus with low density of the lumens. The clotted vessels were easily palpable in this thin woman who had delivered vaginally 3 days earlier.

Pathogenesis and Clinical Course

Episiotomy dehiscence is most commonly associated with infection as discussed above. Other factors include coagulation disorders, smoking, and human papillomavirus infection (Ramin and Gilstrap, 1994). Local pain and dysuria, with or without urinary retention, are common symptoms. Ramin and colleagues (1992), evaluating a series of 34 women with episiotomy dehiscence, reported that the most common findings were pain in 65 percent, purulent discharge in 65 percent, and fever in 44 percent. In extreme cases, the entire vulva may become edematous, ulcerated, and covered with exudate.

Vaginal lacerations may become infected directly or by extension from the perineum. The mucosa becomes red and swollen and may then become necrotic and slough. Parametrial extension may result in lymphangitis.

Cervical lacerations are common but seldom are noticeably infected and may manifest as metritis. Deep lacerations which extend directly into the tissue at the base of the broad ligament may become infected and cause lymphangitis, parametritis, and bacteremia.

Treatment

Infected episiotomies are managed like other infected surgical wounds. Drainage is established, and in most cases, sutures are removed and the infected wound debrided. In some women with obvious cellulitis but no purulence, broad-spectrum

TABLE 31-3. Preoperative Protocol for Early Repair of Episiotomy Dehiscence

Open wound, remove sutures, begin intravenous antimicrobials
Wound care
Sitz bath several times daily or hydrotherapy
Adequate analgesia or anesthesia—regional analgesia or general anesthesia may be necessary for the first few debridements
Scrub wound twice daily with a povidone-iodine solution
Debride necrotic tissue
Closure when afebrile and with pink, healthy granulation tissue
Bowel preparation for fourth-degree repairs

antimicrobial therapy with close observation may be appropriate. With dehiscence, local wound care is continued along with intravenous antimicrobials. Hauth and colleagues (1986) were the first to advocate early repair after infection subsided, and other studies have confirmed the efficacy of this approach. Hankins and co-workers (1990) described early repair of episiotomy dehiscence in 31 women with an average duration of 6 days from dehiscence to episiotomy repair. All but two had a successful repair. Each of the two women with failures developed a pinpoint rectovaginal fistula that was treated successfully with a small rectal flap. Ramin and colleagues (1992) reported successful early repair of episiotomy dehiscence associated with infection in 32 of 34 women (94 percent), and Uygur and colleagues (2004) noted a similarly high percentage. Rarely, intestinal diversion may be required to allow healing (Rose and associates, 2005).

Technique for Early Repair. Before performing early repair, diligent preparation is essential as outlined in Table 31-3. **Most important is that the surgical wound must be properly cleaned and free of infection.** As shown in Figure 31-7, once the surface of the episiotomy wound is free of infection and exudate and covered by pink granulation tissue, secondary repair can be accomplished. The tissue must be adequately mobilized, with special attention to identify and mobilize the anal sphincter muscle. Secondary closure of the episiotomy is accomplished in layers, as described for primary episiotomy closure (see Chap. 17, p. 402). Postoperative care includes local wound care, low-residue diet, stool softeners, and nothing per vagina or rectum until healed.

Necrotizing Fasciitis

A rare but frequently fatal complication of perineal and vaginal wound infections is deep soft-tissue infection involving muscle and fascia. Although women with diabetes or women who are immunocompromised are more vulnerable, these serious infections may develop in otherwise healthy women. Their microbiology appears to be similar to those of other pelvic infections, as well as necrotizing fasciitis of the abdominal wall incision described on page 662. Although uncommon today, Shy and Eschenbach (1979) reported that during the 1970s necrotizing fasciitis of the episiotomy was responsible for three of 15 maternal deaths in King County, Washington.

Necrotizing fasciitis of the episiotomy site may involve any of the several superficial or deep perineal fascial layers, and thus may extend to the thighs, buttocks, and abdominal wall (Fig. 31-8). Although some virulent infections, for example, from group A β-hemolytic streptococci, develop early postpartum, these infections typically do not cause symptoms until 3 to 5 days after delivery. Clinical findings vary, and it is frequently difficult to differentiate more innocuous superficial perineal infections from an ominous deep fascial one. A high index of suspicion, with surgical exploration if the diagnosis is uncertain, may be lifesaving. We aggressively pursue early exploration. Certainly, if myofasciitis progresses, the woman may become ill from septicemia. Profound hemoconcentration from capillary leakage with circulatory failure commonly occurs, and death may soon follow as described in Chapter 42 (p. 933).

Early diagnosis, surgical debridement, antimicrobials, and intensive care are of paramount importance in the successful treatment of necrotizing soft-tissue infections (Gallup and Meguiar, 2004; Urschel, 1999). Surgery includes extensive debridement of all infected tissue, leaving wide margins of healthy tissue. This may include extensive vulvar debridement with unroofing and excision of abdominal, thigh, or buttock fascia (see Fig. 31-8). Mortality is virtually universal without surgical treatment, and rates approach 50 percent even if extensive debridement is performed.

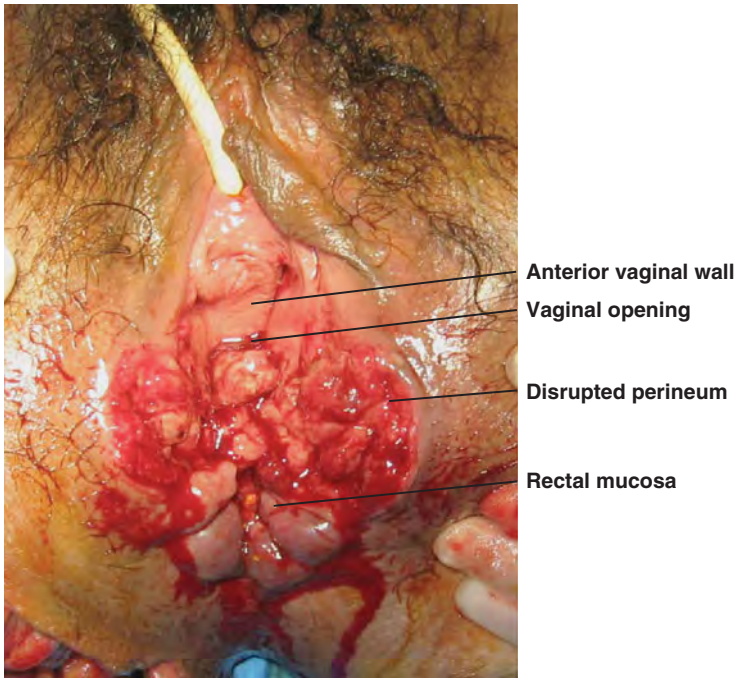

FIGURE 31-7 Dehiscence of fourth-degree episiotomy. Secondary repair is done when the wound surface is free of exudate and covered by pink granulation tissue. (Courtesy of Dr. Scott Roberts.)

FIGURE 31-8 Necrotizing fasciitis complicating an episiotomy infection. Postpartum day 3, this woman had severe perineal pain and edema of the episiotomy site. Prompt extensive debridement and fasciotomy on her right inner thigh was completed. Cultures grew *Escherichia coli, Streptococcus viridans,* group D streptococcus, *Corynebacterium* species, *Bacteroides fragilis,* and *Clostridium* species. Blood cultures were positive for *Bacteroides fragilis.* She survived.

TOXIC SHOCK SYNDROME

This acute febrile illness with severe multisystem derangement has a case-fatality rate of 10 to 15 percent. There is usually fever, headache, mental confusion, diffuse macular erythematous rash, subcutaneous edema, nausea, vomiting, watery diarrhea, and marked hemoconcentration. Renal failure followed by hepatic failure, disseminated intravascular coagulation, and circulatory collapse may follow in rapid sequence. During recovery, the rash-covered areas undergo desquamation. *Staphylococcus aureus* has been recovered from almost all afflicted persons. Specifically, a staphylococcal exotoxin, termed *toxic shock syndrome toxin-1*—TSST-1—causes the clinical manifestations by provoking profound endothelial injury. A very small amount of TSST-1 has been shown to activate 5 to 30 percent of T cells to create a "cytokine storm" as described by Que (2005) and Heying (2007) and their colleagues. Treatment is discussed in Chapter 42 (p. 932).

In some cases, infection is not apparent, and colonization of a mucosal surface is the presumed source. From 10 to 20 percent of pregnant women have vaginal colonization with *S. aureus*, and thus it is not surprising that the disease develops in postpartum women (Chen and colleagues, 2006; Guerinot and co-workers, 1982). Almost identical findings of toxic shock were reported by Robbie and associates (2000) in women with infection complicated by *Clostridium sordellii* colonization.

During the 1990s, sporadic reports of virulent group A β- hemolytic streptococcal infection began to appear as discussed on page 662. Infection is complicated in some cases by *streptococcal toxic shock syndrome* produced when pyrogenic exotoxin is elaborated. Serotypes M1 and M3 are particularly virulent (Beres and associates, 2004; Okumura and colleagues, 2004).

Delayed diagnosis and treatment may be associated with fetal or maternal mortality (Crum and colleagues 2002; Schummer and Schummer 2002). Principal therapy for toxic shock is supportive, while allowing reversal of capillary endothelial injury (see Chap. 42, p. 934). Antimicrobial therapy to include staphylococcal and streptococcal coverage is given. With evidence of pelvic infection, antimicrobial therapy must also include agents used for polymicrobial infections. Women with these infections often require extensive wound debridement and possibly hysterectomy. Because the toxin is so potent, the mortality rate is correspondingly high (Hotchkiss and Karl, 2003).

CHAPTER 32

Contraception

HORMONAL CONTRACEPTIVES 673
INTRAUTERINE DEVICE (IUD) 684
BARRIER METHODS 687
FERTILITY AWARENESS-BASED METHODS 691
EMERGENCY CONTRACEPTION 692
LACTATION 694

For sexually active fertile women who do not use contraception, pregnancy rates approach 90 percent at 1 year. For those who do not desire pregnancy, fertility regulation is now possible, and a variety of effective contraceptive methods are shown in Table 32-1. None is completely without side effects or categorically without danger. **One tenet emphasized throughout this chapter is that contraception usually poses less risk than does pregnancy.**

Nationally representative data concerning contraceptive use are shown in Figure 32-1. With use during the first year, wide variations can be seen between estimated failure rates of perfect and typical use (Table 32-2). Many of these rates can be appreciably reduced with effective motivation and education (Gilliam and co-workers, 2004). The World Health Organization has crafted four evidence-based guides for family planning, which encompass topics of contraceptive selection, patient counseling, and method use. These are available at the World Health Organization website: http://www.who.int/reproductive-health/publications/family_planning.html.

HORMONAL CONTRACEPTIVES

These are currently available in oral, injectable, transdermal-patch, and transvaginal-ring forms. Oral contraceptive pills are a combination of estrogen and progestin—"the pill"—are or progestin only. Other forms contain progestins alone or a combination of estrogen and progestin. Male hormonal contraceptive options have been evaluated in human trials and may be an option in the future (Blithe, 2008; Gu and associates, 2009; Mommers and co-workers, 2008).

Estrogen Plus Progestin Contraceptives

Combination oral contraceptives (COCs) are the most frequently used method of hormonal contraception, and an almost bewildering variety that are marketed are listed in Table 32-3. Most are also available as generics, and the U.S. Food and Drug Administration (FDA) (2008) confirms the bioequivalence of COC generics. Moreover, the American College of Obstetricians and Gynecologists (2007a) supports the use of either branded or generic COCs.

Mechanisms of Action

The contraceptive actions of COCs are multiple, but the most important effect is to prevent ovulation by suppression of hypothalamic gonadotropin-releasing factors. This in turn prevents pituitary secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Progestins prevent ovulation by suppressing LH and also thicken cervical mucus, thereby retarding sperm passage. In addition, they render the endometrium unfavorable for implantation. Estrogen prevents ovulation by suppressing FSH release. It also stabilizes the endometrium, which prevents intermenstrual bleeding—also known as *breakthrough bleeding*.

The net effect is extremely effective ovulation suppression, inhibition of sperm migration through cervical mucus, and creation of an unfavorable endometrium for implantation. Thus, they provide virtually absolute protection against conception if taken as directed.

Pharmacology

In the United States, the *estrogens* used for contraception are *ethinyl estradiol* and much less commonly, its 3-methyl ether,

TABLE 32-1. Contraceptive Methods Currently Used in the United States

Sexual abstinence around the time of ovulation
Breast feeding
Permanent sterilization

mestranol. Almost all currently available *progestins* are 19-nortestosterone derivatives, but one is an aldosterone derivative. Although individual progestins are initially chosen because of their progestational potencies, they are often compared and prescribed based on their presumed progestational, estrogenic, and especially their androgenic effects. A scientific basis for such selective prescribing, however, is lacking (Wallach and Grimes, 2000).

Dosage

Over time, the estrogen and progestin contents of COCs have been reduced remarkably to minimize hormone-related adverse effects. Currently, the lowest acceptable dose is limited by their ability to prevent pregnancy and unacceptable breakthrough bleeding. Although daily estrogen content varies from 20 to 50 μg of ethinyl estradiol, most contain 35 μg or less (see Table 32-3). The amount of progestin varies in two ways. In some formulations, the progestin dose remains constant during the cycle—*monophasic*. In others, the progestin and in some, the estrogen dose varies during the cycle—*biphasic* and *triphasic*.

Phasic pills were developed to reduce the amount of total progestin per cycle without sacrificing contraceptive efficacy or cycle control. The reduction is achieved by beginning with a low dose of progestin and increasing it later in the contraceptive cycle. Despite the theoretic advantage of lower total progesterone dose per cycle, this has not been borne out clinically (Moreau and colleagues, 2007; van Vliet and associates, 2006).

Administration

With the exception of one preparation, COCs are taken daily for a specified time (21 to 81 days) and then omitted for a specified time (4 to 7 days) called the "pill-free interval." During these

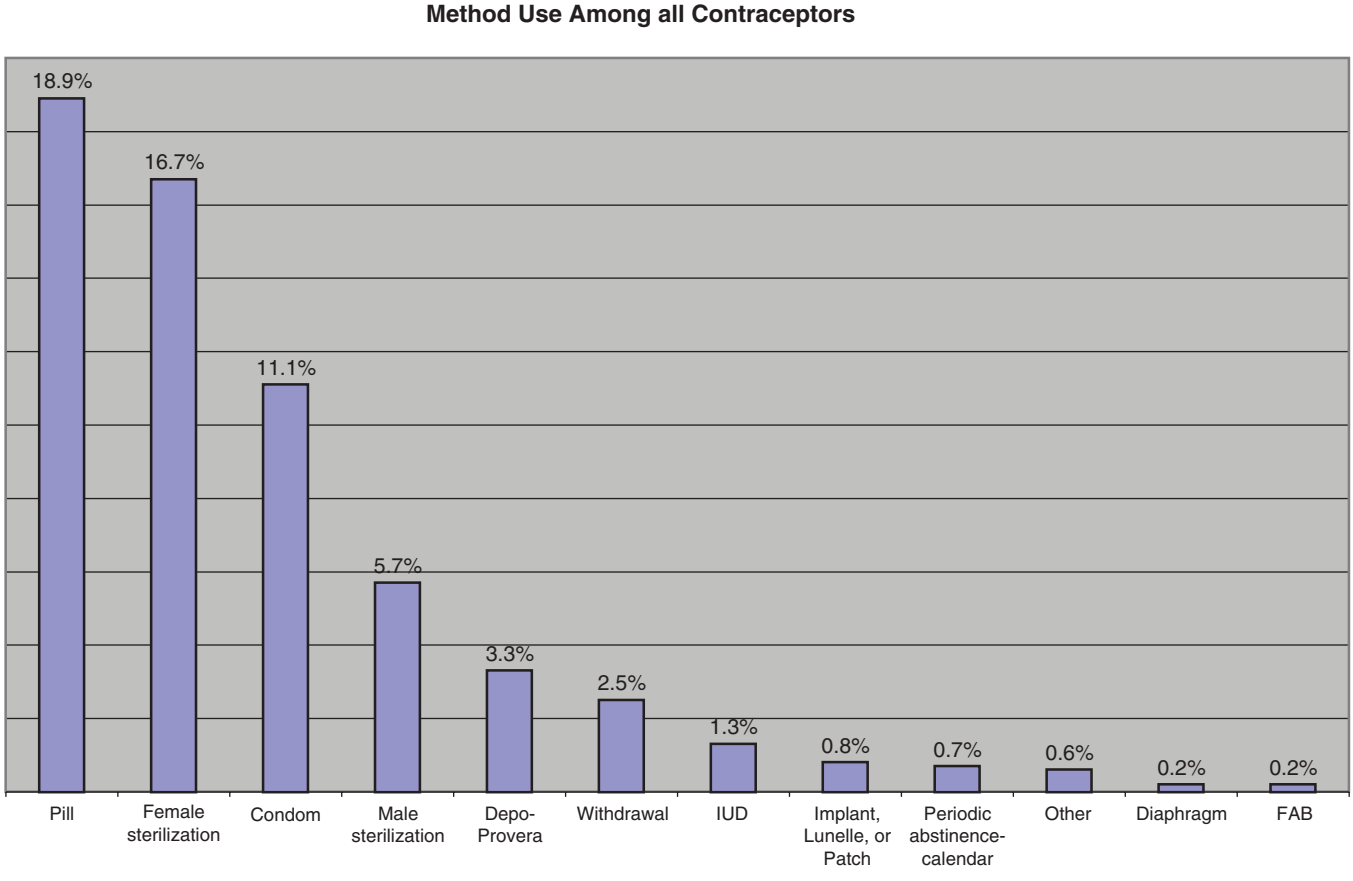

FIGURE 32-1 Contraceptive use in the United States, 2002, for users aged 15 to 44. DMPA = depot medroxyprogesterone acetate; FAB = fertility awareness-based method; IUD = intrauterine device. (Data from Chandra and co-workers, 2005.)

TABLE 32-2. Contraceptive Failure Rates During the First Year of Use

	Percent of Women with Pregnancy

Modified from Speroff and Darney, 2001, and Trussell, 2004.

pill-free days, withdrawal bleeding is expected. One trend of pills with lower estrogen doses is to shorten the pill-free interval, which seems to reduce the occurrence of intermenstrual bleeding (Nakajima and colleagues, 2007). For example, *Loestrin 24 Fe* and *Yaz* provide hormones for 24 days followed by 4 pill-free days. Alternatively, longer durations of active hormone, designed to minimize the number of withdrawal episodes, have been implemented (Edelman and co-workers, 2006). These extended-cycle products, such as *Seasonale* and *Seasonique*, produce a 13-week cycle, that is, 12 weeks of hormone use, followed by a week for withdrawal menses. More recently, in 2007, the FDA approved the first continuous COC, *Lybrel*, which is taken 365 days of each year.

Pill Usage

Ideally, women should begin COCs on the first day of a menstrual cycle, in which case a back-up contraceptive method is unnecessary. With the more traditional "Sunday start," women begin pills on the first Sunday that follows menses onset, and a back-up method is needed for 1 week to prevent conception. With the "Quick Start" method, COCs are started on any day, commonly the day prescribed, regardless of cycle timing. A back-up method is used during the first week. This latter approach improves short-term compliance (Westhoff and co-workers, 2002, 2007b). If the woman is already pregnant during Quick Start initiation, COCs are not teratogenic (see Chap. 14, p. 322) (Lammer and Cordero, 1986). Similarly, same-day initiation can be implemented with the contraceptive vaginal ring or patch (Murthy and co-workers, 2005; Schafer and associates, 2006).

For maximum efficiency, pills should be taken at the same time each day. If one dose is missed, contraception is likely not diminished with higher-dose monophasic COCs. Doubling the next dose will minimize breakthrough bleeding and maintain the pill schedule. If several doses are missed or lower-dose pills are used, the pill may be stopped, and an effective barrier

technique used until menses. The pill may then be restarted after this withdrawal bleeding. Alternatively, a new pack can be started immediately following identification of missed pills, and a barrier method used as a back-up method for 1 week. If there is no withdrawal bleeding, the woman should continue her pills but seek attention to exclude pregnancy.

Drug Interactions

Combination oral contraceptives interfere with the actions of some drugs (Table 32-4). Conversely, some drugs decrease the effectiveness of COCs (Table 32-5).

Beneficial Effects

When used reliably, COCs offer effective rapidly reversible methods of pregnancy prevention. In addition, there are a number of noncontraceptive benefits (European Society of Human Reproduction and Embryology, 2005). Some are listed in Table 32-6.

Possible Adverse Effects

A number of metabolic changes, often qualitatively similar to those of pregnancy, have been identified in women taking oral contraceptives. For example, total plasma thyroxine (T_4) and thyroid-binding proteins are elevated. Plasma cortisol concentration increases with a nearly comparable increase in transcortin. Therefore, these pregnancy-like effects should be considered when evaluating laboratory tests in women using COCs.

Lipoproteins and Lipids. In general, COCs increase serum levels of triglycerides and total cholesterol. Estrogen decreases the concentration of low-density lipoprotein (LDL) cholesterol and increases high-density lipoprotein (HDL) cholesterol. Some progestins cause the reverse. Despite this, the clinical consequences of these perturbations have almost certainly been overstated. Oral contraceptives are not atherogenic, and their impact on lipids is inconsequential for most women (Wallach and Grimes, 2000). But in women with dyslipidemias, the American College of Obstetricians and Gynecologists (2006b) recommends assessment of lipid levels following initiation of COCs. In women with LDL cholesterol levels >160 mg/dL, or if there are multiple additional risk factors for cardiovascular disease, alternative contraceptive methods are recommended.

Carbohydrate Metabolism. There are limited effects on carbohydrate metabolism with current low-dose formulations in women who do not have diabetes. In addition, the risk of developing diabetes is not increased (Lopez and colleagues, 2007; Kim and associates, 2002). Moreover, COCs may be used in nonsmoking, diabetic women younger than 35 years who have no associated vascular disease (American College of Obstetricians and Gynecologists, 2006b).

TABLE 32-4. Drugs Whose Effectiveness Is Influenced by Combination Oral Contraceptives

Interacting Drug	Documentation	Management
Analgesics		
Acetaminophen	Adequate	Larger doses of analgesic may be required
Aspirin	Probable	Larger doses of analgesic may be required
Meperidine	Suspected	Smaller doses of analgesic may be required
Morphine	Probable	Larger doses of analgesic may be required
Anticoagulants		
Dicumarol, warfarin	Controversial	
Antidepressants		
Imipramine	Suspected	Decrease dosage about a third
Tranquilizers		
Diazepam	Suspected	Decrease dose
Alprazolam		
Temazepam	Possible	May need to increase dose
Other benzodiazepines	Suspected	Observe for increased effect
Anti-inflammatories		
Corticosteroids	Adequate	Watch for potentiation of effects, decrease dose accordingly
Bronchodilators		
Aminophylline	Adequate	Reduce starting dose by a third
Theophylline		
Caffeine		
Antihypertensives		
Cyclopenthiazide	Adequate	Increase dose
Metoprolol	Suspected	May need to lower dose
Antibiotics		
Troleandomycin	Suspected liver damage	Avoid
Cyclosporine	Possible	May use smaller dose
Antiretrovirals	Variable	See the manufacturer or other[a]

TABLE 32-5. Drugs That May Reduce Combined Hormonal Contraceptive Efficacy

Interacting Drug	Documentation
Antituberculous	
Rifampin	Established—reduced efficacy <50 μg EE
Antifungals	
Griseofulvin	Strongly suspected
Anticonvulsants and Sedatives	
Phenytoin, mephenytoin, phenobarbital, primidone, carbamazepine, ethosuximide	Strongly suspected—reduced efficacy <50-μg EE, trials lacking
Antibiotics	
Tetracycline, doxycycline	Two small studies find no association
Penicillins	No association documented
Ciprofloxacin	No effect on efficacy of 30-μg EE + desogestrel
Ofloxacin	No effect on efficacy of a 30-μg EE + levonorgestrel
Antiretrovirals	Variable effects—see the manufacturer or other[a]

Modified after Wallach, 2000, with permission.

TABLE 32-6. Some Benefits of Combined Estrogen Plus Progestin Oral Contraceptives

Increased bone density
Reduced menstrual blood loss and anemia
Decreased risk of ectopic pregnancy
Improved dysmenorrhea from endometriosis
Fewer premenstrual complaints
Decreased risk of endometrial and ovarian cancer
Reduction in various benign breast diseases
Inhibition of hirsutism progression
Improvement of acne
Prevention of atherogenesis
Decreased incidence and severity of acute salpingitis
Decreased activity of rheumatoid arthritis

Protein Metabolism. Estrogens increase hepatic production of a variety of globulins. One is sex-hormone binding globulin (SHBG), which leads to decreased bioavailable testosterone concentrations and its consequent effects. Angiotensinogen production is also augmented by COCs, and its conversion by renin to angiotensin I may be associated with "pill-induced hypertension" discussed subsequently. Fibrinogen, and likely factors II, VII, IX, X, XII, and XIII, are all increased in direct proportion to estrogen dose (Comp, 1996; Kaunitz, 1999). Associated risks for venous and arterial thrombosis are also discussed subsequently.

Hepatic Effects. Cholestasis and cholestatic jaundice are uncommon, but they resolve when COCs are discontinued. There are conflicting reports regarding the risk for cholelithiasis and cholecystectomy with COC use. If the risk exists, it appears small (Stuart and colleagues, 2007). Although active hepatitis is a contraindication to COC use, there is no reason to withhold oral contraceptives from women who have recovered.

Neoplasia. A stimulatory effect on some cancers is always a concern with female sex steroids. Fortunately, most studies indicate that overall, COCs are not associated with an increased risk of cancer (Hannaford and associates, 2007). In fact, a protective effect against ovarian and endometrial cancer has been shown (Collaborative Group on Epidemiological Studies of Ovarian Cancer, 2008; Cancer and Steroid Hormone Study, 1987). Protection from these cancers decreases, however, as time from pill use increases (Tworoger and co-workers, 2007). Rates of colorectal cancer appear to be reduced in ever users (Kabat and co-workers, 2008).

Although COC use in the past was linked to development of *hepatic focal nodular hyperplasia* and *benign hepatic adenoma*, large studies do not support this (Heinemann and colleagues, 1998). There is also no evidence for increased risk of *hepatocellular cancer* (Maheshwari and colleagues, 2007).

Because a third of cases of malignant melanoma in women develop during childbearing years, an association with hormonal and reproductive factors has been sought. To date, however, no association between COCs and melanoma has been identified (Lens and associates, 2008).

The relative risk of *cervical dysplasia* and *cervical cancer* is increased in current COC users, but this declines after use is discontinued. Following 10 or more years, risk returns to that of never users (International Collaboration of Epidemiological Studies of Cervical Cancer, 2007). Furthermore, after cervical dysplasia treatment, rates of recurrence are not increased by COC use (Frega and colleagues, 2008).

It is unclear whether COCs contribute to the development of *breast cancer.* The Collaborative Group on Hormonal Factors in Breast Cancer (1996) analyzed data from 54 studies that included more than 53,000 women with and more than 100,000 without breast cancer. There was a small but significantly increased relative risk for breast cancer of 1.24 for current users, 1.16 for those 1 to 4 years after stopping, and 1.07 for those 5 to 9 years after stopping. In this study, tumors associated with COC use tended to be less aggressive and to be detected at an earlier stage—a finding consistent with the possibility that the increased risk of breast cancer was due to greater surveillance among users. In women who are carriers of the BRCA1 or BRCA2 mutation, risks for breast cancer are not increased by COC use (Brohet and associates, 2007). With regard to *benign breast disease*, COCs appear to lower rates (Vessey and Yeates, 2007).

Nutrition. Aberrations in the levels of several *nutrients,* similar to changes induced by normal pregnancy, have been described for women who use oral contraceptives. Lower plasma levels have been described for ascorbic acid, folic acid, vitamin B_6 (pyridoxine), vitamin B_{12}, niacin, riboflavin, and zinc. An adequate diet, however, is sufficient for any detrimental deficiency (Mooij and co-workers, 1991). Although it is widely held that COCs lead to weight gain, studies have not verified this (Gallo and associates, 2008).

Cardiovascular Effects. A number of infrequent but significant cardiovascular risks are associated with COC use. These include thromboembolic disease, myocardial infarction, and stroke. For women with prior history of these events, COCs should not be considered (Table 32-7). And because these complications are increased in women older than 35 years and who smoke, COCs are not recommended for this population.

It has long been known that the risk of *deep-venous thrombosis and pulmonary embolism* is increased in women who use COCs (Stadel, 1981). These clearly are estrogen-dose related, and rates have been substantively decreased with lower-dose formulations containing 20 to 35 μg of ethinyl estradiol (Westhoff, 1998). Even with increased risk, the incidence with COCs use is only 3 to 4 per 10,000 woman-years (Mishell, 2000). Moreover, the risk is lower than the incidence of 5 to 6 per 10,000 woman-years estimated for pregnancy (see Chap. 47, p. 1013). The enhanced risk of thromboembolism appears to decrease rapidly once COCs are stopped.

Those most at risk for venous thrombosis and embolism include women with protein C or S deficiencies (Comp, 1996). Other clinical factors that increase the risk of venous thrombosis and embolism with COC use are hypertension, obesity, diabetes, smoking, and a sedentary lifestyle (Pomp and co-workers, 2007, 2008). Contraceptive use during the month before a major operative procedure appears to double the risk for postoperative

TABLE 32-7. Typical Package Insert Listing Contraindications and a Warning about the Use of Combination Oral Contraceptives

CONTRAINDICATIONS: Combination contraceptives should not be used in women with:

- Thrombophlebitis or thromboembolic disorders
- History of deep-vein thrombophlebitis or thrombotic disorders
- Cerebrovascular or coronary-artery disease
- Thrombogenic cardiac valvulopathies
- Thrombogenic heart arrhythmias
- Diabetes with vascular involvement
- Severe hypertension
- Known or suspected breast carcinoma
- Carcinoma of the endometrium or other known or suspected estrogen-dependent neoplasia
- Undiagnosed abnormal genital bleeding
- Cholestatic jaundice of pregnancy or jaundice with pill use
- Hepatic adenomas or carcinomas, or active liver disease with abnormal liver function
- Known or suspected pregnancy
- Major surgery with prolonged immobilization

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral-contraceptive use. This risk increases with age and with the extent of smoking (in epidemiological studies, 15 or more cigarettes per day was associated with a significantly increased risk) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

From Physicians Desk Reference, 2009.

thromboembolism (Robinson and co-workers, 1991). The American College of Obstetricians and Gynecologists (2007c) recommends balancing the risks of thromboembolism with those of unintended pregnancy during the 4 to 6 weeks required to reverse the thrombogenic effects of COCs prior to surgery.

According to the World Health Organization Collaborative Study (1998), the increase of *ischemic and hemorrhagic strokes* in nonsmoking women younger than 35 years is about 10 and 25 events per 1 million woman years, respectively. Several studies have concluded that the use of COCs by healthy, nonsmoking women is not associated with an increased risk of either type strokes (World Health Organization Collaborative Study, 1996). Conversely, women who have hypertension, smoke, or have migraine headaches with visual aura *and* use oral contraceptives have an increased risk of strokes (MacClellan and associates, 2007). Because the absolute risk of stroke is low, however, the American College of Obstetricians and Gynecologists (2006b) has concluded that COCs may be considered for women with migraines that lack focal neurological signs if they are otherwise healthy, normotensive nonsmokers younger than 35 years.

Oral contraceptives containing low-dose estrogen and low-androgenic progestins are not associated with an increased risk of *myocardial infarction* in nonsmokers (Margolis and associates, 2007; World Health Organization Collaborative Study, 1997). Smoking is an independent risk factor for myocardial infarction, and oral contraceptives act synergistically to increase this risk, especially after age 35 (Craft and Hannaford, 1989).

The estrogen component of COCs increases plasma angiotensinogen (renin substrate) to levels near those found in normal pregnancy. And although most women demonstrate these changes, low-dose COCs formulations rarely, if ever, cause clinically significant hypertension (Chasan-Taber and colleagues, 1996). A history of gestational hypertension does not preclude subsequent COC use. Because the absolute risk of stroke is low in hypertensive women using COCs, those with well-controlled uncomplicated hypertension who are nonsmokers, otherwise healthy, and younger than 35 may be considered for their use (American College of Obstetricians and Gynecologists, 2006b).

Effects on Reproduction. At least 90 percent of women who previously ovulated regularly begin to do so within 3 months after discontinuance of oral contraceptives. There is no evidence that COCs are teratogenic (Rothman and Louik, 1978; Savolainen and associates, 1981).

Lactation. Very small quantities of the hormones are excreted in breast milk, but no adverse effects on infants have been reported (World Health Organization, 1988). There is concern that these agents reduce the volume of breast milk, although data are limited (Truitt and colleagues, 2003). Alternatively, progestin-only oral contraceptives have little effect on lactation, provide excellent contraception, and thus may be preferred in women who are exclusively breast feeding their infants as subsequently discussed (p. 694).

Mood Changes. Low-dose estrogen formulations are not associated with depression or premenstrual mood changes, and indeed, may improve the latter (Joffe and associates, 2007). This is especially true with the drospirenone-containing COCs, *Yaz* and *Yasmin* (Bayer HealthCare, Wayne, NJ). Several studies have shown improvement in symptoms for women with premenstrual dysphoric disorder (PMDD) who use these (Lopez, 2009; Pearlstein, 2005; Yonkers, 2005, and all their associates, 2005). In fact, the FDA has approved indications to include treatment of premenstrual syndrome and moderate acne vulgaris for women requesting oral contraception.

Drospirenone is an analog of the aldosterone antagonist, spironolactone, and the dose of drospirenone in COCs currently marketed has properties similar to 25 mg of this diuretic (Seeger and co-workers, 2007). It displays antiandrogenic activity, and its antimineralocorticoid properties may, in theory, cause potassium retention, leading to hyperkalemia (Krattenmacher, 2000). Thus, drospirenone should not be prescribed for those with renal or adrenal insufficiency or with hepatic dysfunction. Moreover, monitoring of serum potassium levels is recommended in the first month for patients chronically treated concomitantly with any drug associated with potassium retention. These include nonsteroidal anti-inflammatory drugs

(NSAIDs), angiotensin-converting enzyme (ACE) inhibitors, angiotensin II antagonists, heparin, aldosterone antagonists, and potassium-sparing diuretics (Bayer HealthCare Pharmaceuticals, 2007b). All of this is recommended in the face of evidence that oral drospirenone in doses used in current COCs has no significant effect on serum potassium levels in patients with mild or moderate renal insufficiency (Schürmann and co-workers, 2006).

Infection. There are conflicting data concerning a role for COCs and episodic vulvovaginal candidiasis, although lower rates of bacterial vaginosis have been reported (Geiger and Foxman, 1996; Riggs and colleagues, 2007). Most but not all studies show increased rates of *Chlamydia trachomatis* infection in COC users, but not of *Neisseria gonorrhoeae* (Baeten and co-workers, 2001; Stuart and colleagues, 2003). Ness and co-workers (2001) found that COCs did not decrease the incidence of pelvic inflammatory disease but did modify its clinical severity. Some but not all studies suggest that COCs increase susceptibility to human immunodeficiency virus (HIV) infection and its progression (Baeten and associates, 2007a, b; Morrison and co-workers, 2007).

Other Effects. The progestin component of COCs reduces serum free testosterone levels and inhibits 5α-reductase to limit conversion of testosterone to its active metabolite, dihydrotestosterone. The estrogen component increases sex-hormone binding globulin (SHBG) production and also lowers circulating androgen levels. The expected results of these actions are to improve androgen-related conditions such as acne and hirsutism.

Hyperpigmentation of the face and forehead—chloasma—is more likely in women who demonstrated such a change during pregnancy. This is seen less commonly with the low-dose estrogen formulations. *Cervical mucorrhea,* likely due to cervical ectopy, is common in response to the estrogen component of COCs (Critchlow and colleagues, 1995). COCs may decrease formation of uterine *leiomyomas* in some women (Parazzini and co-workers, 1992). Although previously used for treating functional ovarian cysts, low-dose COCs have no effects (Grimes and colleagues, 2006b).

Transdermal Administration

The *Ortho Evra patch* (Ortho-McNeil Pharmaceutical, Raritan, NJ) has an inner layer containing an adhesive and hormone matrix, and a water-resistant outer layer. As a result, women can wear the patch in bathtubs, showers, swimming pools, saunas, and whirlpools without decreased efficacy. The patch may be applied to buttocks, upper outer arm, lower abdomen, or upper torso, but the breasts are avoided (Fig. 32-2). Because the hormones are combined with the adhesive, improper skin adherence will lower hormone absorption and efficacy. Therefore, if a patch is so poorly adhered that it requires reinforcement with tape, it should be replaced.

Initiation of the patch is the same as for COCs, and a new patch is applied weekly for 3 weeks, followed by a patch-free week to allow withdrawal bleeding. Although a patch is ideally worn no longer than 7 days, hormone levels remain in an effective range for up to 9 days, and this affords a 2-day window for patch change delays (Abrams and co-workers, 2001).

FIGURE 32-2 OrthoEvra transdermal contraceptive patch. (Courtesy of Ortho-McNeil Pharmaceuticals.)

Audet and co-workers (2001) found that the patch was slightly more effective than a low-dose oral contraceptive, with respective pregnancy rates 1.2 versus 2.2 pregnancies per 100 woman-years. Moreover, compliance appears to be improved compared with oral regimens (Dittrich and associates, 2002). In general, the patch shows a comparable side effect profile with COC pills. However, application-site reaction and breast tenderness are more frequent during initial cycles in patch wearers (Urdl and co-workers, 2005).

Obesity—90 kg or greater—may be associated with an increased risk for patch contraceptive failure (Zieman and associates, 2002). There is conflicting data that the patch has higher rates of venous thromboembolism (VTE) than COCs, and the package insert reflects these concerns. Specifically, studies by Jick and co-workers (2006a, b, 2007) have shown no increased rates of thromboembolism, ischemic stroke, or myocardial infarction. Conversely, Cole and associates (2007) reported a twofold increased rate of these three.

Summary for the Patch

For women who prefer weekly application rather than daily dosing, the patch provides an effective alternative hormonal contraceptive method. Candidates should weigh less than 90 kg and have no risk factors for cardiovascular disease and thromboembolism. Its other metabolic and physiological effects are substantively the same as for low-dose oral contraceptives, although the accumulated experience with the patch is small compared with that of COCs.

Transvaginal Administration

The *NuvaRing* (Organon USA, Roseland, NJ) is a flexible intravaginal hormonal contraceptive ring. Constructed of ethinyl vinyl acetate, the ring measures 54 mm in diameter and 4 mm in cross-section (Fig. 32-3). Its core contains ethinyl estradiol and the progestin, etonogestrel. These are released at rates of 15 μg and 120 μg per day, respectively and absorbed across the vaginal epithelium. Although this release results in systemic hormone levels lower than that from low-dose oral and patch

FIGURE 32-3 NuvaRing: estrogen-progestin-releasing vaginal contraceptive ring. (Courtesy of Organon, USA.)

contraceptive formulations, ovulation inhibition is complete (van den Heuvel and associates, 2005).

Before dispensing, the rings are refrigerated, and once dispensed, their shelf life is 4 months. The ring is placed within 5 days of menses onset and after 3 weeks of use, is removed for 1 week to allow withdrawal bleeding. Contraception will still be afforded if a ring is left in place for a fourth week. For rings left in place longer than 4 weeks, however, pregnancy should be excluded, a new ring placed, and alternative method used for 7 days (Organon USA, 2005).

Both usage compliance and contraceptive efficacy are comparable with that of COCs (Ahrendt and co-workers, 2006). Breakthrough bleeding is uncommon and appears less frequently than with pill use (Bjarnadóttir and colleagues, 2002). Patient satisfaction is high with this method, although vaginitis, ring-related events, and leukorrhea are more common (Oddsson and associates, 2005). Despite this, no deleterious affect on vaginal flora or on lower reproductive-tract or endometrial epithelia have been found (Bulten, 2005; Fraser, 2000; Veres, 2004, and their co-workers). Approximately 70 percent of partners report being able to feel the ring during intercourse (Dieben and colleagues, 2002). If this is bothersome, the ring may be removed for intercourse but should be replaced within 3 hours.

Intramuscular Administration

Lunelle is a contraceptive injection containing 25 mg of medroxyprogesterone acetate and 5 mg of estradiol cypionate. In 2002, prefilled Lunelle syringes were recalled by the manufacturer due to lack of assurance of full contraceptive potency. Although still FDA-approved, this method is no longer available in the United States.

Progestational Contraceptives

Oral Progestins

So-called *mini-pills* are progestin-only contraceptives that are taken daily. Unlike COCs, they do not reliably inhibit ovulation. Rather, their effectiveness depends more on alterations in cervical mucus and effects on the endometrium. Because mucus changes are not sustained longer than 24 hours, mini-pills should be taken at the same time every day to be maximally effective. These contraceptives have not achieved widespread popularity because of a much higher incidence of irregular bleeding and a somewhat higher pregnancy rate than COCs.

Benefits. Progestin-only pills have minimal if any effect on carbohydrate metabolism or coagulation, and they do not cause or exacerbate hypertension. They may be ideal for some women who are at increased risk of cardiovascular complications. Moreover, the mini-pill is often an excellent choice for lactating women. In combination with breast feeding, it is virtually 100-percent effective for up to 6 months and does not impair milk production.

Disadvantages. These contraceptives must be taken at about the same or nearly the same time each day. **If a progestin-only pill is taken even 4 hours late, a back-up form of contraception must be used for the next 48 hours.** And their effectiveness is decreased by the medications shown in Table 32-5. As with other hormonal contraceptive failures and pregnancy, there is a relative increase in the proportion of ectopic pregnancies (Sivin, 1991). Functional ovarian cysts develop with a greater frequency in women using these agents, although they do not usually necessitate intervention. Irregular uterine bleeding is another distinct disadvantage and may manifest as amenorrhea, metrorrhagia, or menorrhagia.

Contraindications. Progestin-only pills are contraindicated in women with unexplained uterine bleeding, known breast cancer, benign or malignant liver tumors, pregnancy, or acute liver disease (Ortho-McNeil Pharmaceutical, 2007).

Injectable Progestin Contraceptives

Both intramuscular depot medroxyprogesterone acetate (Depo-Provera), 150 mg every 3 months, and norethisterone enanthate (Norigest), 200 mg every 2 months, are injectable progestin contraceptives that have been effectively used worldwide for years. Depot medroxyprogesterone (DMPA) is injected into the deltoid or gluteus muscle without massage to ensure that the drug is released slowly. Alternatively, a subcutaneous version, *depo-SubQ provera 104,* is available and is injected into the subcutaneous tissue of the anterior thigh or abdomen every 3 months. This subcutaneous preparation contains 104 mg of DMPA, which is absorbed more slowly than the intramuscular formulation. Thus, even with a third less medication per dose, it maintains serum progestin levels sufficient to suppress ovulation for 3 months (Jain and associates, 2004). Currently, DMPA contraceptions are used in the United States by about 5 percent of women aged 18 to 44 who use contraception, and this method is particularly popular with adolescents (Mosher and co-workers, 2004).

The mechanisms of action are multiple and include ovulation inhibition, increased cervical mucus viscosity, and creation of an endometrium unfavorable for ovum implantation. Initial injection should begin within the first 5 days following menses onset. Therapeutic serum MPA levels sufficient to exert a consistent contraceptive effect are observed by 24 hours. Thus, no back-up contraceptive method is required if initiated within 5 days of

menses onset (Haider and Darney, 2007). DMPA is an effective method with perfect-use pregnancy rates of 0.3 percent (Said and co-workers, 1986). Typical-use failure rates, however, approximate 7 percent at 12 months (Kost and associates, 2008).

Benefits. Injected progestins offer the convenience of a 3-month dosing schedule, contraceptive effectiveness comparable with or better than COCs, and minimal to no lactation impairment (American College of Obstetricians and Gynecologists, 2000). Iron-deficiency anemia is less likely in long-term users because of amenorrhea, which develops after 5 years in 80 percent of women (Gardner and Mishell, 1970).

Disadvantages. The principal disadvantages of depot progestins include irregular menstrual bleeding and prolonged anovulation after discontinuation, which results in delayed fertility resumption. Cromer and associates (1994) reported that a fourth of women discontinued its use in the first year because of irregular bleeding. After injections are stopped, a fourth do not resume regular menses for up to 1 year (Gardner and Mishell, 1970).

Although DMPA use does not affect overall breast cancer risk, there is a small increased risk in recent or current users (Skegg and co-workers, 1995). Cervical and hepatic malignancy do not appear to be increased, and the risk of ovarian and endometrial cancers is decreased (Kaunitz, 1996; World Health Organization, 1991).

Weight gain is generally attributed to DMPA, although not all studies have found this effect (Bahamondes and co-workers, 2001; Moore and associates, 1995). Weight gain is comparable between the two depot forms (Westhoff and co-workers, 2007c). Breast tenderness is reported by some users, as is depression, although a causal link for the latter has not been demonstrated.

In long-term users, loss of bone mineral density (BMD) is a potential problem (Scholes and colleagues, 1999). In 2004, the FDA added a black box warning to DMPA labeling which notes that this concern is probably most relevant for adolescents, who are building bone mass, and perimenopausal women, who will soon have increased bone loss during menopause. It is the opinion of the World Health Organization (1998) and American College of Obstetricians and Gynecologists (2008) that DMPA should not be restricted in those high-risk groups. However, the overall risks and benefits for continuing use should be reevaluated over time (d'Arcangues, 2006). It is somewhat reassuring that bone loss appears to be reversible after discontinuation of therapy but is still not complete after 18 to 24 months (Clark and colleagues, 2006; Scholes and co-workers, 2002).

DMPA use has not been shown to increase the risk for thromboembolism, stroke, or cardiovascular disease. Still, prior thromboembolism is considered a contraindication to its use. Other contraindications to DMPA include pregnancy, undiagnosed vaginal bleeding, breast cancer, cerebrovascular disease, or significant liver disease (Pfizer, 2006, 2007).

Progestin Implants

Levonorgestrel Implants

The *Norplant System* (Wyeth-Ayerst) provides levonorgestrel in six silastic rods that are implanted subdermally. Despite the effectiveness, safety, and patient satisfaction with this contraceptive, its use waned dramatically in the United States after a flurry of litigation. The manufacturer stopped distributing the system in July 2002.

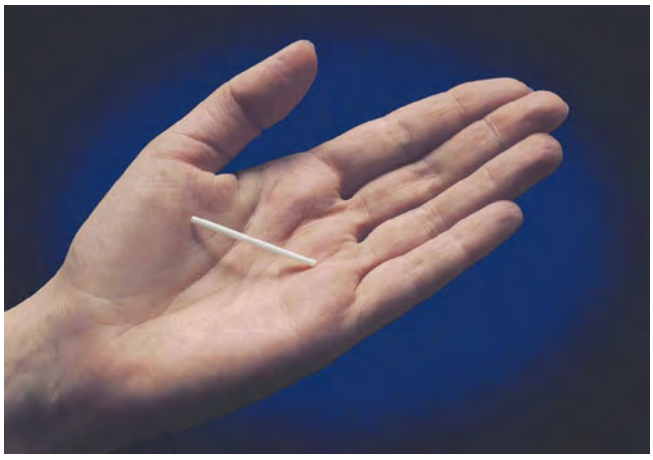

FIGURE 32-4 Implanon insert. (Courtesy of Organon, USA.)

Jadelle (Bayer Schering Pharma Oy, Turku, Finland), originally named Norplant-2, is a two-rod system similar to *Norplant*. It provides similar contraception for 3 years, but its two rods significantly shorten implant removal time (Sivin and co-workers, 2001). *Jadelle* has been approved for use, although it has not been marketed or distributed in the United States (Population Council, 2008).

Etonogestrel Implant

Approved by the FDA in 2006, *Implanon* (Organon, Roseland, NJ) is a single-rod subdermal implant with 68 mg of the progestin etonogestrel (ENG), and an ethylene vinyl acetate copolymer cover (Fig. 32-4). The implant is placed in the medial surface of the upper arm 6 to 8 cm from the elbow in the biceps groove within 5 days of onset of menses. It may be used as contraception for 3 years and then replaced at the same site or opposite arm.

Progestin is released continuously to suppress ovulation as the primary contraceptive action, although cervical mucus thickening and an atrophic endometrium add to its efficacy. Return of ovulation after implant removal is rapid. It is a highly effective method, and Croxatto and Mäkäräinen (1998) reported no pregnancies with its use during 53,530 cycles.

Implanon is not radiopaque, and a misplaced implant may be identified with sonography using a 10- to 15-MHz linear array transducer (Shulman and Gabriel, 2006). In some cases, magnetic resonance imaging may be required (Merki-Feld and associates, 2001).

Weight gain is neither a prominent side effect nor a common reason for implant discontinuation (Funk and co-workers, 2005). The ENG implant does not significantly affect bone mineral density, lipid profile, or liver enzymes (Beerthuizen and associates, 2000; Biswas and co-workers, 2003, 2004). The most frequently reported adverse event leading to removal was prolonged and frequent bleeding (Bitzer and colleagues, 2004). Contraindications for ENG implant use are those for DMPA.

INTRAUTERINE DEVICE (IUD)

In the United States, many are of the opinion that the intrauterine device (IUD) is an underused contraceptive. Although only about 1 percent of reproductive-aged women in the United States use this method, IUDs are the most commonly used method of reversible contraception worldwide (Chandra and colleagues, 2005; d'Arcanques, 2007).

Types of Intrauterine Devices

Devices that are *chemically inert* are composed of a nonabsorbable material, most often polyethylene, and impregnated with barium sulfate for radiopacity. Those that are *chemically active* have continuous elution of copper or a progestin. Currently, only chemically active IUDs are available in the United States. Most IUDs are described as *framed*, that is, formed as a rigid structure. *Frameless* IUDs have higher expulsion rates and are not used in the United States. They contain bracelets of copper that are crimped onto a string and affixed to the fundal myometrium (O'Brien and Marfleet, 2005).

The two chemically active IUDs currently approved for use in the United States include a progestin-releasing device (*Mirena*, Bayer HealthCare Pharmaceuticals, Wayne, NJ). It releases levonorgestrel into the uterus at a relatively constant rate of 20 μg/day, which reduces systemic effects. It has a T-shaped radiopaque frame, whose stem is wrapped with a cylinder reservoir, composed of a polydimethylsiloxane-levonorgestrel mixture. There are two trailing brown strings attached to the stem.

The second device is the T 380A IUD (*ParaGard*, Duramed Pharmaceuticals, Pomona, NY). It is a polyethylene and barium sulfate, T-shaped frame wound with copper. Specifically, 314 mm^2 of fine copper wire wrap the stem, and the arms each have 33-mm^2 copper bracelets, thus totaling 380 mm^2 of copper. Two strings extend from the base of the stem. Originally blue, the strings are now white.

Changing IUD Perceptions

With new information on safety, the IUD is once again gaining in popularity for several reasons:

1. IUDs are "use and forget" effective reversible contraceptive methods that do not have to be replaced for 10 years with the *ParaGard* and for 5 years with the *Mirena*
2. It is now better established that the major actions of IUDs are contraceptive, not abortifacient
3. The risk of pelvic infections is markedly reduced with the currently used monofilament string and with techniques to ensure safer insertion
4. The risk of an associated ectopic pregnancy has been clarified. Specifically, the contraceptive effect decreases the absolute number of ectopic pregnancies by approximately 50 percent compared with that of women not using contraception (World Health Organization, 1985, 1987). With failure, however, pregnancy is more likely to be ectopic (Furlong, 2002)
5. Legal liability appears to be less because the FDA currently classifies IUDs as drugs (Mishell and Sulak, 1997). As such, the manufacturers must provide product information to be read by women prior to insertion (Bayer HealthCare Pharmaceuticals, 2007a; Duramed Pharmaceuticals, 2006). Signed consent forms that include a list of risks and benefits are also required.

Efficacy

These two types of IUDs are effective contraceptives, and their ability to prevent pregnancy is similar overall to that of tubal sterilization (American College of Obstetricians and Gynecologists, 2003). Importantly, pregnancy rates decrease progressively after the first year of use (Vessey and associates, 1983). For example, the levonorgestrel intrauterine system (LNG-IUS) has a typical-user failure rate of 0.1 percent after 1 year of use, and a <0.5-percent cumulative pregnancy rate by 5 years. This is lower than that of the copper-containing ParaGard with a 1-year rate of 0.8 percent and 5-year rates of 0.3 to 0.6 percent (Thonneau and Almont, 2008; Trussell, 2004). Finally, IUDs have 1-year continuation rates of 80 percent, which is slightly greater than that of 70 percent for oral contraceptives.

Contraceptive Action

These mechanisms have not been precisely defined and are a subject of ongoing debate. At one time, interference with successful implantation of the fertilized ovum was believed to be the main mode of IUD action but now is considered less important than its prevention of fertilization (Stanford and Mikolajczyk, 2002).

Within the uterus, an intense local endometrial inflammatory response is induced, especially by copper-containing devices. Cellular and humoral components of this inflammation are expressed in endometrial tissue and in fluid filling the uterine cavity and fallopian tubes. These lead to decreased sperm and egg viability (Ortiz and Croxatto, 2007). In the unlikely event that fertilization does occur, the same inflammatory actions are directed against the blastocyst, and the endometrium is transformed into a hostile site for implantation. With copper IUD, copper levels increase in the mucus of users and lower sperm motility and viability (Jecht and Bernstein, 1973).

With the LNG-IUS, in addition to an inflammatory reaction, progestin release in long-time users causes glandular atrophy and stromal decidualization. Moreover, progestins create scant viscous cervical mucus that hinders sperm motility. The LNG-IUS may also inconsistently release sufficient progestin to inhibit ovulation.

Other Beneficial Effects

Despite higher up-front costs of IUDs, their extended use makes their long-term cost-effectiveness competitive with or superior to other contraceptives (Trussell and co-workers, 2009). Many women with contraindications to COCs can often use these devices. These are quickly reversible method of contraception, and fertility is not impaired (Hov and associates, 2007). There is no increased risk of genital tract or breast neoplasia, and both IUDs are associated with a decreased risk of endometrial cancer (Curtis, 2007; Backman, 2005; Beining, 2008, and all their colleagues). Lastly, the LNG-IUS produces lower

systemic progestin levels compared with DMPA, and thus, bone mineral density losses and weight gain are avoided (Bahamondes and colleagues, 2006; Yela and co-workers, 2006).

Adverse Effects

Adverse effects from IUDs include abnormal uterine bleeding, dysmenorrhea, expulsion, or uterine perforation. With extended use and advancing user age, however, pregnancy, expulsion, and bleeding complications decrease in frequency. Functional ovarian cysts are more frequent in the early months of LNG-IUS use but typically resolve spontaneously (Inki and associates, 2002).

Uterine Perforation

Clinically apparent or silent *uterine perforation* may occur while inserting a uterine sound or during IUD insertion. Rates approximate 1 per 1000 insertions (Harrison-Woolrych and associates, 2003). Although devices may migrate spontaneously into and through the uterine wall, most perforations occur, or at least begin, at the time of insertion. Some have found that IUD perforation, rotation, or embedding may cause excessive bleeding (Faundes and colleagues, 1997; Pizarro and associates, 1989). Evaluation of perforation is discussed subsequently**.** Another adverse effect is *abortion of an unsuspected pregnancy* following insertion, but a urine pregnancy test prior to insertion will obviate this. The frequency of both complications depends on operator skill and the precautions taken to detect pregnancy.

Expulsion

Loss of an IUD from the uterus is most common during the first month. Thus, these women should be examined about 1 month following insertion, usually after menses, to identify the tail trailing from the cervix. Barrier contraception may be desirable during this first month, especially if a device has been expelled previously. Following this, a woman should be instructed to palpate the strings protruding from the cervix each month after menses.

Lost Device

When the tail of an IUD cannot be visualized, the device may have been expelled, or it may have perforated the uterus. In either event, pregnancy is possible. Conversely, the IUD tail simply may be in the uterine cavity along with a normally positioned device. After excluding pregnancy, the uterine cavity is probed gently with a Randall stone clamp or with a specialized rod with a terminal hook to retrieve the string. **Never assume that the device has been expelled unless it was seen.**

When the tail is not visible, and the device is not felt by gentle probing of the uterine cavity, sonography can be used to ascertain if the device is within the uterus. If inconclusive or if no device is seen, then a plain radiograph of the abdomen and pelvis is taken with a sound inserted into the uterine cavity. Computed tomography (CT) scanning, MR imaging, and hysteroscopy are yet other alternatives (Peri and colleagues, 2007). It is safe to perform MR imaging at 1.5 tesla (T) with an IUD in place (Pasquale and associates, 1997). Moreover, at 3 T, it also appears to be safe with copper IUDs (Zieman and Kanal, 2007).

A device may penetrate the muscular uterine wall to varying degrees. Part of the device may extend into the peritoneal cavity, or part may remain firmly fixed in the myometrium, usually running parallel to the long axis of the uterus. It may penetrate into the cervix and actually protrude into the vagina. If located outside the uterus, a device of inert material, such as the Lippes Loop, may or may not cause harm. Chemically inert devices usually are removed easily from the peritoneal cavity by laparoscopy or colpotomy. An extrauterine copper-bearing device induces an intense local inflammatory reaction and adhesions. Thus, copper-bearing devices are more firmly adhered, and laparotomy may be necessary. Perforations of large and small bowel and bowel fistulas, with attendant morbidity, have been reported remote from insertion.

Cramping and Bleeding

Discomfort with insertion may stem from difficult uterine sounding or cervical stenosis, especially in nulliparas. If problematic, cervical softening typically follows use of misoprostol, 400 μg sublingually 1 to 3 hours prior to insertion (Sääv and associates, 2007). *Cramping* and some *bleeding* are common soon after insertion. Cramping is minimized by administering an NSAID an hour prior to insertion.

Menorrhagia

The amount of menstrual bleeding is commonly increased with use of the copper IUD. As this may cause iron-deficiency anemia, iron supplementation is given, and hemoglobin concentration or hematocrit is measured annually. Menorrhagia can be troubling, and up to 15 percent of women have the copper device removed because of this (Hatcher and associates, 1998). NSAIDs reduce bleeding and are considered first-line therapy for this (Grimes and associates, 2006a). In contrast, the LNG-IUS is associated with progressive amenorrhea, which is reported by a third of users after 2 years and by 60 percent after 12 years (Ronnerdag and Odlind, 1999).

Infection

The device-related risk of infection is increased only during the first 20 days following insertion (Farley and associates, 1992). Antimicrobial prophylaxis confers little benefit and is not recommended with insertion (Grimes and Schulz, 2001a; Walsh and colleagues, 1998). Moreover, the American Heart Association does not recommend infective endocarditis prophylaxis with insertion (Wilson and co-workers, 2007).

Fortunately, infection risk is not increased with long-term IUD use. Correspondingly, IUDs appear to cause little, if any, increase in the risk of infertility from infection among women at low risk for sexually transmitted infections (Hubacher and colleagues, 2001). For these reasons, the American College of Obstetricians and Gynecologists (2005b, 2007b) recommends that women who are at low risk for sexually transmitted diseases, including adolescents, are good candidates for IUDs.

Pelvic infection that does develop in a woman with an IUD may be of several forms. *Septic abortion* mandates immediate curettage. *Tubo-ovarian abscesses*—sometimes unilateral—have

been reported and are treated aggressively. With suspected infection, the IUD should be removed.

Actinomyces Infection

Actinomyces israelii is a gram-positive, slow-growing, anaerobic bacterium that rarely leads to infection and abscess. It is found to be part of the indigenous genital flora of healthy women (Persson and Holmberg, 1984). Some have found it more frequently in the vaginal flora of IUD users, and rates of colonization increase with duration of IUD use (Curtis and Pine, 1981). *Actinomyces* is also identified in Papanicolaou smears, and Fiorino (1996) cited a 7-percent incidence in IUD users compared with less than 1 percent in nonusers.

In the absence of symptoms, the incidental finding of *Actinomyces* on cytology is problematic. First, infection is rare, even in those identified to harbor the bacteria. Reviews by Lippes (1999) and Westhoff (2007a) suggest that asymptomatic women may retain their IUD and do not require antibiotic treatment. The American College of Obstetricians and Gynecologists (2005b) lists four management options for asymptomatic women:

1. Expectant management
2. Extended oral antibiotic treatment with the IUD in place
3. IUD removal
4. IUD removal followed by antibiotic treatment.

Importantly, if signs or symptoms of infection develop in women who harbor *Actinomyces*, the device should be removed and antimicrobial therapy instituted. Early findings include fever, weight loss, abdominal pain, and abnormal vaginal bleeding or discharge. *Actinomyces* is sensitive to antimicrobials with gram-positive coverage, notably the penicillins.

Pregnancy with an IUD

It is important to identify women who become pregnant while using an IUD. Until about 14 weeks, the tail may be visible through the cervix, and if seen, it should be removed. This action reduces subsequent complications such as late abortion, sepsis, and preterm birth (Alvior, 1973). Tatum and co-workers (1976) reported an abortion rate of 54 percent with the device left in place compared with a rate of 25 percent if it was promptly removed.

If the tail is not visible, attempts to locate and remove the device may result in abortion. However, some practitioners have successfully used sonography to assist in the removal of devices without visible strings (Schiesser and co-workers, 2004). After fetal viability is reached, it is unclear whether it is better to remove an IUD whose string is visible and accessible or leave it in place. There is no evidence that fetal malformations are increased with a device in place (Tatum and associates, 1976).

Second-trimester abortion with an IUD in place is more likely to be infected (Vessey and associates, 1974). *Sepsis may be fulminant and fatal.* Pregnant women with a device in utero who demonstrate any evidence of pelvic infection are treated with intensive antimicrobial therapy and prompt uterine evacuation. Because of these risks, a woman should be given the option of early pregnancy termination if the device cannot be removed. In women who give birth with a device in place, appropriate steps should be taken at delivery to identify the IUD and to remove it.

TABLE 32-8. Contraindications to Use of an Intrauterine Device (IUD)

General:

1. Pregnancy or suspicion of pregnancy
2. Abnormalities of the uterus resulting in distortion of the uterine cavity
3. Acute pelvic inflammatory disease or a history of pelvic inflammatory disease unless there has been a subsequent uterine pregnancy
4. Postpartum endometritis or infected abortion in the past 3 months
5. Known or suspected uterine or cervical neoplasia, or unresolved abnormal cytological smear
6. Genital bleeding of unknown etiology
7. Untreated acute cervicitis or vaginitis, including bacterial vaginosis, until infection is controlled
8. Woman or her partner has multiple sexual partners
9. Conditions associated with increased susceptibility to infections with microorganisms—these include but are not limited to leukemia, acquired immune deficiency syndrome (AIDS), and intravenous drug abuse
10. History of ectopic pregnancy or condition that would predispose to ectopic pregnancy
11. Genital actinomycosis
12. A previously inserted IUD that has not been removed

Additionally, the ParaGard T 380A® (because of its copper content) should not be inserted when one or more of the following conditions exist:

1. Wilson disease
2. Copper allergy

Additionally, Mirena® insertion is contraindicated when one or more of the following conditions exist:

1. Hypersensitivity to any component of this product
2. Known or suspected carcinoma of the breast
3. Acute liver disease or tumor

Modified from Physicians Desk Reference, 2009.

Contraindications

Shown in Table 32-8 are manufacturers' contraindications to IUD use. Because levonorgestrel released by the LNG-IUS may inhibit tubal mobility, a previous ectopic pregnancy or other predisposing risk factors are additional contraindications. The IUD is safe and effective in HIV-infected women and may be used in other selected immunosuppressed women such as those with systemic lupus erythematosus (American College of Obstetricians and Gynecologists, 2006; Stringer and co-workers, 2007).

Insertion

Timing of insertion influences the ease of placement as well as pregnancy and expulsion rates. Insertion near the end of normal

menstruation, when the cervix is usually softer and somewhat more dilated, may be easier, and at the same time may exclude early pregnancy. But insertion is not limited to this time. For the woman who is sure she is not pregnant and does not want to be pregnant, insertion is done at any time.

Immediate postpartum insertion is practiced in some areas. Grimes and colleagues (2001b) concluded that it is safe to do so, however, the expulsion rate and possibly pregnancy rates are higher than with later insertion. The recommendation has been made, therefore, to wait for at least 6 to 8 weeks after delivery to reduce expulsion rates and to minimize the risk of perforation. Women delivered at Parkland Hospital are seen 3 weeks' postpartum, and IUDs are inserted 6 weeks' postpartum or sooner if involution is complete. After early miscarriage or abortion, the device may be inserted immediately.

Before insertion, several procedural steps are carried out. Any contraindications are identified, and if none, then the woman is counseled and written consent obtained. An oral NSAID, with or without codeine, can be used to allay cramps. Misoprostol, 400 μg sublingually, may soften a rigid or stenotic cervix. Bimanual pelvic examination is performed to identify the position and size of the uterus. Abnormalities are evaluated as they may contraindicate insertion. Mucopurulent cervicitis or significant vaginitis should be appropriately treated and resolved before insertion.

The cervical surface is cleansed with an antiseptic solution, and sterile instruments and a sterile device should be used. A tenaculum is placed on the cervical lip, and the canal and uterine cavity are straightened by applying gentle traction. The uterus is then sounded to identify the direction and depth of the uterine cavity. Specific steps of ParaGard and Mirena insertion are shown in **Figures 32-5** and **32-6** and outlined in their respective package inserts, available at: http://www.paragard.com/custom_images/ppi_eng.pdf and http://berlex.bayerhealthcare.com/html/products/pi/Mirena_PI.pdf?C = &c.

Following insertion, only the threads should be visible trailing from the cervix. These are trimmed to allow 3 to 4 cm to protrude into the vagina and their length is recorded. If there is suspicion that the device is not in the correct position, then placement should be confirmed, using sonography if necessary. If the IUD is not positioned completely within the uterus, it is removed and replaced with a new device. An expelled or partially expelled device should not be reinserted.

BARRIER METHODS

For many years, condoms, vaginal spermicidal agents, and vaginal diaphragms have been used for contraception with variable success (see Table 32-2).

Male Condom

These long-available products provide effective contraception, and their failure rate with strongly motivated couples has been as low as 3 or 4 per 100 couple-years of exposure (Vessey and co-workers, 1982). Generally, and during the first year of use especially, the failure rate is much higher. The contraceptive effectiveness of the male condom is enhanced appreciably by a reservoir tip and probably by the addition of spermicidal lubricant. The contraceptive effectiveness is further improved by use of an intravaginal spermicidal agent. Such agents, as well as those used for lubrication, should be water-based. Oil-based products destroy latex condoms and diaphragms.

Speroff and Darney (2001) emphasize the following key steps to ensure maximal condom effectiveness:

1. A condom must be used with every coital act
2. It should be in place before contact of the penis with the vagina
3. Withdrawal must occur with the penis still erect
4. The base of the condom must be held during withdrawal
5. Either an intravaginal spermicide or a condom lubricated with spermicide should be employed.

Infection Prevention

When used properly, condoms provide considerable but not absolute protection against a broad range of sexually transmitted diseases. These include HIV, gonorrhea, syphilis, herpes, chlamydia, and trichomoniasis. There is also decreased risk for bacterial vaginosis (Hutchinson and co-workers, 2007). Condoms also may prevent and ameliorate premalignant cervical changes, presumably by blocking transmission of human papillomavirus (Manhart and Koutsky, 2002; Winer and colleagues, 2006).

Latex Sensitivity

For individuals sensitive to latex, condoms made from lamb intestines are effective, but they do not provide protection against infection. Fortunately, nonallergenic condoms have been developed and are comprised of polyurethane or of synthetic elastomers. Polyurethane condoms are effective against sexually transmitted diseases but have a higher breakage and slippage rate than latex condoms (Gallo and co-workers, 2006). In a randomized trial of 901 couples, Steiner and colleagues (2003) documented breakage and slippage at 8.4 percent with polyurethane condoms compared with 3.2 percent with latex condoms. Respective 6-month typical pregnancy probabilities were 9.0 compared with 5.4 percent.

Female Condom (Vaginal Pouch)

The only female condom available is marketed as the *FC Female Condom* (The Female Health Company, Chicago, IL). It is a polyurethane sheath with one flexible polyurethane ring at each end. The open ring remains outside the vagina, and the closed internal ring is fitted under the symphysis like a diaphragm (**Fig. 32-7**). The female condom can be used with both water-based and oil-based lubricants. Male condoms should not be used concurrently because simultaneous use may cause friction that leads to condom slipping, tearing, and displacement. Following use, the female condom outer ring should be twisted to seal the condom so that no semen spills out.

The female condom has an acceptability rate of about 60 percent for women and 80 percent for men. However, the pregnancy rate is higher than with the male condom (see Table 32-2). The female condom has a 0.6-percent breakage rate. The slippage and displacement rate is about 3 percent compared with 3 to 8 percent for male condoms. In vitro tests have shown the condom to be impermeable to HIV, cytomegalovirus, and hepatitis B virus.

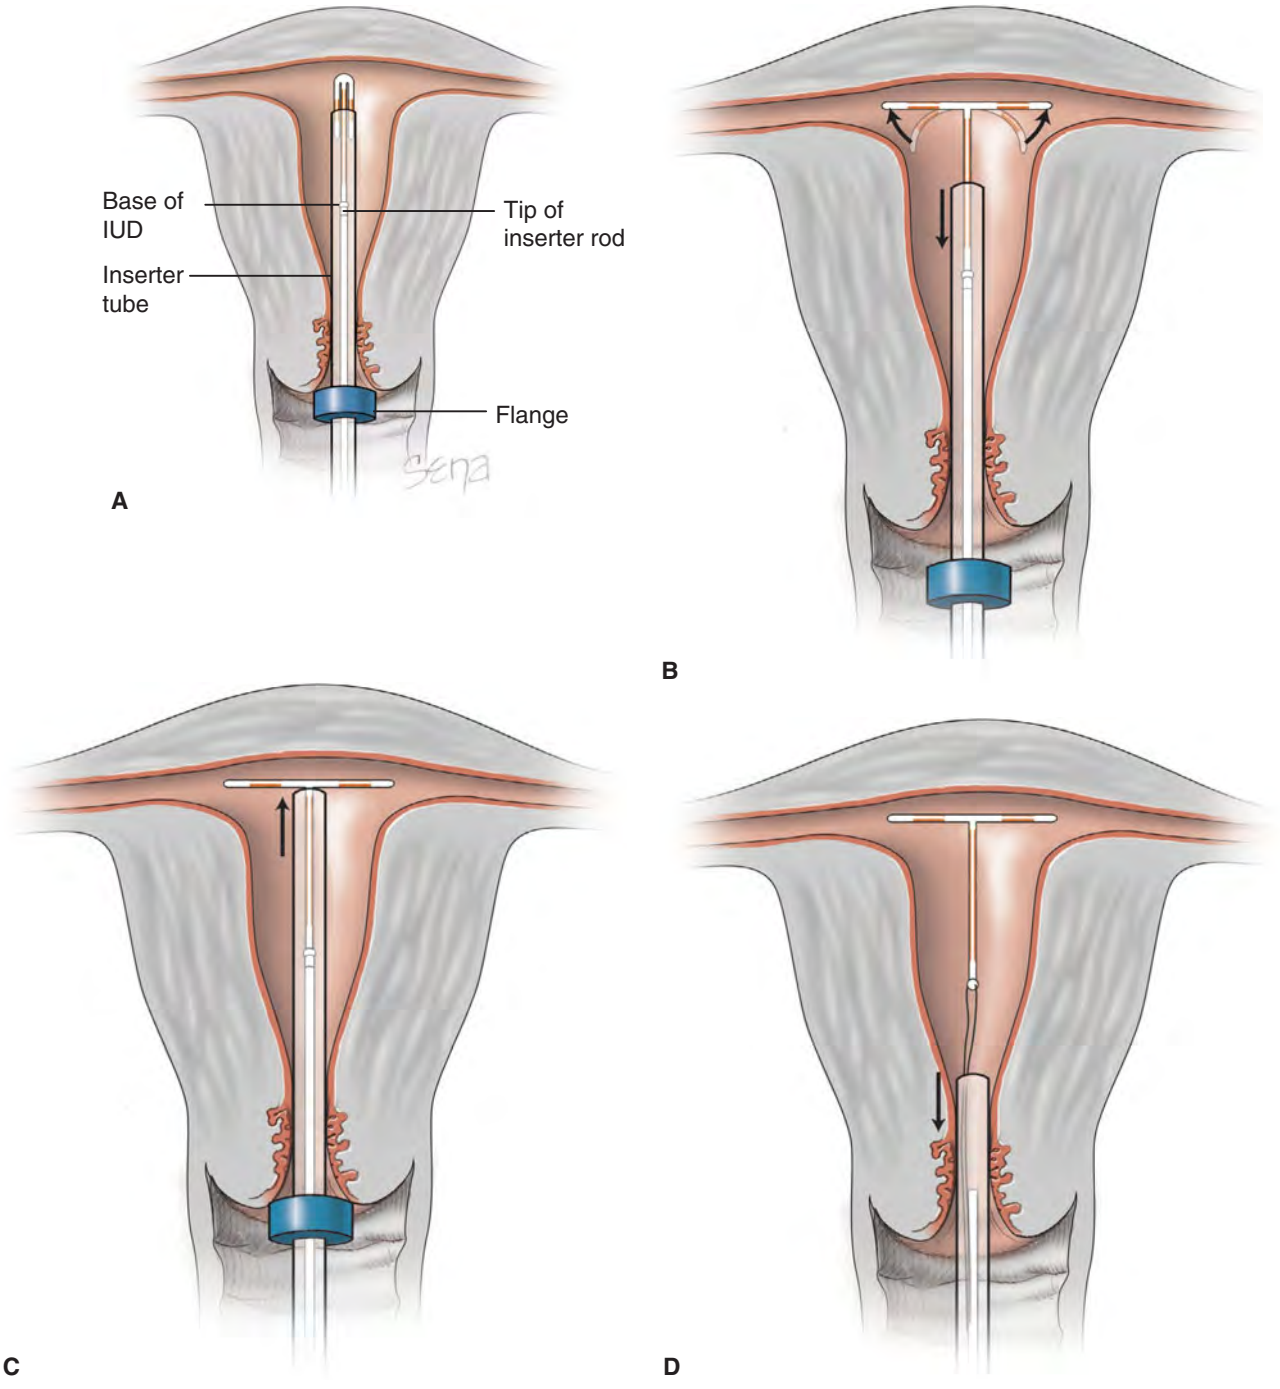

FIGURE 32-5 Insertion of ParaGard T 380A. The uterus is sounded, and the IUD is loaded into its inserter tube not more than 5 minutes before insertion. A blue plastic flange on the outside of the inserter tube is positioned from the IUD tip to reflect this depth. The IUD arms should lie in the same plane as the flat portion of the blue flange. **A.** The inserter tube, with the IUD loaded, is passed into the endometrial cavity. A long, solid, white inserter rod abuts the base of the IUD. When the blue flange contacts the cervix, insertion stops. **B.** To release the IUD arms, the solid white rod within the inserter tube is held steady, while the inserter tube is withdrawn no more than 1 cm. **C.** The inserter tube, not the inserter rod, is then carefully moved upward toward the top of the uterus until slight resistance is felt. At no time during insertion is the inserter rod advanced forward. **D.** First, the solid white rod and then the inserter tube are withdrawn individually. At completion, only the threads should be visible protruding from the cervix. These are trimmed to allow 3 to 4 cm to extend into the vagina.

Spermicides

These contraceptives are marketed variously as creams, jellies, suppositories, films, and aerosol foam. They are used widely in the United States, especially by women who find other methods unacceptable. They are useful especially for women who need temporary protection, for example, during the first week after starting oral contraceptives or while nursing. Most agents can be purchased without a prescription.

Typically, spermicides function by providing a physical barrier to sperm penetration as well as a chemical spermicidal action. The active ingredient is nonoxynol-9 or octoxynol-9.

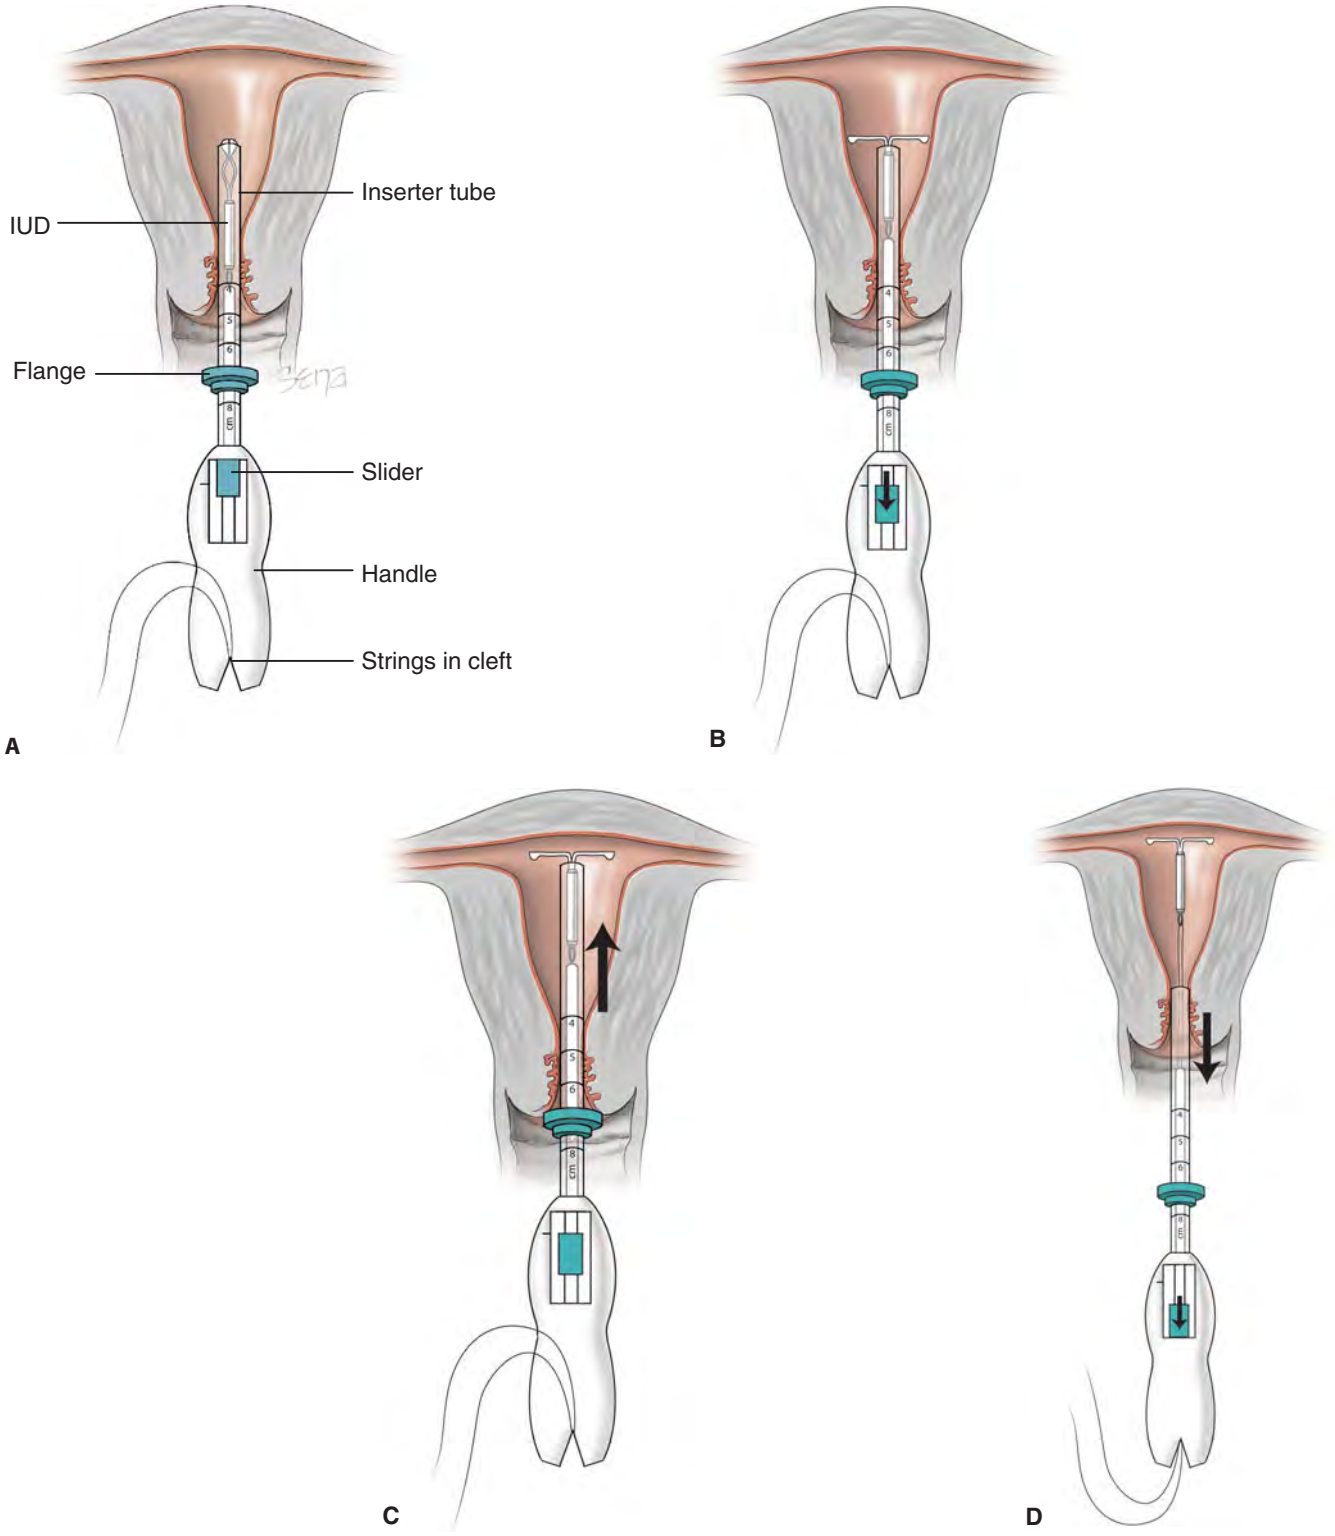

FIGURE 32-6 Insertion of the Mirena intrauterine system. Initially, threads from behind the slider are first released to hang freely. The slider found on the handle should be positioned at the top of the handle nearest the device. The IUD arms are oriented horizontally. A flange on the outside of the inserter tube is positioned from the IUD tip to reflect the depth found with uterine sounding. **A.** As both free threads are pulled, the Mirena IUD is drawn into the inserter tube. The threads are then tightly fixed from below into the handle's cleft. In these depictions, the inserter tube has been foreshortened. The inserter tube is gently inserted into the uterus until the flange lies 1.5 to 2 cm from the external cervical os to allow the arms to open. **B.** While holding the inserter steady, the IUD arms are released by pulling the slider back to reach the raised horizontal mark on the handle but no further. **C.** The inserter is then gently guided into the uterine cavity until its flange touches the cervix. **D.** The device is released by holding the inserter firmly in position, and pulling the slider down all the way. The threads will be released automatically from the cleft. The inserter may then be removed and IUD strings trimmed.

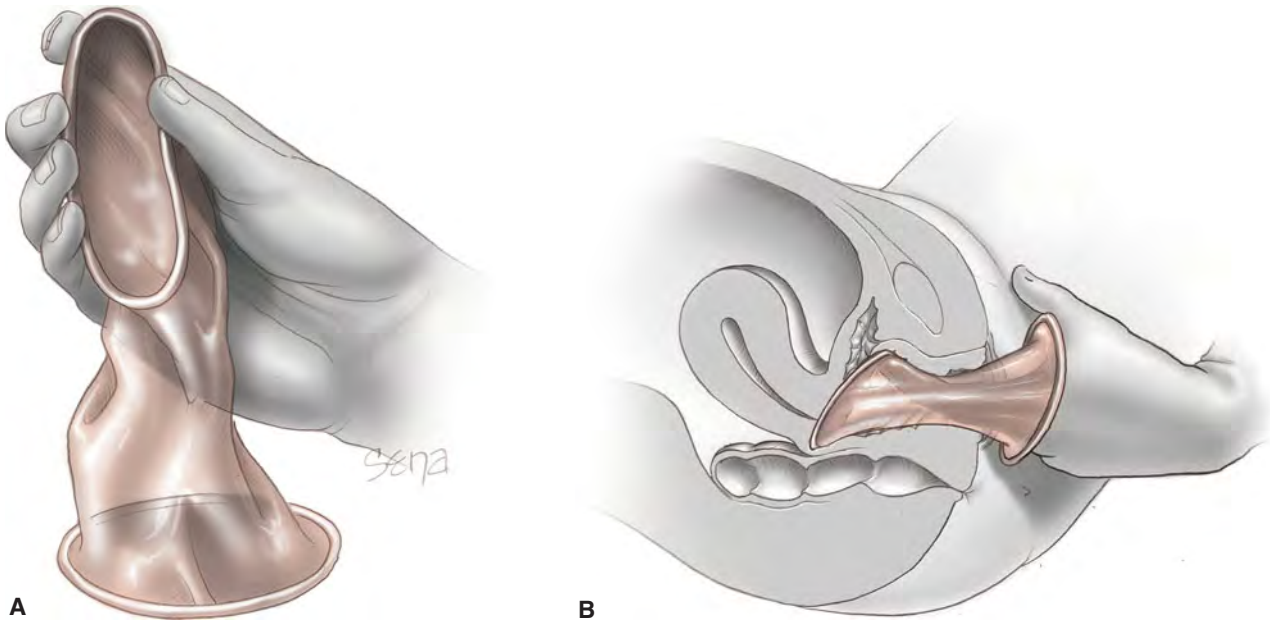

FIGURE 32-7 FC female condom insertion and positioning. **A.** The inner ring is squeezed for insertion. The sheath is inserted similarly to a diaphragm. **B.** The inner ring is pushed inward with an index finger.

Spermicides must be deposited high in the vagina in contact with the cervix shortly before intercourse. Their duration of maximal effectiveness is usually no more than 1 hour. Thereafter, they must be reinserted before repeat intercourse. Douching should be avoided for at least 6 hours after intercourse. High pregnancy rates are primarily attributable to inconsistent use rather than to method failure. Even if inserted regularly and correctly, however, foam preparations probably result in 5 to 12 pregnancies per 100 woman-years of use. They are not teratogenic (Briggs and colleagues, 2005).

Nonoxynol-9 does not provide protection against sexually transmitted infections. There is currently much interest in combination spermicides/microbicides, which are female-controlled contraceptives that can also protect against sexually transmitted diseases, including HIV infection (D'Cruz and Ucken, 2004; Palliser and colleagues, 2006).

Diaphragm Plus Spermicide

The diaphragm consists of a circular latex dome of various diameters supported by a circumferential latex-covered metal spring. It is effective when used in combination with spermicidal jelly or cream. The spermicide is applied into the dome cup and along the rim. The device is then positioned so that the cup faces the cervix and that the cervix, vaginal fornices, and anterior vaginal wall are partitioned effectively from the remainder of the vagina and the penis. In this fashion, the centrally placed spermicidal agent is held against the cervix. When appropriately positioned, one rim is lodged deep in the posterior vaginal fornix, and the opposite rim fits behind the inner surface of the symphysis and immediately below the urethra (Fig. 32-8). If a diaphragm is too small, it will not remain in place. If it is too large, it is uncomfortable when forced into position. A cystocele or uterine prolapse typically leads to instability and expulsion. Because size and spring flexibility must be individualized, the diaphragm is available only by prescription.

With use, the diaphragm and spermicidal agent can be inserted hours before intercourse, but if more than 6 hours elapse, additional spermicide should be placed in the upper vagina for

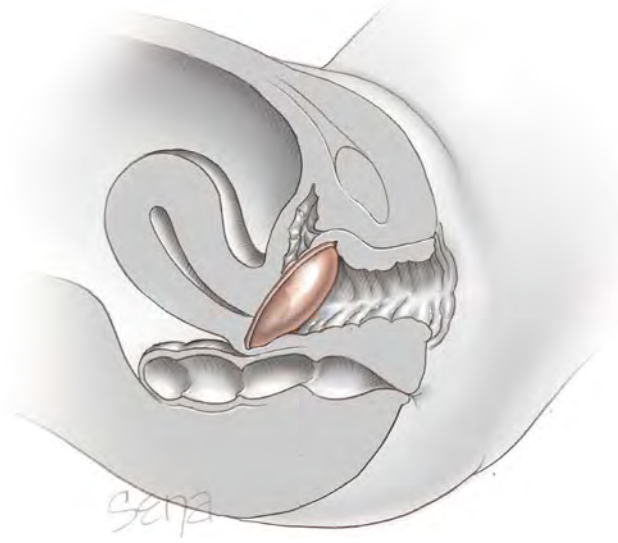

FIGURE 32-8 A diaphragm in place creates a physical barrier between the vagina and cervix.

maximum protection and be reapplied before each coital episode. The diaphragm should not be removed for at least 6 hours after intercourse. Because *toxic shock syndrome* has been described following its use, it may be worthwhile to remove the diaphragm at 6 hours, or at least the next morning, to minimize this uncommon event (see Chap. 31, p. 670). Diaphragm use results in a lower incidence of sexually transmitted diseases compared with condom use (Rosenberg and colleagues, 1992). Conversely, diaphragm use is associated with a slight increase in the rate of urinary infections, presumably from urethral irritation by the ring under the symphysis.

The diaphragm requires a high level of motivation for proper use. Vessey and colleagues (1982) reported a pregnancy rate of only 1.9 to 2.4 per 100 woman-years for motivated users. The unintended pregnancy rate is lower in women older than 35 years than that in those younger than 30.

Contraceptive Sponge

The Today contraceptive sponge (Synova Healthcare, Media, PA) was removed from the market in 1995 because of production modification cost increases. Since 2005, it is again available, from a new manufacturer, as an over-the-counter, one-size-fits-all device. The nonoxynol-9–impregnated polyurethane disc is 2.5 cm thick and 5.5 cm wide, and it has a dimple on one side and satin loop on the other (**Fig. 32-9**). The sponge is moistened with tap water and gently squeezed to create light suds. It is then positioned with the dimple placed directly against the cervix. The sponge can be inserted for up to 24 hours prior to intercourse, and while in place, it provides contraception regardless of coital frequency. It should remain in place for 6 hours after intercourse. Pregnancy is prevented primarily by the spermicide nonoxynol-9 and to a lesser extent, by covering the cervix and absorbing semen.

Although the sponge is possibly more convenient than the diaphragm or condom, it is less effective than either, as seen in Table 32-2 (Kuyoh and co-workers, 2003). Most common causes for method discontinuance are pregnancy, irritation, discomfort, or vaginitis (Beckman and associates, 1989). As discussed in Chapter 31 (p. 670), toxic shock syndrome (TSS) has been reported with the contraceptive sponge. The risk of toxic shock is rare, and there is evidence that the sponge may limit production of the responsible staphylococcal exotoxin (Remington and associates, 1987). Still, it is recommended that the sponge not be used during menses or the puerperium.

FIGURE 32-9 Today sponge.

FIGURE 32-10 Lea's Shield. (Used with permission from the Cervical Barrier Advancement Society and Ibis Reproductive Health.)

Cervical Cap

The *Prentif* cavity-rim cervical cap was approved for use by the FDA in 1988. The flexible, cup-like device is made of natural rubber and is fitted around the base of the cervix. It can be self-inserted and allowed to remain in place for up to 48 hours. It should be used with a spermicide applied once at insertion. If properly fitted and used correctly, the cap is comparable in effectiveness to the diaphragm (Richwald and colleagues, 1989). The cervical cap is relatively costly, and overall, incorrect fitting and/or improper placement make it less effective than the diaphragm plus spermicide (see Table 32-2).

Lea's Shield

Lea's Shield (Yama, Inc., Union, NJ) is a reusable, washable barrier made of silicone, which is placed against the cervix (**Fig. 32-10**). The device comes in one size, which simplifies the fitting process. It may be inserted any time prior to intercourse and must be left in place for at least 8 hours afterwards. When used with spermicide, and adjusted for age, the reported 6-month life-table pregnancy rate was 5.6 per 100 users (Mauck and associates, 1996).

FERTILITY AWARENESS-BASED METHODS

This form of contraception includes all family planning methods that attempt to identify fertile time each cycle and then modify sexual behavior. When fertility awareness-based (FAB) methods involve sexual abstinence during the fertile time, this technique is called *natural family planning—NFP*. When these

methods involve occasionally using a barrier method during the fertile time, the method is called *fertility awareness-combined methods—FACM* (Jennings and colleagues, 2004).

Because the ovum is probably susceptible to successful fertilization for only 12 to 24 hours after ovulation, periodic abstinence has intuitive appeal as a means of birth control. Pregnancy rates, however, with various methods of periodic abstinence have been estimated from 5 to 40 per 100 woman-years (Population Reports, 1981). In other words, the unwanted pregnancy rate during the first year of use is approximately 20 percent (see Table 32-2).

Standard Days Method

This method was developed by the Institute for Reproductive Health at Georgetown University. Its users avoid unprotected intercourse during cycle days 8 through 19. For successful use, women must have regular monthly cycles of 26 to 32 days. Those who use the *standard days method* can use *CycleBeads* (Cycle Technologies, Washington, DC) to keep track of their days.

Calendar Rhythm Method

This method requires counting the number of days in the shortest and longest menstrual cycle during a 6- to 12-month span. From the shortest cycle, 18 days are subtracted to calculate the first fertile day. From the longest cycle, 11 days are subtracted to identify the last fertile day. This is problematic because ovulation most often occurs 14 days before the onset of the next menses. Because this is not necessarily 14 days *after* the onset of the last menses, the *calendar rhythm method* is not reliable.

Temperature Rhythm Method

This method relies on *slight* changes—sustained 0.4 degree Fahrenheit increases—in the basal body temperature that usually occur just before ovulation. This method is much more likely to be successful if, during each menstrual cycle, intercourse is avoided until well after the ovulatory temperature rise. For this method to be most effective, the woman must abstain from intercourse from the first day of menses through the third day after the increase in temperature. For obvious reasons, this is not a popular method! With excellent compliance, however, the unwanted pregnancy is approximately 2 percent the first year.

Cervical Mucus Rhythm Method

This so-called *Billings method* depends on awareness of vaginal "dryness" and "wetness." These are the consequences of changes in the amount and quality of cervical mucus at different times in the menstrual cycle. Abstinence is required from the beginning of menses until 4 days after slippery mucus is identified. Although this method has not achieved popularity, when it is used accurately, the first-year failure rate is approximately 3 percent.

Symptothermal Method

This method combines the use of changes in cervical mucus—onset of fertile period, changes in basal body temperature—end of fertile period, and calculations to estimate the time of ovulation. Although this method is more complex to learn and apply, it does not appreciably improve reliability. The use of home kits to detect LH increases in the urine on the day prior to ovulation may improve the accuracy of periodic abstinence methods (Hatcher and associates, 2007).

EMERGENCY CONTRACEPTION

Many women present for contraceptive care following consensual but unprotected sexual intercourse, or in some cases, following sexual assault. In these situations, a number of methods substantially decrease the likelihood of an unwanted pregnancy when used correctly. Current methods of emergency contraception include COCs, progestin-only products, copper-containing IUDs, and mifepristone. Patients can obtain information regarding emergency contraception by calling 1-888-NOT-2-LATE (888-668-2528) or accessing The Emergency Contraception Website: http://ec.princeton.edu/.

History

For many decades it was known that pharmacological doses of estrogens would prevent pregnancy when given for recent unprotected intercourse. A study by Demers (1971) published in the *New England Journal of Medicine* was entitled "The Morning-After Pill," which referred to diethylstilbestrol (DES) used successfully as a postcoital contraceptive. It was never approved for this purpose, and in fact, the FDA discouraged the practice. Nevertheless, DES was widely prescribed off-label to prevent pregnancy. For example, beginning in the 1960s, it was routinely offered to women who were "at risk" for pregnancy following sexual assault and who were cared for at the Parkland Hospital Ob-Gyn Emergency Room. DES production by Eli Lilly, the last U.S. manufacturer, ceased in 1997.

In 1974, Yuzpe and colleagues published their pilot study of the use of combined hormone—100 μg ethinyl estradiol plus 1.0 mg dL-norgestrel—for postcoital contraception, and subsequently the *Yuzpe method* was found effective. In 1997, the FDA declared the Yuzpe method to be safe and effective for this off-label use and in 1998, approved the Yuzpe-method *Preven Emergency Contraceptive Kit* for prescriptive use. This kit was discontinued by the manufacturer in 2004.

In 1999, the FDA approved *Plan B,* which was the first progestin-only emergency contraceptive for prescriptive use. Because of its efficacy and safety, and especially its intent in preventing unwanted adolescent pregnancy, a number of organizations, including the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics, recommended over-the-counter (OTC) availability (Drazen and colleagues, 2004). In 2009, the FDA allowed the manufacturer to market Plan B without a prescription to women 17 years and older.

Hormonal Emergency Contraception

Estrogen-Progestin Combinations

For reasons discussed above, this is also known as the *Yuzpe method.* A minimum of 100 μg of ethinyl estradiol and 0.5 mg of

levonorgestrel is given as shown in Table 32-9. The only FDA-approved dedicated estrogen- and progesterone-containing product was the *Preven Emergency Contraceptive Kit*, which was for emergency contraception. These COC regimens are more effective the sooner they are taken after unprotected intercourse. The first dose is taken ideally within 72 hours of intercourse but may be given up to 120 hours. The initial dose is followed 12 hours later by a second dose. Emergency hormonal contraceptive regimens are highly effective and decrease the risk of pregnancy by up to 94 percent (American College of Obstetricians and Gynecologists, 2005a).

Nausea and vomiting are major problems due to high-dose estrogen in these regimens. For this reason, an oral antiemetic may be prescribed at least 1 hour before each dose. Oral pretreatment with 50-mg meclizine or with 10 mg of metoclopramide effectively decreases nausea (Ragan and associates, 2003; Raymond and colleagues, 2000). If a woman vomits within 2 hours of a dose, the dose must be repeated.

Progestin-Only Preparations

This progestin-only product provides two tablets, each containing 0.75 mg levonorgestrel. Optimally, the first dose is taken within 72 hours of unprotected coitus but may be given up to 120 hours. The second dose follows 12 hours later, although Ngai and colleagues (2005) showed that a 24-hour interval between the doses was also effective. Alternatively, a single, one-time 1.5-mg dose of levonorgestrel may be used.

The pregnancy rate with Plan B of 1.1 percent compares favorably with that of 3.2 percent in a similar group of women treated with the Yuzpe regimen. The major mechanism with all of these is inhibition or delay of ovulation. Other mechanisms include alteration of the endometrium, sperm penetration, and tubal motility. **Established pregnancies are not harmed.**

Copper-Containing Intrauterine Devices

Fasoli and co-workers (1989) summarized nine studies that included results from 879 women who accepted some type of copper-containing IUD as a sole method of postcoital contraception. The only reported pregnancy aborted spontaneously. Trussell and Stewart (1998) reported that when the IUD was inserted up to 5 days after unprotected intercourse, the failure rate was 1 percent. A secondary advantage is that this method also puts in place an effective 10-year method of contraception.

TABLE 32-9. Prescriptive Equivalents of Dedicated Products and Common Oral Contraceptives for Use as Emergency Contraception

Trade Name	Formulation	Pills per Dose[a]
Dedicated Products		
Plan B	0.75 mg levonorgestrel	1
Oral Contraceptives[b]		
Ogestrel, Ovral	0.05 mg EE 0.5 mg norgestrel	2
Cryselle, Low-Ogestrel, Lo/Ovral,	0.03 mg EE 0.3 mg norgestrel	4
Jolessa, Levlen, Levora, Nordette, Portia Quasense, Seasonale, Seasonique (blue-green)	0.03 mg EE 0.15 mg levonorgestrel	4
TriLevlen (yellow), Triphasil (yellow), Trivora (pink), Enpresse (orange)	0.03 mg EE 0.125 mg levonorgestrel	4
Alesse, Levlite, Aviane, Lutera, Lessina, Sryonx	0.02 mg EE 0.1 mg levonorgestrel	5

[a]Treatment consists of two doses taken 12 hours apart. Use of an antiemetic agent before each dose will lessen the risk of nausea, which is a common side effect.
[b]For these multiphasic formulations, the color in parentheses indicates which pills to use for emergency contraception.
EE = ethinyl estradiol.

Mifepristone (RU 486)

This medication is discussed in Chapter 9 (p. 232) and relies on its antiprogesterone effects to delay or inhibit ovulation as its means of postcoital contraception. A single 10-mg dose provides pregnancy prevention comparable with that of *Plan B* (Task Force on Postovulatory Methods of Fertility Regulation, 1999; von Hertzen and associates, 2002). There are few side effects with mifepristone, and compared with the Yuzpe method it is better tolerated and more effective (Ashok and colleagues, 2002, 2004). In the United States, mifepristone is not used for emergency contraception because of its high cost and because it is not manufactured or marketed in an appropriate dose. Another progesterone-receptor modulator—CDB-2914—was reported by Creinin and colleagues (2006) to be as effective as levonorgestrel in preliminary studies.

LACTATION

For mothers who are nursing exclusively, ovulation during the first 10 weeks after delivery is unlikely. Nursing, however, is not a reliable method of family planning for women whose infants are on a daytime-only feeding schedule. **Waiting for first menses involves a risk of pregnancy, because ovulation usually antedates menstruation.** Certainly, after the first menses, contraception is essential unless the woman desires pregnancy. Estrogen-progestin contraceptives may reduce both the rate and the duration of milk production. The benefits from prevention of pregnancy by the use of combined oral contraceptives would appear to outweigh the risks in selected patients. According to the American College of Obstetricians and Gynecologists (2000), progestin-only contraceptives are the preferred choice in most cases. In addition, IUDs have been recommended for the lactating sexually active woman following uterine involution.

CHAPTER 33

Sterilization

FEMALE STERILIZATION 698
MALE STERILIZATION 702

Sterilization has become a popular choice of contraceptive for millions of men and women in the United States as well as in many countries worldwide. This procedure is indicated in those requesting sterilization and who clearly understand its permanence and its difficult and often unsuccessful reversal. A woman should be counseled regarding alternative contraceptive choices (American College of Obstetricians and Gynecologists, 2007).

FEMALE STERILIZATION

Female sterilization is the contraceptive method selected by 28 percent of couples in the United States (American College of Obstetricians and Gynecologists, 2003). And for women aged 35 to 44 years, surgical sterilization was their most commonly reported form of contraception (Bensyl and associates, 2005; Huber and Huber, 2009).

Sterilization is usually accomplished by occlusion or division of the fallopian tubes. This can be performed at any time, but at least half are performed in conjunction with cesarean or vaginal delivery and are termed *puerperal* (MacKay and associates, 2001). *Nonpuerperal* surgical tubal sterilization is usually accomplished via laparoscopy in an outpatient surgical center. Hysteroscopic or minilaparotomy approaches to occlusion are also available.

Puerperal Tubal Sterilization

For several days after delivery, the fallopian tubes are accessible at the umbilicus directly beneath the abdominal wall. Wall laxity allows easy repositioning of the abdominal incision over each uterine cornu. Thus, puerperal sterilization is technically simple, and hospitalization need not be prolonged. Some prefer to perform sterilization immediately following delivery, although others wait for 12 to 24 hours (Bucklin and Smith, 1999). At Parkland and the University of Alabama Hospitals, puerperal tubal ligation is performed in the obstetrical surgical suite the morning after delivery. This minimizes hospital stays but allows the likelihood of postpartum hemorrhage to diminish. In addition, the status of the newborn can be better ascertained.

Various techniques are now used to disrupt tubal patency. In general, a midtubal segment of fallopian tube is excised, and the severed ends seal by fibrosis and reperitonealization. Commonly used methods of interval sterilization include the Parkland, Pomeroy, and modified Pomeroy techniques (American College of Obstetricians and Gynecologists, 2003). Irving and Uchida techniques or Kroener fimbriectomy are rarely used because they involve increased dissection, operative time, and chance of mesosalpingeal injury. With fimbriectomy, unfavorably high failure rates stem from recanalization of the proximal tubal portion (Pati and Cullins, 2000).

Surgical Technique

A small infraumbilical incision is made. The fallopian tube is identified by grasping its midportion with a Babcock clamp, and the distal fimbria is identified. This prevents confusing the round ligament with the midportion of the tube. A common reason for sterilization failure is ligation of the wrong structure, typically the round ligament. Therefore, identification and isolation of the distal tube prior to ligation is required. **Whenever the tube is inadvertently dropped, it is mandatory to repeat this identification procedure.** Surgical steps are outlined for each method in Figures 33-1 and 33-2.

Failure Rates

Puerperal sterilization fails for two major reasons. First, surgical errors include transection of the round ligament or only partial transection of the tube. Thus, both tubal segments are submitted

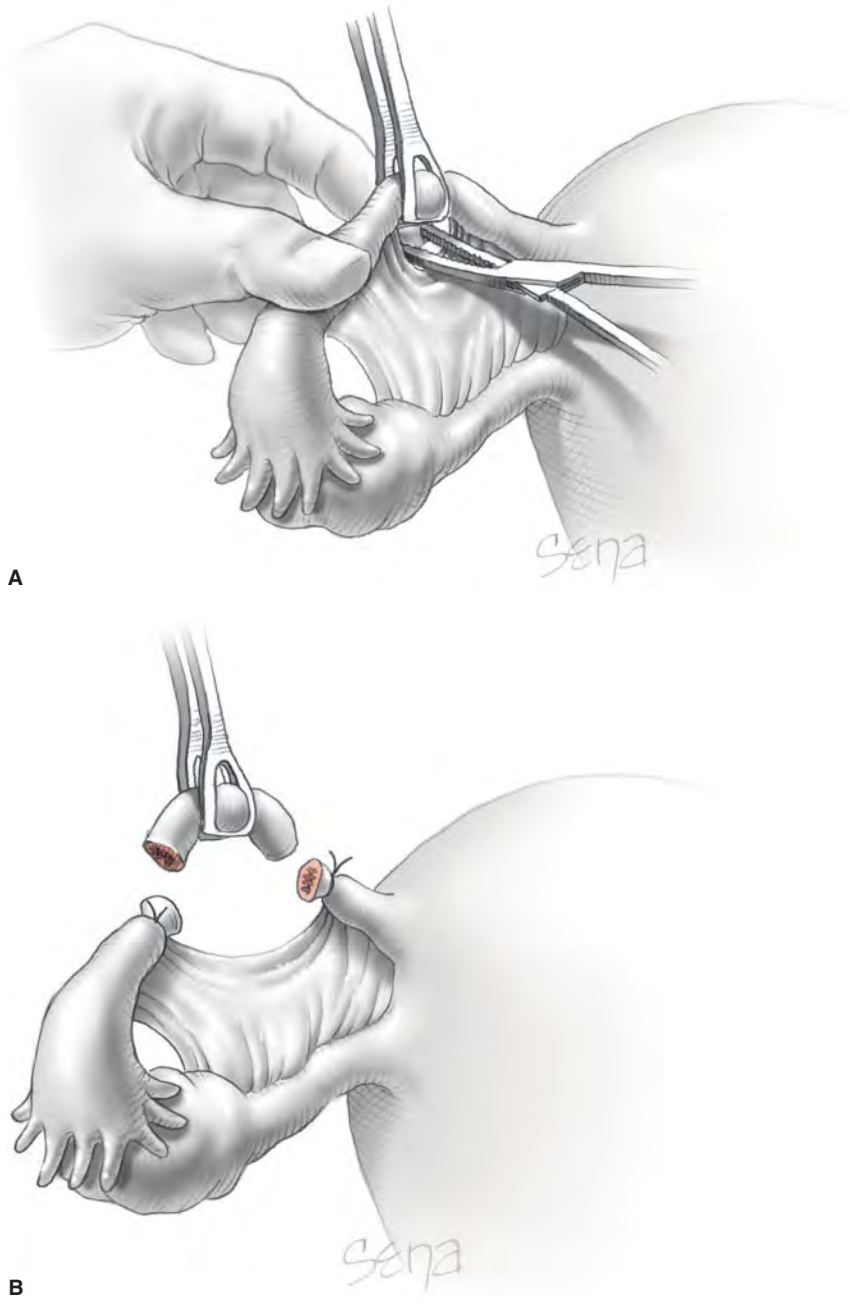

FIGURE 33-1 Parkland method. **A.** An avascular site in the mesosalpinx adjacent to the fallopian tube is perforated with a small hemostat. The jaws are opened to separate the fallopian tube from the adjacent mesosalpinx for approximately 2.5 cm. **B.** The freed fallopian tube is ligated proximally and distally with 0-chromic suture. The intervening segment of approximately 2 cm is excised, and the excision site is inspected for hemostasis. This method was designed to avoid the initial intimate proximity of the cut ends of the fallopian tube inherent with the Pomeroy procedure. (From Hoffman, 2008, with permission.)

for pathological confirmation. Secondly, a fistulous tract or spontaneous reanastomosis forms between the severed tubal stumps.

In their first report, investigators from the Collaborative Review of Sterilization (CREST) study described follow-up of 10,863 women who had undergone tubal sterilization from 1978 through 1986 (Peterson and colleagues, 1996). The failure rates for various procedures are summarized in Figure 33-3. Specifically, with the Parkland method, during four decades, the failure rate has been less than 1 in 400 procedures. It is readily apparent that puerperal sterilization is highly effective, with a short- and long-term failure rate that is better than those of most interval procedures.

Nonpuerperal (Interval) Surgical Tubal Sterilization

Techniques for surgical nonpuerperal tubal sterilization, including modifications, basically consist of:

1. ligation and resection at laparotomy, as described earlier for puerperal sterilization
2. application of a variety of permanent rings, clips, or inserts to the fallopian tubes, by laparoscopy or hysteroscopy
3. electrocoagulation of a tubal segment, again usually through a laparoscope.

Surgical Approaches

In the United States, laparoscopic tubal ligation is the leading method of interval female sterilization (American College of Obstetricians and Gynecologists, 2003). The procedure is frequently performed in an ambulatory surgical setting under general anesthesia. In almost all cases, the woman can be discharged within several hours.

Minilaparotomy using a 3-cm suprapubic incision is also popular, especially in resource-poor countries (Kulier and colleagues, 2002). Although not commonly used, the peritoneal cavity can be entered through the posterior vaginal fornix—*colpotomy* or *culdotomy*—to perform tubal interruption.

Major morbidity is rare with either minilaparotomy or laparoscopy. In the study by Kulier and associates (2002), minor morbidity was twice as common with a minilaparotomy.

Laparoscopic Methods of Tubal Interruption

A number of techniques or devices can be used to accomplish tubal sterilization via laparoscopy. Details of these have been provided by a number of reviews (Hoffman, 2008; Pati and Cullins, 2000; Peterson, 2008).

Electrocoagulation is used for destruction of a segment of tube with either unipolar or bipolar electrical current. Although unipolar electrocoagulation has the lowest long-term failure rate, it also has the highest serious complication rate (see Fig. 33-3). For this reason, bipolar coagulation is usually chosen (American College of Obstetricians and Gynecologists, 2003). Because electrosurgical coagulation destroys a large segment of tube, surgical reversal is difficult if not impossible.

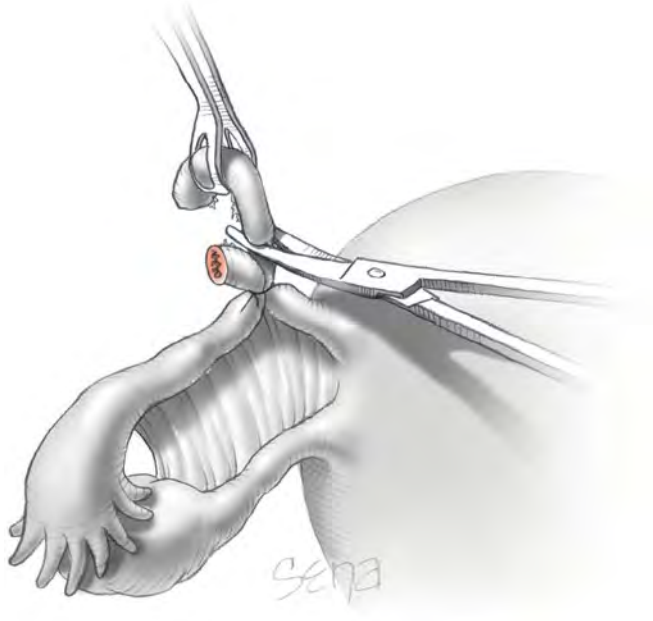

FIGURE 33-2 Surgical sterilization: Pomeroy method. Plain catgut is used to ligate a knuckle of tube to ensure prompt absorption of the ligature and subsequent separation of the severed tubal ends. (From Hoffman, 2008, with permission.)

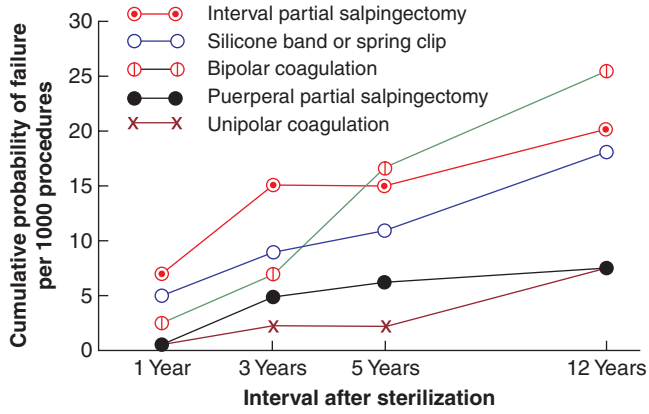

FIGURE 33-3 Data from the U.S. Collaborative Review of Sterilization (CREST) shows the cumulative probability of pregnancy per 1000 procedures by five methods of tubal sterilization. (Data from Peterson and co-workers, 1996.)

Mechanical methods of occlusion can be accomplished with a silastic rubber band such as the Falope Ring and the Tubal Ring; the spring-loaded Hulka-Clemens Clip—also known as the Wolf Clip; or the silicone-lined titanium Filshie Clip (**Fig. 33-4**). As shown in Figure 33-3, all these methods have favorable long-term success rates.

Failure Rates

The reasons for failure of surgical interval tubal sterilization are not always apparent, but some are:

1. Surgical errors likely account for 30 to 50 percent of cases
2. An occlusion method failure may result from fistula formation, especially with electrosurgical procedures. Faulty clips may not be sufficiently occlusive, or the fallopian tube may spontaneously reanastomose
3. Equipment failure, such as a defective current for electrosurgery, may be causative
4. The woman was already pregnant at the time of surgery—a so-called *luteal phase pregnancy*. To limit this possibility, surgery may ideally be performed during the follicular phase, and an effective contraceptive method used prior to surgery
5. In some cases, proper placement of clips is documented, and no reason is found (Belot and colleagues, 2008)

Some sterilization methods have lower failure rates than others. Even with the same procedure, there are variations in failure rates. For example, when fewer than three tubal sites are coagulated, the 5-year cumulative probability of pregnancy is about 12 per 1000 procedures. This compares with only 3 per 1000 if three or more sites are coagulated (Peterson and associates, 1999). Importantly, Soderstrom (1985) found that most sterilization failures were not preventable. The American College of Obstetricians and Gynecologists (1996) concluded that "pregnancies after sterilization may occur without any technical errors."

Long-Term Complications

In addition to the 15-year cumulative pregnancy rates shown in Figure 33-3, there are other long-term effects.

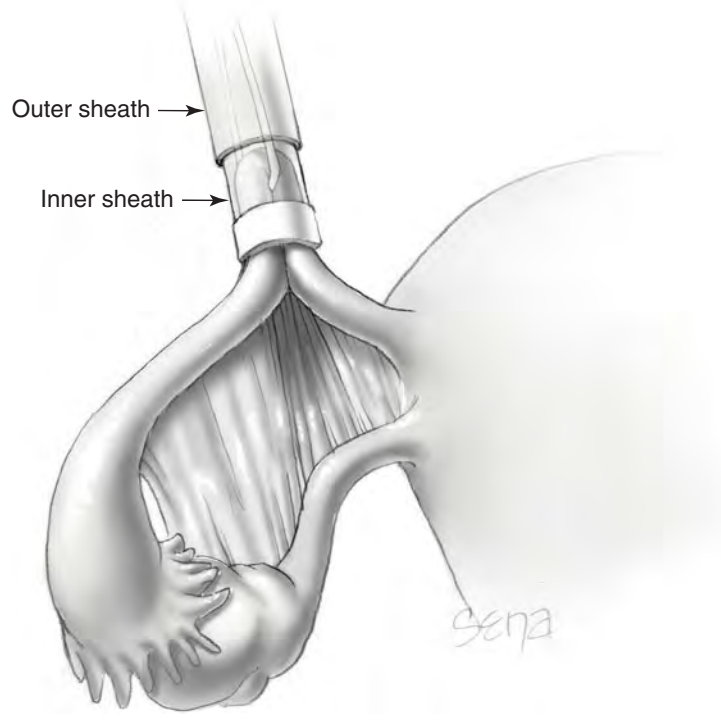

FIGURE 33-4 Silastic band (Falope Ring) placement. Applicator tongs draw a portion of tube up into an inner sheath. An outer sheath then pushes a silastic band off the inner sheath and onto the base of the tubal loop. (From Hoffman, 2008, with permission.)

Ectopic Pregnancy. Approximately half of pregnancies that follow a failed electrocoagulation procedure are ectopic, compared with only 10 percent following failure of a ring, clip, or tubal resection method (Hatcher and colleagues, 1990; Hendrix and associates, 1999). **Any symptoms of pregnancy in a woman after tubal sterilization must be investigated, and an ectopic pregnancy should be excluded.** Diagnosis and management are discussed in detail in Chapter 10.

Other Effects. Following sterilization *ovarian* and *breast cancer* risks are either decreased or unaffected (Eliassen, 2006; Iversen, 2007; Tworoger, 2007; Westhoff 2000, and all their co-workers). Moreover, Levgur and Duvivier (2000) reported that women who had undergone tubal sterilization were highly unlikely to subsequently have *salpingitis*. Holt and colleagues (2003) noted that an almost twofold increased incidence of *functional ovarian cysts* follows tubal sterilization.

Less objective but important psychological sequelae of sterilization have also been evaluated. In the CREST study, Costello and colleagues (2002) found that tubal ligation did not change *sexual interest or pleasure* in 80 percent of women. In most of the 20 percent of women who did report a change, *positive effects* were 10 to 15 times more likely.

Invariably, a number of women express *regrets about sterilization* (Curtis and colleagues, 2006; Kelekçi and co-workers, 2005). In the CREST study, Jamieson and co-workers (2002) reported that by 5 years, 7 percent of women who had undergone tubal ligation had regrets. This is not limited to their own sterilization, because 6.1 percent of women whose husbands had undergone vasectomy had similar regrets.

Posttubal Ligation Syndrome. Menorrhagia and intermenstrual bleeding following sterilization has been termed the *posttubal ligation syndrome*. Observations from the CREST study have questioned such an association. Peterson and colleagues (2000) compared long-term outcomes of 9514 women who had undergone tubal sterilization with a cohort of 573 women whose partners had undergone vasectomy. They found that both groups had similar risks for menorrhagia, intermenstrual bleeding, and dysmenorrhea. In fact, they found that women who had undergone sterilization had *decreased* duration and volume of menstrual flow as well as *less* dysmenorrhea. There was, however, an increased incidence of cycle irregularity in the sterilized women.

The cause of these findings remains enigmatic. Several investigators have reported no significant change in serum levels of sex steroid hormones or their releasing factors (Gentile and associates, 2006; Harlow and co-workers, 2002). Timonen and co-workers (2002) reported a transient increase in follicular phase serum estradiol levels that normalized by 12 months.

Reversal of Tubal Sterilization

No woman should undergo tubal sterilization believing that subsequent fertility is guaranteed by either surgery or in vitro fertilization. Both approaches are technically difficult, expensive, and not always successful. Success rates vary greatly depending on the age of the woman, the amount of tube remaining, and the technology used (Boeckxstaens and colleagues, 2007). With surgical reversals, pregnancy rates varied from 45 to 85 percent (Trussell and associates, 2003; Van Voorhis, 2000). **Almost 10 percent of women who undergo reversal of tubal sterilization have an ectopic pregnancy.**

Hysterectomy

In the absence of uterine or other pelvic disease, hysterectomy solely for sterilization at the time of cesarean delivery, early in the puerperium, or even remote from pregnancy is difficult to justify. It carries significantly increased surgical morbidity compared with tubal sterilization (Jamieson and co-workers, 2000; Johnson and colleagues, 2005).

Transcervical Sterilization

Sterilization has been performed using hysteroscopy to visualize the tubal ostia and obliterate them with a variety of compounds or devices.

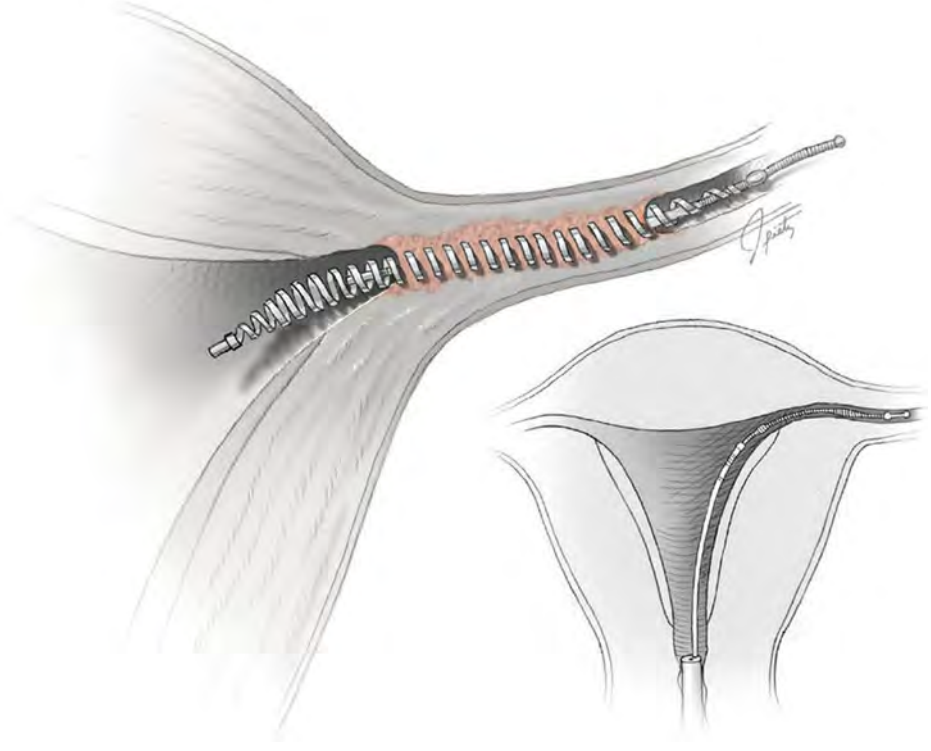

FIGURE 33-5 Essure microinsert placement hysteroscopically and ingrowth of tissue. (From Hoffman, 2008, with permission.)

Intratubal Devices

Tubes can be occluded by hysteroscopic insertion of some type of mechanical device into the proximal tube (Fig. 33-5). One of these, *Essure*, was approved by the Food and Drug Administration in 2002. This device is a microinsert that has a fine stainless steel inner coil enclosed in polyester fibers and an expandable outer coil of *Nitinol*—a nickel and titanium alloy. The outer coil expands after placement allowing the inner fibers also to expand. Over time, these synthetic fibers incite a chronic inflammatory response and prompt local tissue ingrowth from the surrounding tube (Valle and colleagues, 2001). This ingrowth leads to complete tubal lumen occlusion. This procedure requires hysterosalpingography 3 months following surgery to confirm occlusion (Wittmer and associates, 2006a, b). Some have evaluated the effectiveness of sonography to confirm occlusion or alternatively, dislodgement (Booker, 2008; Veersema, 2005; Weston, 2005, and all their colleagues).

Sedation, paracervical block, or both may be used for hysteroscopic placement of Essure microinserts. Bilateral placement is achieved in 88 to 96 percent of cases (Kerin, 2003; Levie, 2006; Miño, 2007; Ubeda, 2004, and all their colleagues). Thus, these devices cannot be placed in all women, and some do not tolerate the procedure awake (Duffy and colleagues, 2005). Postprocedure, a few women cannot tolerate the device because of intractable pelvic pain (Beckwith, 2008).

Preliminary results with this device have been encouraging (Association of Reproductive Health Professionals, 2002; Magos, 2004). Cooper and associates (2003) reported proper insertion in 464 of 507 women, and there were no pregnancies in more than 9600 woman-months.

Causes for pregnancy following Essure placement include conception prior to insertion, insert migration, uterine perforation, and noncompliance with hysterosalpingography or its misinterpretation (Levy, 2007; Moses, 2007; Ory, 2008, and all their colleagues).

Two additional inserts, *Ovion* and *Adiana*, similarly rely on tissue ingrowth for tubal occlusion. These currently are not available (Abbott, 2007; Vancaillie and associates, 2009; Zurawin and Ayensu-Coker, 2007).

Intratubal Chemical Methods

Several compounds may be used in tubal sterilization to sclerose or obstruct the tubal ostia, but none is currently available for use in the United States (Ogburn and Espey, 2007). Liquid silicone may be injected transcervically into the tubes, where it hardens, forming *silicone plugs* (Reed and Erb, 1983). Alternatively, tubal injections with the adhesive *methylcyanoacrylate* cause inflammation, necrosis, and fibrosis (Brundin, 1991). Tubal insertion of *quinacrine pellets* has been done in hundreds of thousands of women in other countries to achieve tubal occlusion. Because of concerns about carcinogenesis, the World Health Organization at one time recommended halting quinacrine use (Lippes, 2002). Since then, long-term follow-up studies from Vietnam have not shown an increased risk of cancer. However, investigators report high 1-, 5-, and 10-year cumulative pregnancy rates of 3, 10, and 12 percent, respectively (Sokal and colleagues, 2008a, b). Alternatively, *erythromycin* placed tubally to incite inflammation has been investigated, but it has an unacceptably high one-year failure rate of 36 percent (Bairagy and Mullick, 2004). Other mechanical inserts are less commonly used and are described by Abbott (2005, 2007) in his reviews.

MALE STERILIZATION

Availability of male contraceptives has traditionally been limited to condoms and vasectomy. According to their review, Page and associates (2008) cite 90- to 95-percent efficacy rates for experimental hormonal-based male contraceptives. They also cite promising nonhormonal methods of targeting sperm motility. But these are currently unavailable.

At this time, up to a half million men in the United States undergo vasectomy each year (Barone and co-workers, 2006; Magnani and colleagues, 1999). Through a small incision or alternatively through a puncture in the scrotum, the lumen of the vas deferens is disrupted to block the passage of sperm from the testes (Fig. 33-6). There are fewer minor surgical complications with the no-scalpel method than with the traditional incision technique, but each is equally effective (Cook and co-workers, 2007). In addition to surgical transection, obstruction with vas deferens plugs or clips is under investigation (Rowlands, 2009).

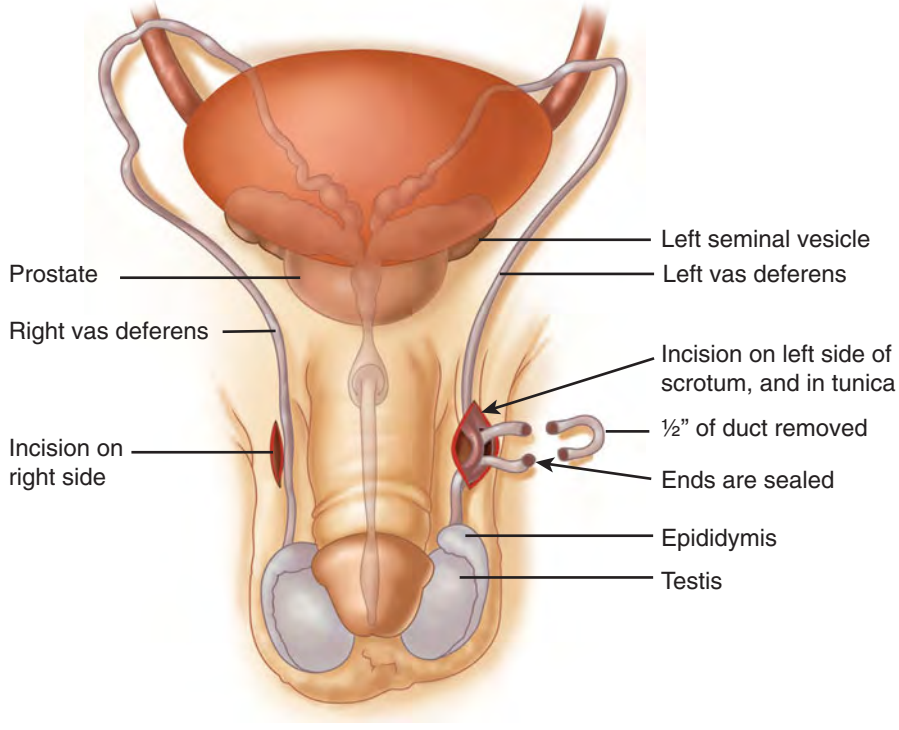

FIGURE 33-6 Anatomy of male reproductive system, showing procedure for vasectomy.

There is no doubt that vasectomy is safer than tubal sterilization because it is less invasive and is performed with local analgesia (American College of Obstetricians and Gynecologists, 2003). In their review, Hendrix and colleagues (1999) found that, compared with vasectomy, female tubal sterilization has a 20-fold increased complication rate, a 10- to 37-fold failure rate, and costs three times as much. Teachey (2008) described a rare death from a massive pulmonary embolism in a healthy 35-year-old man thought to be induced by limited mobilization following vasectomy.

Disadvantageously, sterilization following vasectomy is not immediate. Complete expulsion of sperm stored in the reproductive tract beyond the interrupted vas deferens takes about 3 months or 20 ejaculations (American College of Obstetricians and Gynecologists, 1996). Although most protocols dictate that semen should be analyzed until two consecutive sperm counts are zero, many investigators suggest that collection of only one azoospermic semen analysis is sufficient evidence of sterility (Bodiwala, 2007; Bradshaw, 2001; Griffin, 2005, and all their associates). During the period before azoospermia is documented, another form of contraception should be used.

The failure rate for vasectomy during the first year is 9.4 per 1000 procedures but only 11.4 per 1000 at 2, 3, and 5 years (Jamieson and colleagues, 2004). Failures result from unprotected intercourse too soon after ligation, incomplete occlusion of the vas deferens, or recanalization (Awsare, 2005; Deneux-Tharaux, 2004; Jamieson, 2004, and all their associates).

Restoration of Fertility

Success after vasectomy reversal depends on several factors, and fibrosis increases with time (Raleigh and colleagues, 2004). With reversal, results typically are superior using microsurgical techniques (American Society of Reproductive Medicine Practice Committee, 2006). Bolduc and associates (2007) reported that success was more likely with shorter obstructive intervals, same female partner, use of surgical clips when vasectomy was done, and presence of a sperm granuloma.

Long-Term Effects

Other than regrets, long-term consequences are rare (Amundsen and Ramakrishnan, 2004). Although formerly items of concern, increased atherogenesis or immune-complex mediated disease are no longer linked to vasectomy (Giovannucci, 1992; Goldacre, 1983; Massey, 1984, and all their associates). Moreover, there is no convincing evidence of an increased incidence of *testicular cancer* following vasectomy (Møller and co-workers, 1994). Earlier studies found evidence to associate development of *prostatic carcinoma* after vasectomy (Giovannucci and associates, 1993a, b; Hayes and co-workers, 1993). However, most reviewers have found no strong causal association between the two (Bernal-Delgado and colleagues, 1998; Holt and associates, 2008; Schwingl and Guess, 2000). A weak association may be explicable by greater scrutiny of men who have undergone vasectomy (Grönberg, 2003). Indeed, the long-term effects of vasectomy are few, although troublesome chronic scrotal pain may develop in up to 15 percent of men (Choe, 1996; Leslie, 2007; Manikandan, 2004; McMahon, 1992, and all their co-workers).

SECTION 7

OBSTETRICAL COMPLICATIONS

CHAPTER 34

Pregnancy Hypertension

TERMINOLOGY AND CLASSIFICATION 706
DIAGNOSIS 707
INCIDENCE AND RISK FACTORS 709
ETIOPATHOGENESIS 709
PATHOPHYSIOLOGY 715
PREDICTION AND PREVENTION 725
MANAGEMENT 728
LONG-TERM CONSEQUENCES 747

Hypertensive disorders complicate 5 to 10 percent of all pregnancies, and together they form one member of the deadly triad, along with hemorrhage and infection, that contribute greatly to maternal morbidity and mortality rates. With hypertension, the *preeclampsia syndrome*, either alone or superimposed on chronic hypertension, is the most dangerous. As subsequently discussed, new-onset nonproteinuric hypertension during pregnancy—termed *gestational hypertension*—is followed by signs and symptoms of preeclampsia almost half the time, and preeclampsia is identified in 3.9 percent of all pregnancies (Martin and colleagues, 2009). The World Health Organization systematically reviews maternal mortality worldwide (Khan and colleagues, 2006). In developed countries, 16 percent of maternal deaths were due to hypertensive disorders. This percentage is greater than three other leading causes: hemorrhage—13 percent, abortion—8 percent, and sepsis—2 percent. In the United States from 1991 to 1997, Berg and colleagues (2003) reported that almost 16 percent of 3201 maternal deaths were from complications of pregnancy-related hypertension. Importantly, Berg and co-workers (2005) later reported that over half of these hypertension-related deaths were preventable.

How pregnancy incites or aggravates hypertension remains unsolved despite decades of intensive research. Indeed, hypertensive disorders remain among the most significant and intriguing unsolved problems in obstetrics.

TERMINOLOGY AND CLASSIFICATION

The term gestational hypertension as used in previous editions of this book was chosen by Dr. Jack Pritchard to describe any new-onset uncomplicated hypertension during pregnancy when no evidence of the preeclampsia syndrome was apparent. Unfortunately, confusion arose by some using the term for both gestational hypertension and preeclampsia. We have thus adopted the schema of the Working Group of the NHBPEP—National High Blood Pressure Education Program (2000).

The Working Group classification of hypertensive disorders complicating pregnancy as shown in **Table 34-1** describes four types of hypertensive disease:

1. Gestational hypertension—formerly termed pregnancy-induced hypertension. If preeclampsia syndrome does not develop and hypertension resolves by 12 weeks postpartum, it is redesignated as transient hypertension
2. Preeclampsia and eclampsia syndrome
3. Preeclampsia syndrome superimposed on chronic hypertension
4. Chronic hypertension.

An important feature of this classification is differentiating preeclampsia and eclampsia from other hypertensive disorders because the former two are potentially more ominous. This concept is also important to interpret and appreciate studies that address the etiology, pathogenesis, and clinical management of pregnancy-related hypertensive disorders.

TABLE 34-1. Diagnosis of Hypertensive Disorders Complicating Pregnancy

Gestational Hypertension:
- Systolic BP ≥140 or diastolic BP ≥90 mm Hg for first time during pregnancy
- No proteinuria
- BP returns to normal before 12 weeks postpartum
- Final diagnosis made only postpartum
- May have other signs or symptoms of preeclampsia, for example, epigastric discomfort or thrombocytopenia

Preeclampsia:

Minimum criteria:
- BP ≥ 140/90 mm Hg after 20 weeks' gestation
- Proteinuria ≥ 300 mg/24 hours or ≥ 1+ dipstick

Increased certainty of preeclampsia:
- BP ≥ 160/110 mm Hg
- Proteinuria 2.0 g/24 hours or ≥ 2+ dipstick
- Serum creatinine >1.2 mg/dL unless known to be previously elevated
- Platelets < 100,000/μL
- Microangiopathic hemolysis—increased LDH
- Elevated serum transaminase levels—ALT or AST
- Persistent headache or other cerebral or visual disturbance
- Persistent epigastric pain

Eclampsia:
- Seizures that cannot be attributed to other causes in a woman with preeclampsia

Superimposed Preeclampsia On Chronic Hypertension:
- New-onset proteinuria ≥ 300 mg/24 hours in hypertensive women but no proteinuria before 20 weeks' gestation
- A sudden increase in proteinuria or blood pressure or platelet count < 100,000/μL in women with hypertension and proteinuria before 20 weeks' gestation

Chronic Hypertension:
- BP ≥ 140/90 mm Hg before pregnancy or diagnosed before 20 weeks' gestation not attributable to gestational trophoblastic disease

or

- Hypertension first diagnosed after 20 weeks' gestation and persistent after 12 weeks postpartum

ALT = alanine aminotransferase; AST = aspartate aminotransferase; BP = blood pressure; LDH = lactate dehydrogenase.
National High Blood Pressure Education Program Working Group Report on High Blood Pressure in Pregnancy (2000).

DIAGNOSIS

Hypertension is diagnosed empirically when appropriately taken blood pressure exceeds 140 mm Hg systolic or 90 mm Hg diastolic. Korotkoff phase V is used to define diastolic pressure. In the past, it had been recommended that an incremental increase from midpregnancy values by 30 mm Hg systolic or 15 mm Hg diastolic pressure be used as diagnostic criteria, even when absolute values were below 140/90 mm Hg. These criteria are no longer recommended because evidence shows that such women are not likely to experience increased adverse pregnancy outcomes (Levine and co-workers, 2000; North and colleagues, 1999). That said, women who have a rise in pressure of 30 mm Hg systolic or 15 mm Hg diastolic should be seen more frequently. There is no doubt that eclamptic seizures develop in some women whose blood pressures have been below 140/90 mm Hg (Alexander and associates, 2006). Edema is also no longer used as a diagnostic criterion because it is too common in normal pregnancy to be discriminant.

Gestational Hypertension

The diagnosis of gestational hypertension is made in women whose blood pressure reaches 140/90 mm Hg or greater for the first time after midpregnancy, but in whom *proteinuria is not identified* (see Table 34-1). Almost half of these women subsequently develop preeclampsia syndrome, which includes signs such as proteinuria and thrombocytopenia or symptoms such as headaches or epigastric pain. Gestational hypertension is

reclassified as *transient hypertension* if evidence for preeclampsia does not develop, and the blood pressure returns to normal by 12 weeks postpartum.

Proteinuria is the surrogate objective marker that defines the system wide endothelial leak, which characterizes the preeclampsia syndrome. Even so, when blood pressure increases appreciably, it is dangerous to both mother and fetus to ignore this rise because proteinuria has not yet developed. As Chesley (1985) emphasized, 10 percent of eclamptic seizures develop before overt proteinuria is identified.

Preeclampsia

As shown throughout this chapter, preeclampsia is best described as a *pregnancy-specific syndrome that can affect virtually every organ system.* As discussed, although preeclampsia is much more than simply gestational hypertension with proteinuria, appearance of proteinuria remains an important objective diagnostic criterion. Proteinuria is defined by 24-hour urinary protein excretion exceeding 300 mg, a urine protein:creatinine ratio of ≥ 0.3, or persistent 30 mg/dL (1+ dipstick) protein in random urine samples (Lindheimer and colleagues, 2008a). None of these values are sacrosanct. Urine concentrations vary widely during the day, and so too will dipstick readings. Thus, assessment may even show a 1+ to 2+ value from concentrated urine specimens from women who excrete < 300 mg/day. As discussed on page 719, it is likely that determination of a spot urine:creatinine ratio will be a suitable replacement for a 24-hour measurement.

As emphasized in Table 34-1, the more severe the hypertension or proteinuria, the more certain is the diagnosis of preeclampsia as well as its adverse outcomes. Similarly, abnormal laboratory findings in tests of renal, hepatic, and hematological function increase the certainty of preeclampsia. Persistent premonitory symptoms of eclampsia, such as headache and epigastric pain, also increase the certainty. That said, some women may have *atypical preeclampsia* with all aspects of the syndrome, but without hypertension or proteinuria, or both (Sibai and Stella, 2009).

Indicators of Severity of Preeclampsia

The markers listed in Table 34-1 are also used to classify the severity of the preeclampsia syndrome. Many use the American College of Obstetricians and Gynecologists dichotomous "mild" and "severe." Thus, in many classifications, criteria are given for the diagnosis of "severe" preeclampsia, and the alternate classification is either implied or specifically termed "mild," "less severe," or "nonsevere" (Alexander and associates, 2003; Lindheimer and co-workers, 2008b). These are used because there are no generally agreed-upon criteria for "moderate" preeclampsia—an elusive third category. Criteria listed in **Table 34-2** are categorized as "severe" versus "nonsevere." Parenthetically, the latter includes "moderate" and "mild," although they are not specifically defined.

Headaches or *visual disturbances* such as *scotomata* can be premonitory symptoms of eclampsia. *Epigastric or right upper quadrant pain* frequently accompanies hepatocellular necrosis, ischemia, and edema that stretch Glisson capsule. This characteristic pain is frequently accompanied by elevated serum hepatic transaminase levels. *Thrombocytopenia* is also characteristic of worsening preeclampsia. It probably is caused by platelet activation and aggregation as well as microangiopathic hemolysis induced by severe vasospasm. Other factors indicative of severe preeclampsia include renal or cardiac involvement as well as obvious fetal-growth restriction, which attest to its duration.

The more profound these signs and symptoms, the less likely it is that they can be temporized, and the more likely it is that delivery will be indicated. **The differentiation between nonsevere and severe gestational hypertension or preeclampsia can be misleading because what might be apparently mild disease may progress rapidly to severe disease.**

Eclampsia

The onset of convulsions in a woman with preeclampsia that cannot be attributed to other causes is termed *eclampsia.* The seizures are generalized and may appear before, during, or after

TABLE 34-2. Indicators of Severity of Gestational Hypertensive Disorders[a]

Abnormality	Nonsevere	Severe
Diastolic blood pressure	<110 mm Hg	≥110 mm Hg
Systolic blood pressure	<160 mm Hg	≥160 mm Hg
Proteinuria	≤2+	≥3+
Headache	Absent	Present
Visual disturbances	Absent	Present
Upper abdominal pain	Absent	Present
Oliguria	Absent	Present
Convulsion (eclampsia)	Absent	Present
Serum creatinine	Normal	Elevated
Thrombocytopenia	Absent	Present
Serum transaminase elevation	Minimal	Marked
Fetal-growth restriction	Absent	Obvious
Pulmonary edema	Absent	Present

[a]Compare with criteria in Table 34-1.

labor. In older reports, up to 10 percent of eclamptic women, especially nulliparas, did not develop seizures until after 48 hours postpartum (Sibai, 2005). Others have reported that up to a fourth of eclamptic seizures developed beyond 48 hours postpartum (Chames and co-workers, 2002). Our experiences from Parkland Hospital are that delayed postpartum eclampsia continues to occur in less than 10 percent of cases as we first reported more than 20 years ago (Alexander and co-workers, 2006; Brown and colleagues, 1987). These also are the observations from 222 women with eclampsia during a recent 2-year period in The Netherlands (Zwart and associates, 2008).

Preeclampsia Superimposed on Chronic Hypertension

All *chronic hypertensive disorders*, regardless of their cause, predispose to development of superimposed preeclampsia and eclampsia. The diagnosis of chronic underlying hypertension is based on findings listed in Table 34-1. These disorders can create difficult problems with diagnosis and management in women who are not seen until after midpregnancy. This is because blood pressure normally decreases during the second and early third trimesters in both normotensive and chronically hypertensive women (see Chap. 45, p. 984). Thus, a woman with previously undiagnosed chronic vascular disease, who is seen for the first time at 20 weeks, frequently has blood pressure within the normal range. During the third trimester, however, as blood pressure returns to its originally hypertensive level, it may be difficult to determine whether hypertension is chronic or induced by pregnancy. Even a careful search for evidence of preexisting end-organ damage may be futile as many of these women have mild disease. Thus, there may be no evidence of ventricular hypertrophy, chronic retinal vascular changes, or mild renal dysfunction.

In some women with chronic hypertension, blood pressure increases to obviously abnormal levels, and this is typically after 24 weeks. If accompanied by proteinuria, then superimposed preeclampsia is diagnosed. Superimposed preeclampsia commonly may develop earlier in pregnancy than "pure" preeclampsia. Superimposed disease tends to be more severe and often is accompanied by fetal-growth restriction. The same criteria shown in Table 34-2 are also used to further characterize severity of superimposed preeclampsia.

INCIDENCE AND RISK FACTORS

Preeclampsia often affects young and nulliparous women, whereas older women are at greater risk for chronic hypertension with superimposed preeclampsia. Also, the incidence is markedly influenced by race and ethnicity—and thus by genetic predisposition. Other factors include environmental, socioeconomic, and even seasonal influences (Lawlor, 2005; Palmer, 1999; Spencer, 2009, and all their co-workers).

With consideration for these vicissitudes, in a number of worldwide studies reviewed by Sibai and Cunningham (2009), the incidence of preeclampsia in nulliparous populations ranges from 3 to 10 percent. The incidence of preeclampsia in multiparas is also variable but is less than that for nulliparas. However, Ananth and Basso (2009) reported that the risk for stillbirths was more likely in hypertensive multiparas compared with nulliparas.

Other risk factors associated with preeclampsia include obesity, multifetal gestation, maternal age older than 35 years, and African-American ethnicity (Conde-Agudelo and Belizan, 2000; Sibai and colleagues, 1997; Walker, 2000). The relationship between maternal weight and the risk of preeclampsia is progressive. It increases from 4.3 percent for women with a body mass index (BMI) < 20 kg/m^2 to 13.3 percent in those with a BMI > 35 kg/m^2. In women with a twin gestation compared with those with singletons, the incidence of gestational hypertension—13 versus 6 percent, and the incidence of preeclampsia—13 versus 5 percent, are both significantly increased (Sibai and co-workers, 2000). The incidence is unrelated to zygosity (Maxwell and associates, 2001).

Although smoking during pregnancy causes a variety of adverse pregnancy outcomes, ironically, it has consistently been associated with a *reduced risk* of hypertension during pregnancy (Bainbridge and associates, 2005; Zhang and colleagues, 1999). Placenta previa has also been reported to reduce the risk of hypertensive disorders in pregnancy (Ananth and colleagues, 1997).

In the woman who was normotensive during her first pregnancy, the incidence of preeclampsia in a subsequent pregnancy is lower than cited above. In a population-based retrospective cohort analysis, Getahun and colleagues (2007) studied almost 137,000 second pregnancies in such women. The incidence for preeclampsia in white women was 1.8 percent compared with 3 percent in African-American women. Again, obesity was a major risk factor.

Eclampsia Incidence

Because it is somewhat preventable by adequate prenatal care, the incidence of eclampsia has decreased over the years. In developed countries, its incidence probably averages 1 in 2000 deliveries. In the National Vital Statistics Report, Ventura and colleagues (2000) estimated that the incidence in the United States in 1998 was approximately 1 in 3250. According to the Royal College of Obstetricians and Gynaecologists (2006), in the United Kingdom, it approximates 1 in 2000. And Akkawi and co-workers (2009) reported it to be 1 in 2500 in Dublin, Andersgaard and associates (2006) as 1 per 2000 for Scandinavia, and Zwart and co-workers (2008) as 1 per 1600 for The Netherlands.

ETIOPATHOGENESIS

Any satisfactory theory concerning the etiology and pathogenesis of preeclampsia must account for the observation that gestational hypertensive disorders are more likely to develop in women who:

- Are exposed to chorionic villi for the first time
- Are exposed to a superabundance of chorionic villi, as with twins or hydatidiform mole
- Have preexisting renal or cardiovascular disease
- Are genetically predisposed to hypertension developing during pregnancy.

A fetus is not a requisite for preeclampsia. And although chorionic villi are essential, they need not be located within the uterus. For example, Worley and associates (2008) reported a 30-percent incidence in women with an extrauterine pregnancy exceeding 18 weeks' gestation. Regardless of precipitating etiology, the cascade of events that leads to the preeclampsia syndrome is characterized by a host of abnormalities that result in vascular endothelial damage and subsequent vasospasm, transudation of plasma, and ischemic and thrombotic sequelae.

Preeclampsia as a Two-Stage Disorder

Observations that abnormal interfaces between maternal, paternal, and fetal tissues may cause preeclampsia have led to hypotheses that the syndrome is a two-stage disorder. In this scenario, there is a spectrum to include "maternal and placental preeclampsia" (Ness and Roberts, 1996). According to Redman and colleagues (2009), stage 1 is caused by faulty endovascular trophoblastic remodeling that downstream causes the stage 2 clinical syndrome (**Fig. 34-1**). There certainly is evidence that *some* cases of preeclampsia fit this theory. Importantly, stage 2 is susceptible to modification by preexisting maternal conditions that include cardiac or renal disease, diabetes, obesity, or hereditary influences. Such compartmentalization seems artificial, and it seems logical that there likely is a continuous process.

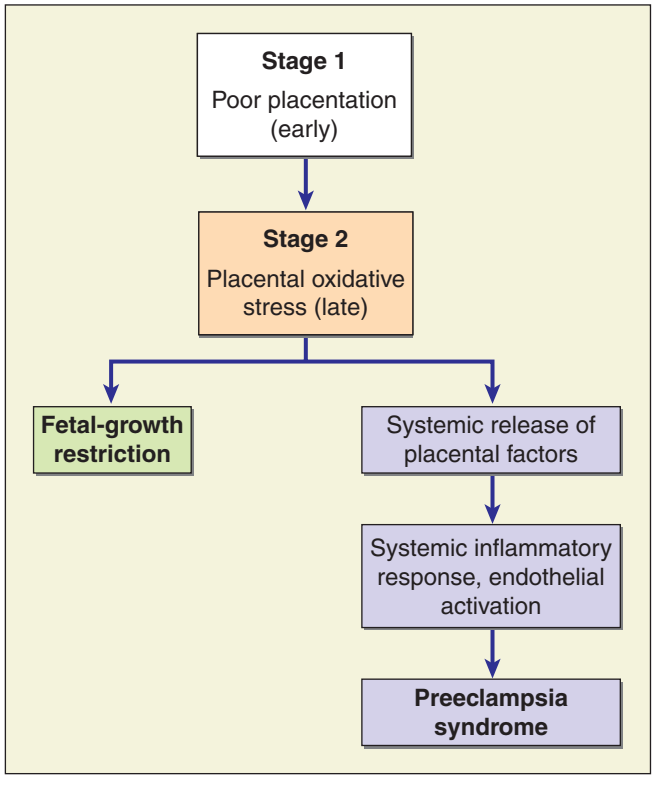

FIGURE 34-1 Schematic outlines the theory that the preeclampsia syndrome is a "two-stage disorder." Stage 1 is preclinical and characterized by faulty trophoblastic vascular remodeling of uterine arteries that causes placental hypoxia. Stage 2 is caused by release of placental factors into the maternal circulation causing systemic inflammatory response and endothelial activation. (Adapted from Borzychowski, 2006, and Redman, 2009, and their colleagues.)

Thus, although perhaps helpful to classify the syndrome for research purposes, preeclampsia is clinically more realistically a continuum of worsening disease. Moreover, evidence is accruing that many "isoforms" exist as discussed below.

Etiology

Writings describing eclampsia have been traced as far back as 2200 BC (Lindheimer and colleagues, 2009). And an imposing number of mechanisms have been proposed to explain its cause. Instead of being simply "one disease," preeclampsia appears to be a culmination of factors that likely involve a number of maternal, placental, and fetal factors. Those currently considered important include:

1. Placental implantation with abnormal trophoblastic invasion of uterine vessels
2. Immunological maladaptive tolerance between maternal, paternal (placental), and fetal tissues
3. Maternal maladaptation to cardiovascular or inflammatory changes of normal pregnancy
4. Genetic factors including inherited predisposing genes as well as epigenetic influences.

Abnormal Trophoblastic Invasion

In normal implantation, shown schematically in **Figure 34-2**, the uterine spiral arterioles undergo extensive remodeling as they are invaded by endovascular trophoblasts (see also Chap. 3, p. 54). These cells replace the vascular endothelial and muscular linings to enlarge the vessel diameter. The veins are invaded only superficially. In preeclampsia, however, there may be *incomplete trophoblastic invasion*. With such shallow invasion, decidual vessels, but not myometrial vessels, become lined with endovascular trophoblasts. The deeper myometrial arterioles do not lose their endothelial lining and musculoelastic tissue, and their mean external diameter is only half that of vessels in normal placentas (Fisher and colleagues, 2009). Madazli and associates (2000) showed that the magnitude of defective trophoblastic invasion of the spiral arteries correlates with the severity of the hypertensive disorder.

Using electron microscopy, De Wolf and co-workers (1980) examined arteries taken from the implantation site. They reported that early preeclamptic changes included endothelial damage, insudation of plasma constituents into vessel walls, proliferation of myointimal cells, and medial necrosis. Lipid accumulated first in myointimal cells and then within macrophages. Such lipid-laden cells and associated findings, as shown in **Figure 34-3,** were referred to as *atherosis* by Hertig (1945). Typically, the vessels affected by atherosis develop aneurysmal dilatation (Khong, 1991).

Thus, it is likely that the abnormally narrow spiral arteriolar lumen impairs placental blood flow. Diminished perfusion and a hypoxic environment eventually lead to release of *placental debris* that incites a systemic inflammatory response as described by Redman and Sargent (2008) and subsequently discussed. Fisher and colleagues (2009) have recently provided an elegant review of the molecular mechanisms involved in these interactions.

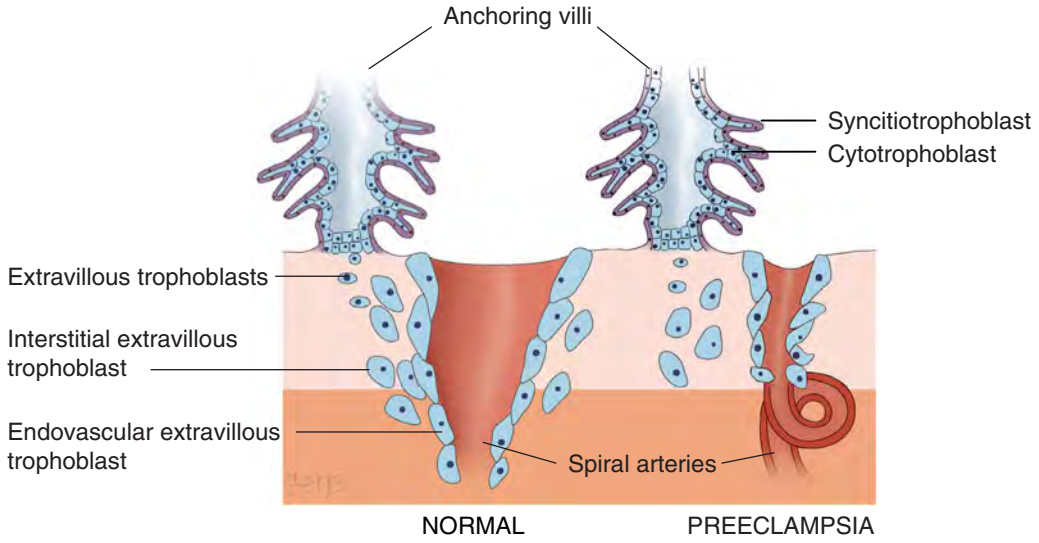

FIGURE 34-2 A. Normal third-trimester placental implantation shows proliferation of extravillous trophoblasts from an anchoring villus. These trophoblasts invade the decidua and extend into the walls of the spiral arteriole to replace the endothelium and muscular wall. This remodeling creates a dilated low-resistance vessel. **B.** Placenta in preeclamptic or fetal-growth restricted pregnancy shows defective implantation. This is characterized by incomplete invasion of the spiral arteriolar wall by extravillous trophoblasts and results in a small-caliber vessel with high resistance.

Immunological Factors

Maternal immune tolerance to paternally derived placental and fetal antigens is discussed in Chapter 3 (p. 58). Loss of this tolerance, or perhaps its *dysregulation*, is another theory cited to account for preeclampsia syndrome. Certainly the histological changes at the maternal-placental interface are suggestive of acute graft rejection (Labarrere, 1988). Some of these factors are shown in **Table 34-3**.

There are also inferential data that suggest an immune-mediated disorder. For example, the risk of preeclampsia is appreciably enhanced in circumstances in which formation of blocking antibodies to placental antigenic sites *might* be impaired. In this scenario, the first pregnancy would carry a higher risk. Tolerance dysregulation might also explain an increased risk when the paternal antigenic load is increased, that is, with two sets of paternal chromosomes—a "double dose." For example, women with molar pregnancies have a high incidence of early-onset preeclampsia. Also, women with a trisomy 13 fetus have a 30- to 40-percent incidence of preeclampsia. Bdolah and associates (2006) showed that these women also have elevated serum levels of antiangiogenic factors. The gene for one of these factors, sFLT-1, is on chromosome 13. Conversely, women previously exposed to paternal antigens, such as a prior pregnancy—with the same, but not different partner—are "immunized" against preeclampsia. This phenomenon is not as apparent in women with a prior abortion. Strickland and

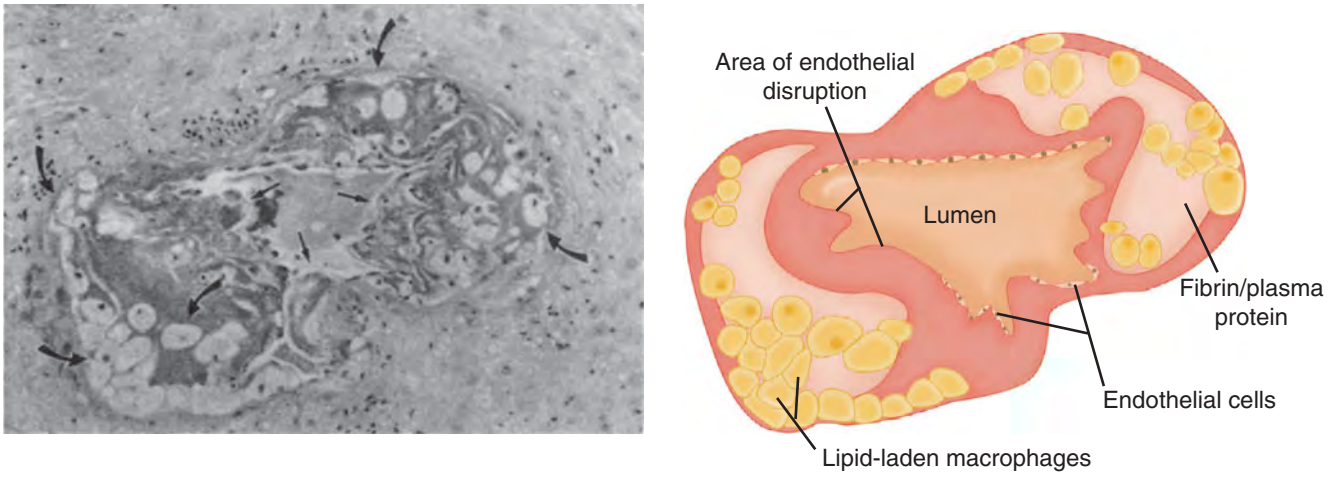

FIGURE 34-3 Atherosis is demonstrated in this blood vessel from a placental bed (*left*, photomicrograph; *right*, schematic diagram of the photomicrograph). Disruption of the endothelium results in a narrowed lumen because of accumulation of plasma proteins and foamy macrophages beneath the endothelium. In the left photograph, some of the foamy macrophages are shown by *curved arrows*, and *straight arrows* highlight areas of endothelial disruption. (Modified from BB Rogers, SL Bloom, and KJ Leveno, Atherosis revisited: Current concepts on the pathophysiology of implantation site, *Obstetrical & Gynecological Survey,* Vol. 54, No. 3, pp. 189–195, 1999, with permission.)

TABLE 34-3. Some Examples of Inherited Immunogenetic Factors That May Modify Genotype and Phenotype Expression in Preeclampsia

"Immunization" from a prior gestation
Inherited haplotypes for HLA-A, -B, -D, -Ia, -II
Inherited haplotypes for NK-cell receptors—also called killer-immunoglobulin-like receptors—KIR
Possibly shared susceptibility genes with diabetes and chronic hypertension

HLA = human leukocyte antigen; NK = natural killer.
From Ward and Lindheimer (2009).

associates (1986) studied more than 29,000 pregnancies at Parkland Hospital and reported that hypertensive disorders were significantly decreased, but not by much—22 versus 25 percent—in women who previously had miscarried compared with nulligravidas. Other studies have shown that multiparous women impregnated by a new consort have an increased risk of preeclampsia (Mostello and co-workers, 2002).

Redman and colleagues (2009) recently reviewed the possible role of *immune maladaptation* in the pathophysiology of preeclampsia. Early in a pregnancy destined to be preeclamptic, extravillous trophoblast express reduced amounts of immunosuppressive human leukocyte antigen G (HLA-G). This may contribute to defective placental vascularization in stage 1. Recall that as discussed in Chapter 3 (p. 59), during normal pregnancy, T-helper (Th) lymphocytes are produced so that type 2 activity is increased in relation to type 1—termed *type 2 bias* (Redman and Sargent, 2008). Th_2 cells promote humoral immunity, whereas Th_1 cells stimulate inflammatory cytokine secretion. Beginning in the early second trimester in women who develop preeclampsia, Th_1 action is increased and the Th_1/Th_2 ratio changes. Contributors to an enhanced immunologically mediated inflammatory reaction are stimulated by placental *microparticles*, as well as by adipocytes (Redman and Sargent, 2008).

Endothelial Cell Activation

In many ways, inflammatory changes are thought to be a continuation of the stage 1 changes caused by defective placentation discussed above. In response to placental factors released by ischemic changes or by any other inciting cause, a cascade of events is set in motion (Taylor and colleagues, 2009). Thus, antiangiogenic and metabolic factors and other inflammatory mediators are thought to provoke endothelial cell injury.

It has been proposed that endothelial cell dysfunction is due to an extreme activated state of leukocytes in the maternal circulation (Faas, 2000; Gervasi, 2001; Redman, 1999, and all their colleagues). Briefly, cytokines such as tumor necrosis factor-α (TNF-α) and the interleukins (IL) may contribute to the oxidative stress associated with preeclampsia. This is characterized by reactive oxygen species and free radicals that lead to formation of self-propagating lipid peroxides (Manten and associates, 2005). These in turn generate highly toxic radicals that injure endothelial cells, modify their nitric oxide production, and interfere with prostaglandin balance. Other consequences of oxidative stress include production of the lipid-laden macrophage foam cells seen in atherosis and shown in Figure 34-2; activation of microvascular coagulation manifest by thrombocytopenia; and increased capillary permeability manifest by edema and proteinuria.

These observations on the effects of oxidative stress in preeclampsia have given rise to increased interest in the potential benefit of antioxidants to prevent preeclampsia. Antioxidants are from a diverse family of compounds that function to prevent overproduction of and damage caused by noxious free radicals. Examples of antioxidants include vitamin E (α-tocopherol), vitamin C (ascorbic acid), and β-carotene. Dietary supplementation with these antioxidants to prevent preeclampsia has thus far proven unsuccessful and is discussed further on page 727.

Nutritional Factors

John and co-workers (2002) showed that in the general population a diet high in fruits and vegetables that have antioxidant activity is associated with decreased blood pressure. Zhang and associates (2002) reported that the incidence of preeclampsia was doubled in women whose daily intake of ascorbic acid was less than 85 mg. These studies were followed by randomized trials to study dietary supplementation. Villar and associates (2006) showed that calcium supplementation in populations with a *low dietary calcium intake* had a small effect to lower perinatal mortality rates, but no effect on the incidence of preeclampsia (see p. 727). In a number of trials, supplementation with the antioxidant vitamins C and E showed no beneficial effects.

Genetic Factors

Preeclampsia is a multifactorial, polygenic disorder. In their comprehensive review, Ward and Lindheimer (2009) cite an incident risk for preeclampsia of 20 to 40 percent for daughters of preeclamptic mothers; 11 to 37 percent for sisters of preeclamptic women; and 22 to 47 percent in twin studies. In a study by Nilsson and co-workers (2004) that included almost 1.2 million Swedish births, they reported a genetic component for gestational hypertension as well as preeclampsia. They also reported 60-percent concordance in monozygotic female twin pairs.

This hereditary predisposition likely is the result of interactions of literally hundreds of inherited genes—both maternal and paternal—that control myriad enzymatic and metabolic functions throughout every organ system. Thus, the clinical manifestation in any given woman with the preeclampsia syndrome will occupy a spectrum as discussed under the two-stage concept on page 710. In this regard, phenotypic expression will differ among similar genotypes depending on interactions with environmental factors.

Candidate Genes. From their recent review, Ward and Lindheimer (2009) found that more than 70 genes have been studied for their possible association with preeclampsia. Seven of

TABLE 34-4. Genes Frequently Studied for Their Association with Preeclampsia Syndrome

Gene (Polymorphism)	Function Affected	Chromosome	Biological Association
MTHFR (C677T)	Methylene tetrahydrofolate reductase	1p36.3	Vascular diseases
F5 (Leiden)	Factor V_{Leiden}	1q23	Thrombophilia—may coexist with other thrombophilic genes
AGT (M235T)	Angiotensinogen	1q42-q43	Blood pressure regulation, linked to essential hypertension
HLA (Various)	Human leukocyte antigens	6p21.3	Immunity
NOS3 (Glu 298 Asp)	Endothelial nitric oxide	7q36	Vascular endothelial function
F2 (G20210A)	Prothrombin (factor II)	11p11-q12	Coagulation—weakly associated, studied with other thrombophilic genes
ACE (I/D[at]Intron 16)	Angiotensin-converting enzyme	17q23	Blood pressure regulation

Adapted from Ward and Lindheimer, 2009.

these that have been investigated widely are listed in Table 34-4. More than 100 studies of these seven genes were considered, and fewer than half reported a positive significant association with the gene(s) analyzed. Polymorphisms of the genes for Fas, hypoxia-inducible factor-1α protein (HIF-1α), IL-1β, lymphotoxin-α, transforming growth factor beta 3 (TGF-β3), and TNF have also been studied with varying results (Borowski, 2009; Hefler, 2001; Lachmeijer, 2001; Livingston, 2001; Wilson, 2009, and all their colleagues).

Because of the heterogeneity of the preeclampsia syndrome, and especially the other genetic and environmental factors that interact with its complex phenotypic expression, it is doubtful that any *one* candidate gene will be found responsible.

Other Genetic Variables. There is an extensive list of other variables that affect genotypic and phenotypic expression of the preeclampsia syndrome. Some include:

1. Multiple genotypes: maternal and paternal (fetal and placental)
2. Subgroups: associated disorders such as diabetes and characteristics such as parity
3. Genomic ethnicity: frequency of polymorphisms, genetic drift, founder effect, and selection
4. Gene-gene interaction: specific alleles or products of two or more genes affect one another and thus the phenotype
5. Epigenetic phenomena: variations in expression of a functional stable gene, for example, monozygotic twin differences
6. Gene-environmental interactions—these are infinite.

Pathogenesis

Vasospasm

The concept of vasospasm was advanced by Volhard (1918) based on his direct observations of small blood vessels in the nail beds, ocular fundi, and bulbar conjunctivae. It was also surmised from histological changes seen in various affected organs (Hinselmann, 1924; Landesman and co-workers, 1954). Vascular constriction causes increased resistance and subsequent hypertension. At the same time, endothelial cell damage causes interstitial leakage through which blood constituents, including platelets and fibrinogen, are deposited subendothelially. Wang and colleagues (2002) have also demonstrated disruption of endothelial junctional proteins. Suzuki and co-workers (2003) described ultrastructural changes in the subendothelial region of resistance arteries in preeclamptic women. With diminished blood flow because of maldistribution, ischemia of the surrounding tissues would lead to necrosis, hemorrhage, and other end-organ disturbances characteristic of the syndrome.

Endothelial Cell Activation

During the past two decades, endothelial cell activation has become the centerpiece in the contemporary understanding of the pathogenesis of preeclampsia. In this scheme, unknown factor(s)—likely placental in origin—are secreted into the maternal circulation and provoke activation and dysfunction of the vascular endothelium. The clinical syndrome of preeclampsia is thought to result from these widespread endothelial cell changes. In addition to microparticles, Grundmann and associates (2008) have reported that *circulating endothelial cell—CEC*—levels are significantly elevated fourfold in the peripheral blood of preeclamptic women.

Intact endothelium has anticoagulant properties, and endothelial cells blunt the response of vascular smooth muscle to agonists by releasing nitric oxide. Damaged or activated endothelial cells may produce less nitric oxide and secrete substances that promote coagulation and increase sensitivity to vasopressors (Gant and co-workers, 1974). Further evidence of endothelial activation includes the characteristic changes in glomerular capillary endothelial morphology, increased capillary permeability, and elevated blood concentrations of

substances associated with endothelial activation. These latter substances are transferable, and serum from women with preeclampsia stimulates some of these substances in greater amounts. It seems likely that multiple factors in plasma of preeclamptic women combine to have these vasoactive effects (Myers and associates, 2007; Walsh, 2009).

Increased Pressor Responses. As discussed in Chapter 5 (p. 120), pregnant women normally develop refractoriness to infused vasopressors (Abdul-Karim and Assali, 1961). Women with early preeclampsia, however, have increased vascular reactivity to infused norepinephrine and angiotensin II (Raab and co-workers, 1956; Talledo and associates, 1968). Moreover, increased sensitivity to angiotensin II clearly precedes the onset of gestational hypertension. Gant and colleagues (1974) showed that normotensive nulliparas remained refractory to infused angiotensin II, but those who subsequently became hypertensive lost this refractoriness several weeks before the onset of hypertension.

Prostaglandins. A number of prostanoids are thought to be central to the pathophysiology of the preeclampsia syndrome. Specifically, the blunted pressor response seen in normal pregnancy is at least partially due to decreased vascular responsiveness mediated by endothelial prostaglandin synthesis. For example, compared with normal pregnancy, endothelial prostacyclin (PGI_2) production is decreased in preeclampsia. This action appears to be mediated by phospholipase A_2 (Taylor and Roberts, 1999). At the same time, thromboxane A_2 secretion by platelets is increased, and the prostacyclin:thromboxane A_2 ratio decreases. The net result favors increased sensitivity to infused angiotensin II, and ultimately, vasoconstriction (Spitz and colleagues, 1988). Chavarria and co-workers (2003) have provided evidence that these changes are apparent as early as 22 weeks in women who later develop preeclampsia.

Nitric Oxide. This potent vasodilator is synthesized from L-arginine by endothelial cells. Withdrawal of nitric oxide results in a clinical picture similar to preeclampsia in a pregnant animal model (Conrad and Vernier, 1989). Inhibition of nitric oxide synthesis increases mean arterial pressure, decreases heart rate, and reverses the pregnancy-induced refractoriness to vasopressors. In humans, nitric oxide likely is the compound that maintains the normal low-pressure vasodilated state characteristic of fetoplacental perfusion (Myatt and co-workers, 1992; Weiner and associates, 1992). It also is produced by fetal endothelium and is increased in response to preeclampsia, diabetes, and infection (Parra and associates, 2001; von Mandach and co-workers, 2003).

The effects of nitric oxide production in preeclampsia are unclear (Taylor and associates, 2009). It appears that the syndrome is associated with decreased endothelial nitric oxide synthase expression, thus increasing nitric oxide inactivation. These responses may be race-related, with African-American women producing more nitric oxide (Wallace and co-workers, 2009).

Endothelins

These 21-amino acid peptides are potent vasoconstrictors, and endothelin-1 (ET-1) is the primary isoform produced by human endothelium (Mastrogiannis and co-workers, 1991). Plasma ET-1 levels are increased in normotensive pregnant women, but women with preeclampsia have even higher levels (Ajne, 2003; Clark, 1992; Nova, 1991, and all their associates). According to Taylor and Roberts (1999), the placenta is not the source of increased ET-1 concentrations, and they likely arise from systemic endothelial activation. Interestingly, treatment of preeclamptic women with magnesium sulfate lowers ET-1 concentrations (Sagsoz and Kucukozkan, 2003).

Angiogenic and Antiangiogenic Proteins

Placental vasculogenesis is evident by 21 days after conception. There is an ever-expanding list of pro- and antiangiogenic substances involved in placental vascular development. The families of vascular endothelial growth factor (VEGF) and angiopoietins (Ang) gene products are most extensively studied. *Angiogenic imbalance* is used to describe excessive amounts of antiangiogenic factors that are hypothesized to be stimulated by worsening hypoxia at the uteroplacental interface. Trophoblastic tissue of women destined to develop preeclampsia overproduces at least two antiangiogenic peptides that enter the maternal circulation (Karumanchi and colleagues, 2009):

1. *Soluble Fms-like tyrosine kinase 1 (sFlt-1)* is a variant of the Flt-1 receptor for placental growth factor (PlGF) and vascular endothelial growth factor (VEGF). Increased maternal sFlt-1 levels inactivate and decrease circulating free PlGF and VEGF concentrations leading to endothelial dysfunction (Maynard and associates, 2003). As shown in **Figure 34-4A**, sFlt-1 levels begin to increase in maternal serum months before preeclampsia is evident.
2. *Soluble endoglin (sEng)* is a placenta-derived 65-kDa molecule that blocks endoglin—also called CD105—which is a co-receptor for the TGF-β family. This soluble form of endoglin inhibits various TGF-β isotopes from binding to endothelial receptors and results in decreased endothelial nitric oxide-dependent vasodilatation (Levine and co-workers, 2006; Venkatesha and associates, 2006). As shown in **Figure 34-4B**, sEng serum levels also begin to increase months before clinical preeclampsia develops.

The cause of placental overproduction of antiangiogenic proteins remains an enigma. The soluble forms are not increased in the fetal circulation or amnionic fluid, and their levels in maternal blood dissipate after delivery (Staff and co-workers, 2007). Research currently is focused on immunological mechanisms, oxidative stress, mitochondrial pathology, and hypoxia genes (Karumanchi and colleagues, 2009). Clinical research is directed at use of antiangiogenic proteins in the prediction and diagnosis of preeclampsia. In a systematic review, Widmer and associates (2007) concluded that retrospective studies show that third-trimester elevation of Sflt-1 levels and decreased PlGF concentrations correlate with preeclampsia development after 25 weeks. These results require verification in prospective studies.

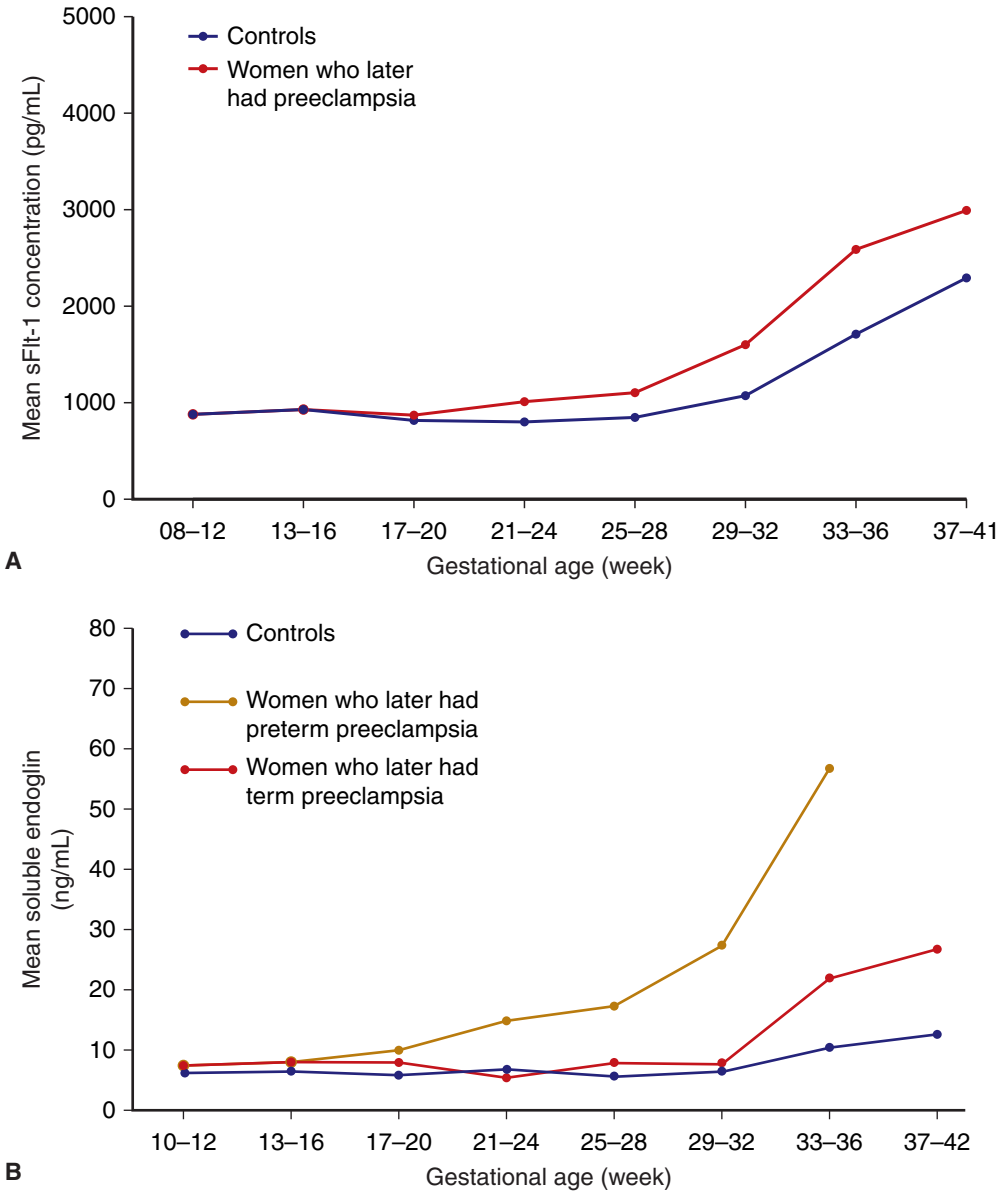

FIGURE 34-4 Angiogenic factors measured across pregnancy in women with and without preeclampsia. **A.** Mean sFlt-1 serum concentrations after logarithmic transformation show divergence of values before and after preeclampsia developed. **B.** Mean serum concentrations of soluble endoglin after logarithmic transformation also show divergence before and after preeclampsia developed. (Adapted from Levine and co-workers, 2006.)

PATHOPHYSIOLOGY

Although the cause of preeclampsia still remains unknown, evidence for its manifestation begins early in pregnancy with covert pathophysiological changes that gain momentum across gestation and eventually become clinically apparent. Unless delivery supervenes, these changes ultimately result in multi-organ involvement with a clinical spectrum ranging from barely noticeable to one of cataclysmic pathophysiological deterioration that can be life threatening for both mother and fetus. As discussed, these are thought to be a consequence of vasospasm, endothelial dysfunction, and ischemia. Although the myriad of maternal consequences of the preeclampsia syndrome are usually described in terms of individual organ systems, they frequently are multiple and they clinically overlap.

Cardiovascular System

Severe disturbances of normal cardiovascular function are common with preeclampsia or eclampsia. These are related to: (1) increased cardiac afterload caused by hypertension; (2) cardiac preload, which is substantively affected by pathologically diminished hypervolemia of pregnancy or is iatrogenically increased by intravenous crystalloid or oncotic solutions; and (3) endothelial activation with extravasation of intravascular fluid into the extracellular space, and importantly, into the lungs

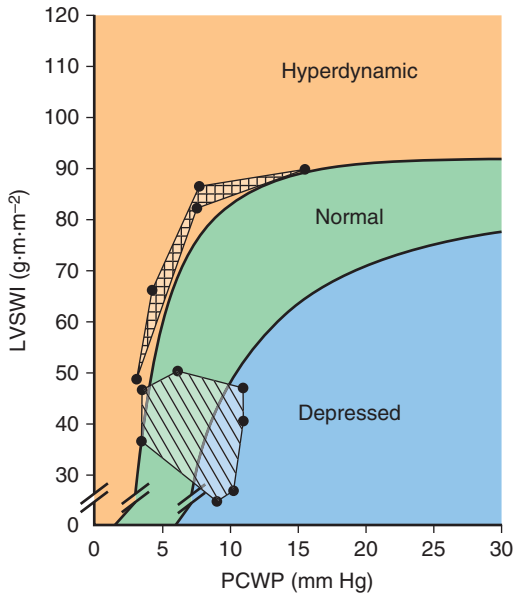

FIGURE 34-5 Ventricular function in normally pregnant women (*striped area*) and in women with eclampsia (*boxed area*) is plotted on a Braunwald ventricular function curve. Normal values are from Clark and colleagues (1989) and those for eclampsia are from Hankins and associates (1984).

(see Chap. 42, p. 929). As discussed in Chapter 5 (p. 118), during normal pregnancy, left ventricular mass increases, but there is no convincing evidence that additional structural changes are induced by preeclampsia (Hibbard and colleagues, 2009).

Hemodynamic Changes

The cardiovascular aberrations of pregnancy-related hypertensive disorders vary depending on a number of factors. These aberrations center around increased afterload and include severity of hypertension, presence of underlying chronic disease, presence of preeclampsia, and stage of the clinical course in which they are studied. There are claims that in some women these changes may even precede the onset of hypertension (Bosio, 1999; De Paco, 2008; Easterling, 1990; Hibbard, 2009, and all their colleagues). Nevertheless, with the clinical onset of preeclampsia, there is reduction in cardiac output likely due to increased peripheral resistance.

There are a number of studies in which data were obtained using invasive hemodynamic methods. Importantly, both nonhypertensive pregnant women and those with severe preeclampsia have normal or hyperdynamic ventricular function, as shown in **Figure 34-5**. In both of these groups, cardiac output is appropriate for left-sided filling pressures. Data from preeclamptic women obtained by invasive hemodynamic studies are confounded because of the heterogeneity of populations and interventions that also may significantly alter these measurements, such as substantive crystalloid infusions, antihypertensive agents, and magnesium sulfate. Ventricular function studies of preeclamptic women from a number of investigations are shown in **Figure 34-6**. Although cardiac function was hyperdynamic in all women, filling pressures were dependent on intravenous fluid infusions. Specifically, aggressive hydration resulted in hyperdynamic ventricular function in most women. Importantly, this is also accompanied by elevated pulmonary capillary wedge pressures. In some of these women, pulmonary edema may develop despite normal ventricular function because of an alveolar endothelial-epithelial leak that is compounded by decreased oncotic pressure from a low serum albumin concentration (American College of Obstetricians and Gynecologists, 2002a). Similar values of cardiac function were reported earlier by Lang and co-workers (1991) and more recently by Tihtonen and colleagues (2006), who used noninvasive impedance cardiography.

Thus, hyperdynamic ventricular function was largely a result of low wedge pressures and not a result of augmented myocardial contractility measured as left ventricular stroke work index. By comparison, women given appreciably larger volumes of fluid commonly had filling pressures that exceeded normal, but their ventricular function remained hyperdynamic because of increased cardiac output.

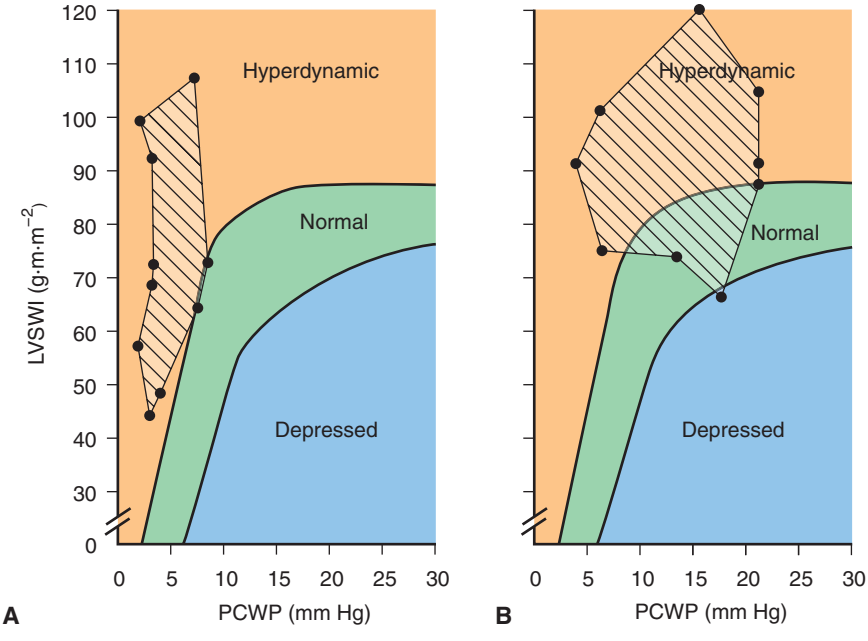

FIGURE 34-6 Ventricular function in women with severe preeclampsia–eclampsia plotted on the Braunwald ventricular function curve. The pulmonary capillary wedge pressures (PCWP) are lower in those managed with restricted fluid administration (*striped area in* **A**) compared with women managed with aggressive fluid therapy (*striped area in* **B**). In those managed with aggressive fluid infusions, eight developed pulmonary edema despite normal to hyperdynamic ventricular function in all but one. Data for **A** are from Benedetti (1980) and Hankins (1984) and colleagues and for **B** from Rafferty and Berkowitz (1980) and Phelan and Yurth (1982).

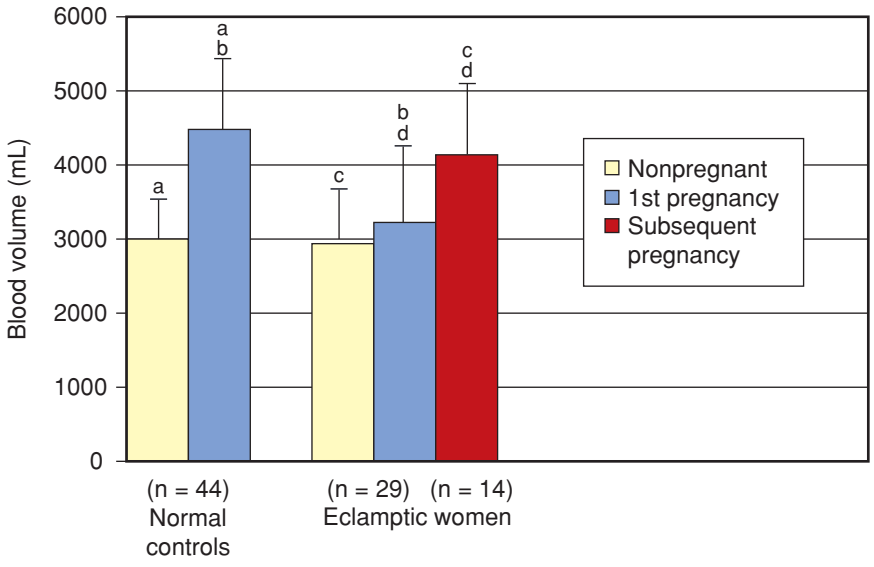

FIGURE 34-7 Bar graph comparing nonpregnant mean blood volumes with those obtained at the time of delivery in a group of women with normal pregnancy, eclampsia in their first pregnancy, and subsequent normal pregnancy in some of the women who had eclampsia. Extensions above bars represent one standard deviation. Comparison between values with identical lowercase letters, that is, a-a, b-b, c-c, d-d, are significant $p < .001$. (Data from Zeeman and Cunningham, 2009, with permission.)

From these studies, it is reasonable to conclude that aggressive fluid administration to women with severe preeclampsia causes normal left-sided filling pressures to become substantively elevated and increases an already normal cardiac output to supranormal levels.

Blood Volume

It has been known for nearly 100 years that *hemoconcentration* is a hallmark of eclampsia. Zeeman and colleagues (2009a) expanded the previous observations of Pritchard and co-workers (1984). They found that in *eclamptic* women, the normally expected hypervolemia is severely curtailed and in some women, even absent (Fig. 34-7). Women of average size should have a blood volume of nearly 5000 mL during the last several weeks of a normal pregnancy, compared with approximately 3500 mL when not pregnant. With eclampsia, however, much or all of the anticipated normal excess 1500 mL is lost. Such hemoconcentration results from generalized vasoconstriction that follows endothelial activation and leakage of plasma into the interstitial space because of increased permeability. In women with *preeclampsia*, and depending on its severity, hemoconcentration is usually not as marked. Women with gestational hypertension, but without preeclampsia, usually have a normal blood volume (Silver and colleagues, 1998).

For women with severe hemoconcentration, it was once taught that an acute fall in hematocrit suggested resolution of preeclampsia. In this scenario, hemodilution follows endothelial healing with return of interstitial fluid into the intravascular space. **While this is somewhat correct, it is important to recognize that a substantive cause of this fall in hematocrit is usually the consequence of blood loss at delivery.** It may also be partially the result of increased erythrocyte destruction as subsequently described. Vasospasm and endothelial leakage of plasma may persist for a variable amount of time after delivery as the endothelium undergoes repair. As this takes place, vasoconstriction reverses, and as the blood volume increases, the hematocrit usually falls. Thus, women with eclampsia:

- Are unduly sensitive to vigorous fluid therapy administered in an attempt to expand the contracted blood volume to normal pregnancy levels.
- Are sensitive to amounts of blood loss at delivery that are considered normal for a normotensive woman.

Blood and Coagulation

Hematological abnormalities develop in some women with preeclampsia. Among those commonly identified is thrombocytopenia, which at times may become so severe as to be life threatening. In addition, the levels of some plasma clotting factors may be decreased, and erythrocytes may display bizarre shapes and undergo rapid hemolysis.

Thrombocytopenia

Thrombocytopenia with eclampsia has been described at least since 1922 by Stancke. Because it is common, the platelet count is routinely measured in women with any form of gestational hypertension. The frequency and intensity of thrombocytopenia vary and are dependent on the severity and duration of the preeclampsia syndrome as well as the frequency with which platelet counts are performed (Heilmann and colleagues, 2007; Hupuczi and coworkers, 2007). Overt thrombocytopenia—defined by a platelet count $< 100{,}000/\mu L$—indicates severe disease (see Table 34-2). In general, the lower the platelet count, the higher the rates of maternal and fetal morbidity and mortality (Leduc and co-workers, 1992). In most cases, delivery is advisable because thrombocytopenia usually continues to worsen. After delivery, the platelet count may continue to decrease for the first day or so. It then usually increases progressively to reach a normal level usually within 3 to 5 days. In some instances, for example, with HELLP syndrome, the platelet count continues to fall after delivery. In some women whose platelet counts do not nadir until 48 to 72 hours, preeclampsia syndrome may be incorrectly attributed to one of the thrombotic microangiopathies (see Chap. 51, p. 1095).

Other Platelet Abnormalities. In addition to thrombocytopenia, there are myriad other platelet alterations described with the preeclampsia syndrome. These were recently reviewed by Kenny and associates (2009) and include platelet activation with increased degranulation, thromboxane A_2 release, and decreased lifespan. Paradoxically, in most studies, in vitro platelet aggregation is decreased compared with the normal increase characteristic of pregnancy (Kenny and associates, 2009). This

likely is due to platelet "exhaustion" following in vivo activation. Although the cause is unknown, immunological processes or simply platelet deposition at sites of endothelial damage may be implicated. Platelet-bound and circulating platelet-bindable immunoglobulins are increased, which suggest platelet surface alterations (Samuels and colleagues, 1987).

Neonatal Thrombocytopenia. In a large clinical study, Pritchard and colleagues (1987) showed that severe thrombocytopenia did not develop in the fetus or infant in preeclamptic women. In fact, these investigators found no cases of fetal thrombocytopenia despite severe maternal thrombocytopenia. *Maternal thrombocytopenia in hypertensive women is not a fetal indication for cesarean delivery.*

Hemolysis

Severe preeclampsia is frequently accompanied by evidence of hemolysis, which is semiquantified by elevated serum lactate dehydrogenase levels. Other evidence comes from schizocytosis, spherocytosis, and reticulocytosis in peripheral blood (Cunningham and associates, 1985; Pritchard and colleagues, 1954, 1976). These derangements result in part from microangiopathic hemolysis caused by endothelial disruption with platelet adherence and fibrin deposition. Sanchez-Ramos and colleagues (1994) described increased erythrocyte membrane fluidity with HELLP syndrome, and Cunningham and co-workers (1995) postulated that these changes were due to serum lipid alterations. Erythrocytic membrane changes, increased adhesiveness, and aggregation may also facilitate a hypercoagulable state (Gamzu and co-workers, 2001; Grisaru and associates, 1997).

HELLP Syndrome. In addition to hemolysis and thrombocytopenia, it also became appreciated that elevated serum liver transaminase levels were commonly found with severe preeclampsia and were indicative of hepatocellular necrosis (Chesley, 1978). Weinstein (1982) referred to this combination of events as the *HELLP syndrome*—and this moniker now is used worldwide. As shown in Table 34-2, facets of the HELLP syndrome are included in criteria that differentiate severe from nonsevere preeclampsia. It is discussed in further detail on page 720.

Coagulation

Subtle changes consistent with intravascular coagulation, and less often erythrocyte destruction, commonly are found with preeclampsia and especially eclampsia (Kenny and colleagues, 2009). Some of these changes include increased factor VIII consumption, increased levels of fibrinopeptides A and B and of fibrin degradation products, and decreased levels of regulatory proteins—antithrombin III and protein C and S. That said, there is little evidence that these abnormalities are clinically significant (Chesley, 1978; Pritchard and associates, 1984). Except for thrombocytopenia discussed above, coagulation aberrations generally are mild. Unless there is associated placental abruption, plasma fibrinogen levels do not differ remarkably from levels found in normal pregnancy, and fibrin degradation products are elevated only occasionally. Barron and colleagues (1999) found that routine laboratory assessment of coagulation, including prothrombin time, activated partial thromboplastin time, and plasma fibrinogen level, to be unnecessary in the management of pregnancy-associated hypertensive disorders.

Other Clotting Factors. The *thrombophilias* are clotting factor deficiencies that lead to hypercoagulability. They may be associated with early-onset preeclampsia (see Table 47-3, p. 1018). *Fibronectin*, a glycoprotein associated with vascular endothelial cell basement membrane, is elevated in women with preeclampsia (Brubaker and colleagues, 1992). This observation is consistent with the view that preeclampsia causes vascular endothelial injury with subsequent hematological aberrations.

Volume Homeostasis

Endocrine Changes

Plasma levels of *renin, angiotensin II, angiotensin 1-7, and aldosterone* are substantively increased during normal pregnancy. With preeclampsia, and despite decreased blood volume, these values decrease substantively, but still remain above nonpregnant values (Luft and colleagues, 2009).

Deoxycorticosterone (DOC) is a potent mineralocorticoid that is increased remarkably in normal pregnancy (see Chap. 5, p. 129). This results from conversion of plasma progesterone to DOC rather than increased maternal adrenal secretion. Because of this, DOC secretion is not reduced by sodium retention or hypertension, and it may explain why women with preeclampsia retain sodium (Winkel and co-workers, 1980).

Vasopressin levels are similar in nonpregnant, normally pregnant, and preeclamptic women even though the latter two have substantively decreased plasma osmolality (Dürr and Lindheimer, 1999). It is yet unclear whether serum concentrations of *atrial natriuretic peptide* remain unchanged, or whether they are increased during normal pregnancy despite the increased plasma volume (Luft and colleagues, 2009). This peptide is released on atrial wall stretching from blood volume expansion, and it responds to cardiac contractility. Secretion of atrial natriuretic peptide is increased in women with preeclampsia (Borghi and associates, 2000; Luft and colleagues, 2009).

Fluid and Electrolyte Changes

In women with severe preeclampsia, the volume of *extracellular fluid,* manifest as edema, is usually much greater than that of normal pregnant women. The mechanism responsible for pathological fluid retention is thought to be endothelial injury. In addition to generalized edema and proteinuria, these women have reduced plasma oncotic pressure. This reduction creates a filtration imbalance and further displaces intravascular fluid into the surrounding interstitium.

Electrolyte concentrations do not differ appreciably in women with preeclampsia compared with those of normal pregnant women. This may not be the case if there has been vigorous diuretic therapy, sodium restriction, or administration of free water with sufficient oxytocin to produce antidiuresis.

Following an eclamptic convulsion, the serum pH and *bicarbonate* concentration are lowered due to lactic acidosis and compensatory respiratory loss of carbon dioxide. The intensity of acidosis relates to the amount of lactic acid produced and the rate at which carbon dioxide is exhaled.

Kidney

During normal pregnancy, renal blood flow and glomerular filtration rate are increased appreciably (see Chap. 5, p. 123 and Appendix). With development of preeclampsia, there may be a number of reversible anatomical and pathophysiological changes. Of clinical importance, renal perfusion and glomerular filtration are reduced. Levels that are much less than normal nonpregnant values are infrequent and are the consequence of severe disease.

Mildly diminished glomerular filtration may result from a reduced plasma volume. Most of the decrement is probably from increased renal afferent arteriolar resistance that may be elevated up to fivefold (Conrad and co-workers, 2009). There are also morphological changes characterized by glomerular endotheliosis blocking the filtration barrier. Diminished filtration causes serum creatinine values to rise to values seen in nonpregnant individuals, that is, 1 mg/mL, but sometimes even higher (Lindheimer and colleagues, 2008a).

In most preeclamptic women, urine sodium concentration is elevated. Urine osmolality, urine:plasma creatinine ratio, and fractional excretion of sodium are also indicative that a prerenal mechanism is involved. Kirshon and co-workers (1988) infused dopamine intravenously into oliguric women with preeclampsia, and this renal vasodilator stimulated increased urine output, fractional sodium excretion, and free water clearance. As was shown in Figure 34-6, crystalloid infusion increases left ventricular filling pressure, and although oliguria temporarily improves, rapid infusions may cause clinically apparent pulmonary edema. *Intensive intravenous fluid therapy is not indicated for these women with oliguria, unless diminished urine output is caused by hemorrhage.*

Plasma uric acid concentration is typically elevated in preeclampsia. The elevation exceeds the reduction in glomerular filtration rate and likely is also due to enhanced tubular reabsorption (Chesley and Williams, 1945). At the same time, preeclampsia is associated with diminished urinary excretion of calcium perhaps because of increased tubular reabsorption (Taufield and associates, 1987). Another possibility is from increased placental urate production compensatory to increased oxidative stress.

Proteinuria

At least some degree of proteinuria will establish the diagnosis of preeclampsia-eclampsia. Proteinuria may develop late, and some women may be delivered—or have an eclamptic convulsion—before it appears. For example, Sibai (2004) reported that 10 to 15 percent of women with HELLP syndrome did not have proteinuria at presentation. Zwart and associates (2008) reported that 17 percent of eclamptic women did not have proteinuria by the time of seizures.

Another problem is that the optimal method of establishing either abnormal levels of urine protein or albumin remains to be defined. Chen and co-workers (2008) have shown that clean-catch and catheterized urine specimens correlate well. But dipstick qualitative determinations depend on urinary concentration and are notorious for false-positive and negative results. For a 24-hour quantitative specimen, the standard "consensus" threshold value used is $>$ 300 mg/24 h—or its extrapolated equivalent in shorter collections. Importantly, this has not been irrefutably established.

Determination of urinary protein: or albumin:creatinine ratio may supplant the cumbersome 24-hour quantification (Kyle and colleagues, 2008). In a recent systematic review, Papanna and associates (2008) concluded that random urine protein: creatinine ratios that are below 130 to 150 mg/g—0.13 to 0.15—indicate that the likelihood of proteinuria exceeding 300 mg/day is low. Midrange ratios, that is, 300 mg/g—0.3—have poor sensitivity and specificity. These investigators recommend that with midrange values, a 24-hour specimen be measured for accuracy.

There are several methods used to measure proteinuria, and none detect all of the various proteins normally excreted. A more accurate method involves measurement of albumin excretion. Albumin filtration exceeds that of larger globulins, and with glomerular disease such as preeclampsia, much of the protein in urine is albumin. Newly available test kits permit rapid measurement of urinary albumin:creatinine ratios in an outpatient setting (Kyle and co-workers, 2008).

Finally, although worsening or nephrotic-range proteinuria has been considered by most to be a sign of severe disease, this may not be the case (Airoldi and Weinstein, 2007). Thus, the quantity of protein excretion alone as an indicator of preeclampsia severity is currently being investigated.

Anatomical Changes

Changes identifiable by light and electron microscopy were commonly found in the kidney of eclamptic women at autopsy by Sheehan and Lynch (1973). Glomeruli are enlarged by approximately 20 percent, they are "bloodless," and capillary loops variably are dilated and contracted. Endothelial cells are swollen, and this was termed *glomerular capillary endotheliosis* by Spargo and associates (1959). Endothelial cells are often so swollen that they block or partially block the capillary lumens (**Fig. 34-8**). Homogeneous subendothelial deposits of proteins and fibrin-like material are seen.

There is evidence that endothelial swelling results from angiogenic factor "withdrawal" that is caused by the free protein complexing with the circulating antiangiogenic protein receptor discussed on page 714 (Eremina and associates, 2007; Karumanchi and colleagues, 2009). The angiogenic protein is crucial for podocyte health, and its inactivation by the antiangiogenic receptors leads to podocyte dysfunction and endothelial swelling. Consistent with this, Garovic and co-workers (2007) have shown increased excretion of urinary podocyte cells with eclampsia, a phenomenon shared by other proteinuric disorders. Of interest, podocytes are epithelial cells, and thus renal pathology is both endothelial and epithelial (see Fig. 34-8).

Acute Renal Failure (Acute Kidney Injury)

Rarely is *acute tubular necrosis* caused by preeclampsia alone. Although mild degrees are encountered in neglected cases, clinically apparent renal failure is invariably induced by coexistent hemorrhagic hypotension. This is usually caused by severe

obstetrical hemorrhage for which adequate blood replacement was not given (see Chap. 48, p. 1045). Drakeley and co-workers (2002) described 72 women with preeclampsia and renal failure. Half had HELLP syndrome and a third had placental abruption. As discussed on page 721, Haddad and colleagues (2000) reported that 5 percent of 183 women with HELLP syndrome developed acute renal failure. Half of these also had a placental abruption, and most had postpartum hemorrhage. Rarely, irreversible *renal cortical necrosis* develops.

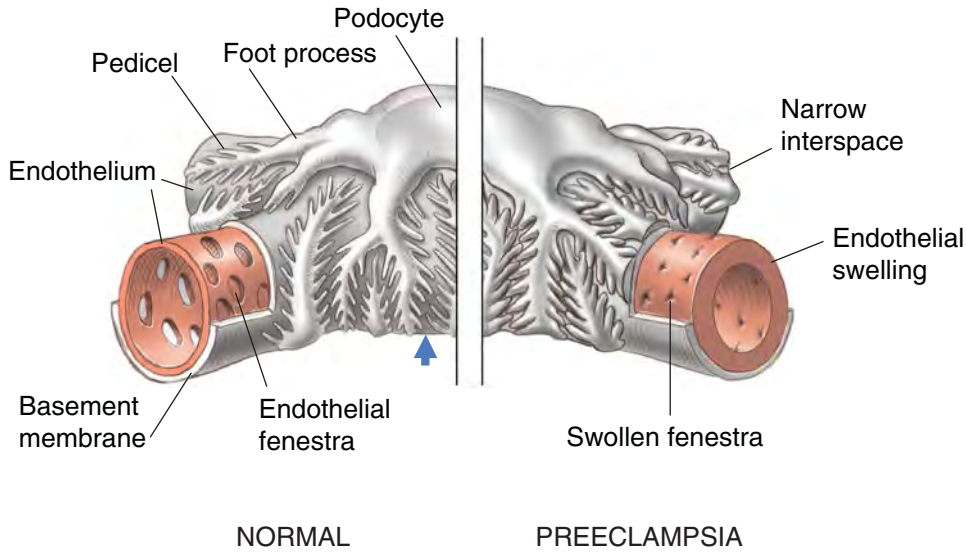

FIGURE 34-8 Schematic showing glomerular capillary endotheliosis. The capillary of the normal glomerulus shown on the left has wide endothelial fenestrations, and the pedicels emanating from the podocytes are widely spaced (*arrow*). The illustration on the right is of a glomerulus with changes induced by the preeclampsia syndrome. The endothelial cells are swollen and their fenestrae narrowed, as are the pedicels that now abut each other.

Liver

Hepatic changes in women with fatal eclampsia were described in 1856 by Virchow. The characteristic lesions commonly found were regions of periportal hemorrhage in the liver periphery. In their elegant autopsy studies, Sheehan and Lynch (1973) described that some degree of hepatic infarction accompanied hemorrhage in almost half of women who died with eclampsia. These corresponded with reports that had appeared during the 1960s describing elevated serum hepatic transaminase levels. Along with the earlier observations by Pritchard and colleagues (1954), who described hemolysis and thrombocytopenia with eclampsia, this constellation of hemolysis, hepatocellular necrosis, and thrombocytopenia was later termed *HELLP syndrome* by Weinstein (1985) to call attention to its seriousness (see p. 718).

Extensive anatomical lesions such as shown in **Figure 34-9** are seldom identified with liver biopsy in nonfatal cases (Barton and colleagues, 1992). From a pragmatic point, liver involvement with preeclampsia may be clinically significant in the following circumstances:

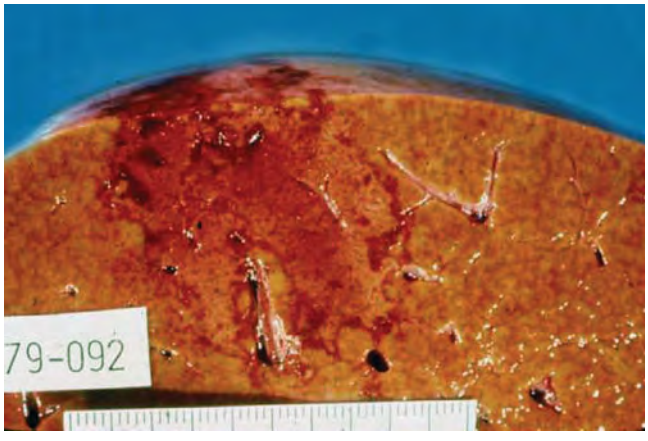

FIGURE 34-9 Gross liver specimen from a woman with preeclampsia who died from severe acidosis and liver failure. Periportal hemorrhagic necrosis was seen microscopically. (From Cunningham, 1993.)

1. Symptomatic involvement, typically manifest by moderate to severe right-upper or midepigastric pain and tenderness, is usually only seen with severe disease. In many cases, such women also have elevated serum aminotransferase levels—aspartate transferase (AST) or alanine transferase (ALT). In some cases, however, the amount of hepatic tissue involved with infarction may be surprisingly extensive, yet still clinically insignificant. In our experiences, infarction may be worsened by hypotension from obstetrical hemorrhage, and it may result in hepatic failure (Alexander and colleagues, 2009).
2. Asymptomatic elevations of serum hepatic transaminase levels—AST and ALT—are considered markers for severe preeclampsia. Values seldom exceed 500 U/L, but have been reported to exceed 2000 U/L in some women (see also Chap. 50, p. 1064). In general, serum levels inversely follow platelet levels, and they both usually normalize within 3 days following delivery.
3. Hepatic hemorrhage from areas of infarction may extend to form a hepatic hematoma. These in turn may extend to form a subcapsular hematoma that may rupture. They can be identified using computed tomography (CT) scanning or magnetic resonance (MR) imaging as shown in **Figure 34-10**. Unruptured hematomas are probably more common than clinically suspected, and are more likely with HELLP syndrome (Carlson and Bader, 2004; Rosen and colleagues, 2003). Although once considered a surgical condition, contemporaneous management usually consists of observation and conservative treatment of hematomas unless hemorrhage is ongoing (Barton and Sibai, 1999). In

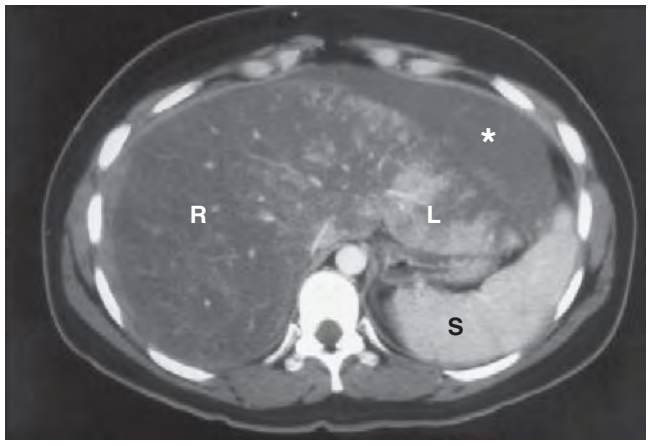

FIGURE 34-10 Abdominal CT-imaging performed postpartum in a woman with severe HELLP syndrome. A large subcapsular hematoma (*asterisk*) extends over the left lobe (*L*). The right lobe (*R*) has a heterogenous, hypodense appearance that represents widespread necrosis but with "sparing" of the left lobe—compare perfusion with normal spleen (*S*). (From Hay JE, Liver disease in pregnancy, *Hepatology,* vol. 47, no. 3, pp. 1067–1076. Copyright © 2008 American Association for the Study of Liver Diseases. Reproduced with permission of John Wiley & Sons, Inc.)

some cases, however, prompt surgical intervention may be lifesaving. Rinehart and co-workers (1999) reviewed 121 cases associated with preeclampsia, and the mortality rate was 30 percent. Rarely, liver transplant becomes necessary (Hunter and associates, 1995; Wicke and colleagues, 2004).

4. Acute fatty liver of pregnancy is sometimes confused with preeclampsia (Sibai, 2007). It too has an onset in late pregnancy, and often there is accompanying hypertension, elevated serum transaminase and creatinine levels, and thrombocytopenia (see Chap. 50**,** p. 1065).

Because there is no universally accepted definition of HELLP syndrome, its incidence varies by investigator, but when it is identified, the likelihood of hepatic hematoma and rupture is substantively increased. In a multicenter study, Haddad and colleagues (2000) described 183 women with HELLP syndrome of whom 40 percent had adverse outcomes including two maternal deaths. The incidence of subcapsular liver hematoma was 1.6 percent. Other complications included eclampsia—6 percent, placental abruption—10 percent, acute kidney injury—5 percent, and pulmonary edema—10 percent. Other serious complications included stroke, coagulopathy, acute respiratory distress syndrome, and sepsis.

There seems to be little doubt that women with preeclampsia complicated by the HELLP syndrome have worse outcomes than those without these findings. In their review of 693 women with HELLP syndrome, Keiser and co-workers (2009) reported that 10 percent had concurrent eclampsia. Sep and colleagues (2009) also described a significantly increased risk for complications in women with HELLP syndrome compared with those with "isolated preeclampsia." These included eclampsia—15 vs 4 percent, preterm birth—93 vs 78 percent, and perinatal mortality rate—9 vs 4 percent, respectively. They postulate that because of these marked clinical differences that the two disorders likely have distinct pathogenesis. Given all of the variables contributing to the incidence and pathophysiology of preeclampsia as discussed on page 709, this is a reasonable conclusion. Sibai and Stella (2009) recently discussed some of these aspects under the rubric of "atypical preeclampsia-eclampsia."

Brain

Headaches and visual symptoms are common with severe preeclampsia, and associated convulsions define eclampsia. The earliest anatomical descriptions of brain involvement came from autopsy specimens, but CT- and MR-imaging and Doppler studies have added much new and important insight into cerebrovascular involvement.

Neuroanatomical Lesions

Most descriptions of the brain in eclamptic women are taken from eras when mortality rates were high. One consistent finding was that brain pathology accounted for only about a third of fatal cases such as the one shown in **Figure 34-11**. Most deaths were from pulmonary edema, and brain lesions were coincidental. Thus, although gross intracerebral hemorrhage was seen in up to 60 percent of eclamptic women, it was fatal in only half of these (Melrose, 1984; Richards and colleagues, 1988; Sheehan and Lynch, 1973). As shown in **Figure 34-12**, other principal lesions found at autopsy of eclamptic women were cortical and subcortical petechial hemorrhages. Other frequently described major lesions include subcortical edema, multiple nonhemorrhagic areas of "softening" throughout the brain, hemorrhagic areas in the white matter, and hemorrhage in the basal ganglia or pons, often with rupture into the ventricles. The classical microscopic vascular lesions consist of fibrinoid necrosis of the arterial wall and perivascular microinfarcts and hemorrhages.

Cerebrovascular Pathophysiology

Within the past several decades, clinical, pathological, and neuroimaging findings have led to two general theories to explain cerebral abnormalities associated with eclampsia. Importantly,

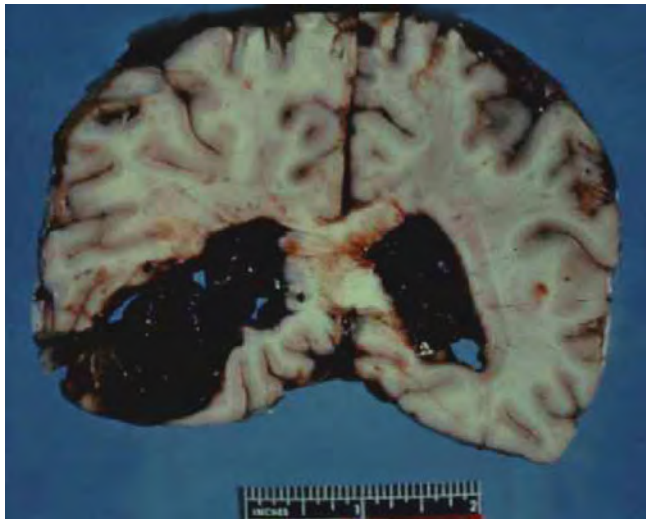

FIGURE 34-11 Fatal hypertensive hemorrhage in a primigravid woman with eclampsia.

endothelial cell dysfunction that characterizes the preeclampsia syndrome likely plays a key role in both:

1. The first theory suggests that in response to acute and severe hypertension, cerebrovascular overregulation leads to vasospasm (Trommer and associates, 1988). This presumption is based on the angiographic appearance of diffuse or multifocal segmental narrowings suggestive of vasospasm (Ito and co-workers, 1995). In this scheme, diminished cerebral blood flow is hypothesized to result in ischemia, cytotoxic edema, and eventually, tissue infarction. There is little objective evidence to support this.
2. The second theory is that sudden elevations in systemic blood pressure exceed the normal cerebrovascular autoregulatory capacity (Hauser and associates, 1988; Schwartz and co-workers, 2000). Regions of forced vasodilation and vasoconstriction develop, especially in arterial boundary zones. At the capillary level, disruption of the end-capillary pressure causes increased hydrostatic pressure, hyperperfusion, and extravasation of plasma and red cells through endothelial tight-junction openings leading to the accumulation of vasogenic edema. This theory is incomplete also because few eclamptic women have mean arterial pressures that exceed limits of autoregulation—approximately 160 mm Hg.

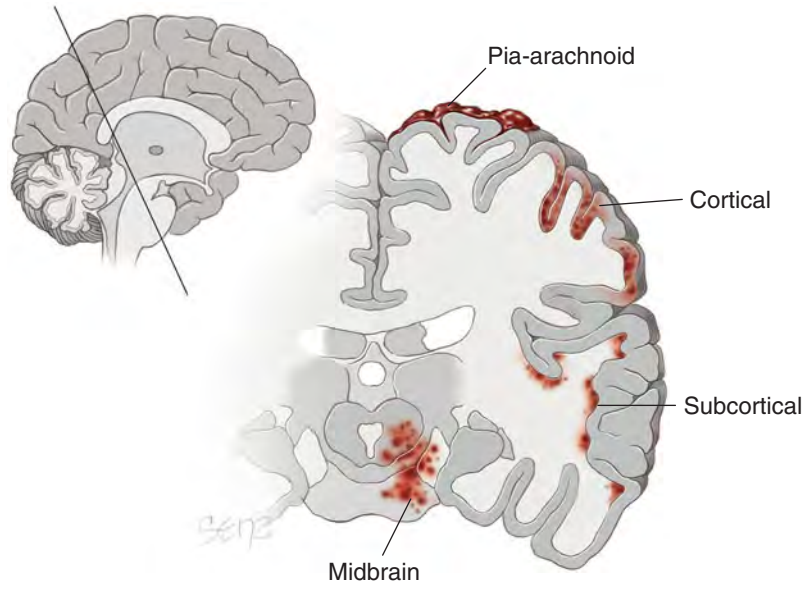

FIGURE 34-12 Composite illustration showing location of cerebral hemorrhages and petechiae in women with eclampsia. Insert shows the level of the brain from which the main image was constructed. (Data from Sheehan and Lynch, 1973.)

It seems reasonable to conclude that the most likely mechanism is a combination of the two. Thus, the preeclampsia syndrome has endothelial activation that is associated with an interendothelial cell leak that develops at blood pressure levels much lower than those causing vasogenic edema and has a loss of upper-limit autoregulation (Zeeman and colleagues, 2009b). This was described as the *reversible posterior leukoencephalopathy syndrome* by Hinchey and colleagues (1996). More recently, it is usually referred to as the *posterior reversible encephalopathy syndrome—PRES* (Narbone and associates, 2006).

Seizures consist of excessive release of excitatory neurotransmitters—especially glutamate; massive depolarization of network neurons; and bursts of action potentials (Meldrum, 2002). Clinical and experimental evidence suggest that extended seizures can cause significant brain injury and later brain dysfunction.

Cerebral Blood Flow

Autoregulation is the mechanism by which cerebral blood flow remains relatively constant despite alterations in cerebral perfusion pressure. In nonpregnant individuals, this mechanism protects the brain from hyperperfusion during mean arterial pressures up to 160 mm Hg. These are pressures far greater than those seen in all but a few women with eclampsia. Thus, to explain eclamptic seizures, it was theorized that autoregulation must be altered by pregnancy. And although species differences must be considered, studies by Cipolla and colleagues (2007, 2009) have convincingly shown that autoregulation is unchanged across pregnancy in rats.

Using exacting MR imaging techniques, Zeeman and colleagues (2003) showed that cerebral blood flow across pregnancy is similar to nonpregnant values until it decreases significantly by 20 percent during the last trimester. Zeeman and co-workers (2004b) also documented significantly increased cerebral blood flow in women with severe preeclampsia compared with that of normotensive pregnant controls. Taken together, these findings suggest that eclampsia occurs when cerebral hyperperfusion forces capillary fluid interstitially because of endothelial activation and leads to perivascular edema seen with the preeclampsia syndrome. In this regard, eclampsia has similarities to PRES.

Clinical Manifestations

There are several neurological manifestations of the preeclampsia syndrome. Each signifies severe involvement and requires immediate attention:

1. *Headache and scotomata* are thought to arise from cerebrovascular hyperperfusion that has a predilection for the occipital lobes. According to Sibai (2005) and Zwart and associates (2008), 50 to 75 percent of women have headaches and 20 to 30 percent have visual changes preceding eclamptic convulsions. The headaches may be mild to severe and intermittent to constant. In our experiences, they are unique in that they usually improve after magnesium sulfate infusion is initiated.
2. Convulsions are diagnostic for eclampsia.
3. *Blindness* is rare with preeclampsia alone, but it complicates eclamptic convulsions in up to 15 percent of women (Cunningham and colleagues, 1995). Blindness has been reported to develop up to a week or more following

delivery (Chambers and Cain, 2004). There are at least two types of blindness as discussed subsequently.

4. *Generalized cerebral edema* may develop and is usually manifest by mental status changes that vary from confusion to coma. This situation is particularly dangerous because fatal supratentorial herniation may result.

Neuroimaging Studies. With CT imaging, localized hypodense lesions at the gray-white matter junction, primarily in the parieto-occipital lobes, are typically found in eclampsia. Such lesions may also be seen in the frontal and inferior temporal lobes, the basal ganglia, and thalamus (Brown and colleagues, 1988). The spectrum of brain involvement is wide, and increasing involvement can be identified with CT imaging. Involvement of the occipital lobes or diffuse cerebral edema may create symptoms such as blindness, lethargy, and confusion (Cunningham and Twickler, 2000). In the latter cases, widespread edema shows as a marked compression or even obliteration of the cerebral ventricles. Such women may develop signs of impending life-threatening transtentorial herniation.

A number of MR imaging acquisitions are used to study eclamptic women. Common findings are hyperintense T2 lesions in the subcortical and cortical regions of the parietal and occipital lobes, with occasional involvement of basal ganglia and/or the brainstem (Zeeman and associates, 2004a). An example demonstrating involvement of the occipital lobes is shown in Figure 34-13. Although these PRES lesions are almost universal in women with eclampsia, their incidence in women with preeclampsia is less frequent. They are more likely to be found in women who have severe disease and who have neurological symptoms (Schwartz and co-workers, 2000). And although usually reversible, a fourth of these hyperintense lesions represent cerebral infarctions that have persistent findings (Loureiro and associates, 2003; Zeeman and co-workers, 2004a).

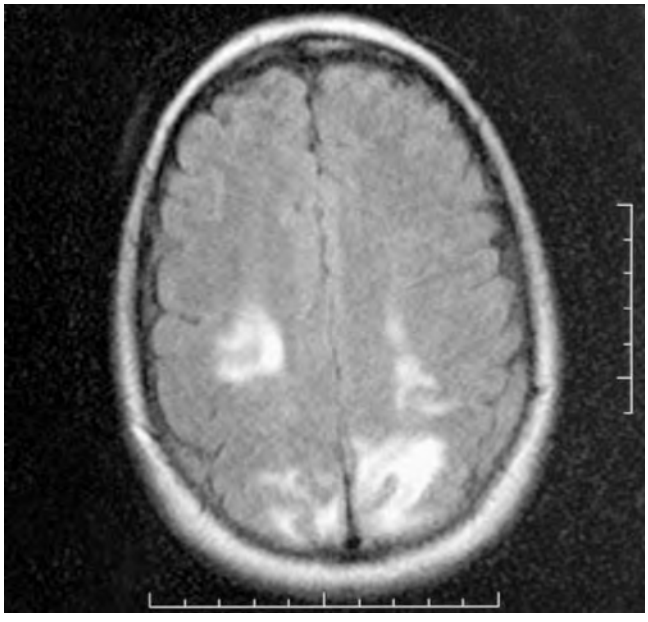

FIGURE 34-13 Magnetic resonance imaging in a nulliparous woman with eclampsia. Multilobe T2-flair high-signal lesions are apparent. (Courtesy of Dr. Gerda Zeeman.)

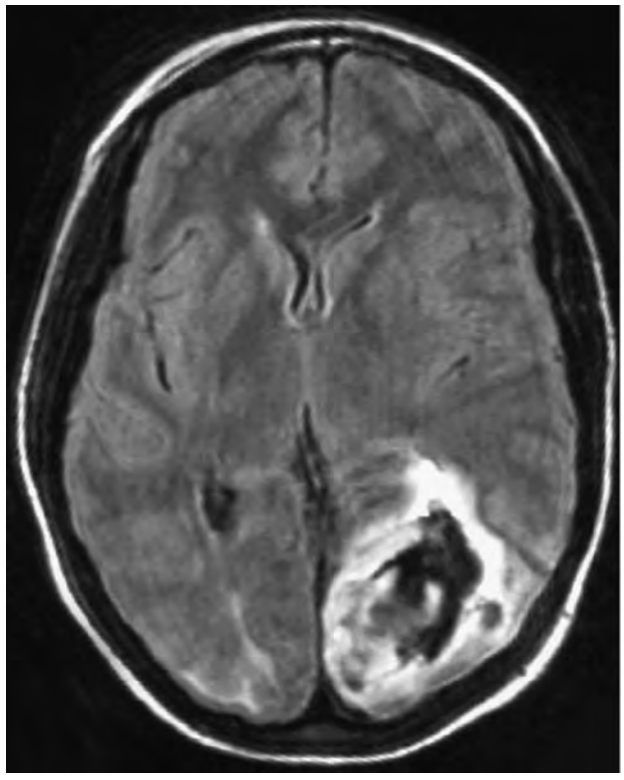

FIGURE 34-14 Cranial magnetic resonance imaging performed 3 days postpartum in a woman with eclampsia and HELLP syndrome. Neurovisual defects persisted at 1 year causing job disability. (From Murphy and Ayazifar, 2005, with permission.)

Visual Changes and Blindness

Scotomata, blurred vision, or diplopia are common with severe preeclampsia and eclampsia. These usually abate with magnesium sulfate therapy and/or lowered blood pressure. Blindness is less common, is usually reversible, and may arise from three potential areas. These are the visual cortex of the occipital lobe, the lateral geniculate nuclei, and retina. In the retina, lesions may include ischemia, infarction, and detachment.

Occipital blindness is also called *amaurosis*—from the Greek *dimming*. Affected women usually have evidence of extensive occipital lobe vasogenic edema on imaging studies. Of 15 women cared for at Parkland Hospital, blindness lasted from 4 hours to 8 days, but it resolved completely in all cases (Cunningham and associates, 1995). Rarely, extensive cerebral infarctions may result in total or partial visual defects (Fig. 34-14).

Blindness from retinal lesions caused by either retinal ischemia or infarction is also called *Purtscher retinopathy* (Fig. 34-15). Moseman and Shelton (2002) described a woman with permanent blindness due to a combination of infarctions in the retina as well as in the lateral geniculate nucleus bilaterally. In many cases of eclampsia-associated blindness, visual acuity improves, but if caused by retinal artery occlusion, vision may be permanently impaired (Blodi and associates, 1990; Lara-Torre and colleagues, 2002).

Finally, *retinal detachment* may also cause altered vision, although it is usually unilateral and seldom causes total visual loss. Occasionally, it coexists with cortical edema and accompanying visual defects. Asymptomatic serous retinal detachment is

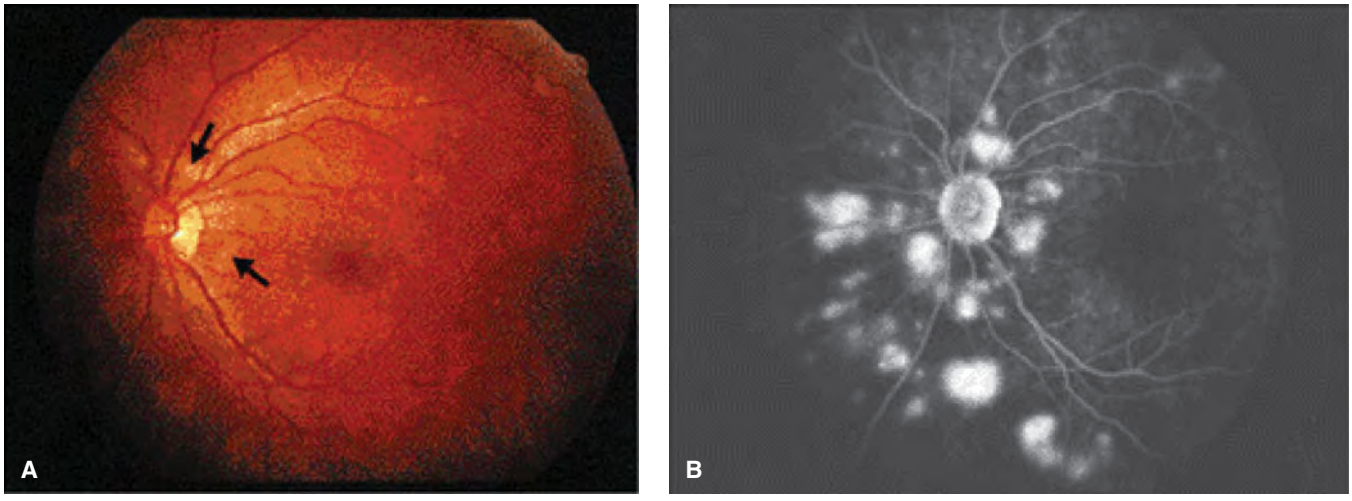

FIGURE 34-15 Purtscher retinopathy caused by choroidal ischemia in preeclampsia syndrome. **A.** Ophthalmoscopy shows scattered yellowish, opaque lesions of the retina (*arrows*). **B.** The late phase of fluorescein angiography shows areas of intense hyperfluorescence representing pooling of extravasated dye. (From Lam and Chan, 2001, with permission.)

relatively common and is obvious by examination (Saito and Tano, 1998). Surgical treatment is seldom indicated, the prognosis generally is good, and vision usually returns to normal within a week.

Cerebral Edema

Clinical manifestations suggesting widespread cerebral edema are worrisome. During a 13-year period, 10 of 175 women with eclampsia at Parkland Hospital were diagnosed with symptomatic cerebral edema (Cunningham and Twickler, 2000). Symptoms ranged from lethargy, confusion, and blurred vision to obtundation and coma. In some cases, symptoms waxed and waned. Mental status changes generally correlated with the degree of involvement seen with CT and MR imaging studies. Three women with generalized edema were comatose and had imaging findings of impending transtentorial herniation. One of these died from herniation.

Clinically, we have observed that these women are very susceptible to sudden and severe blood pressure elevations, which acutely worsen the widespread vasogenic edema. Thus, careful blood pressure control is essential. Consideration is given for treatment with mannitol or dexamethasone.

Long-Term Neurocognitive Sequelae

Women with eclampsia have been shown to suffer excessive cognitive decline when studied 5 to 10 years following an eclamptic pregnancy. This is discussed further on page 749.

Uteroplacental Perfusion

Defects in trophoblastic invasion and placentation germane to development of the preeclampsia syndrome and fetal-growth restriction were discussed on page 710. And of immense clinical importance, compromised uteroplacental perfusion from vasospasm is almost certainly a major culprit in the genesis of increased perinatal morbidity and mortality rates. Thus, measurement of uterine, intervillous, and placental blood flow would likely be informative. Attempts to assess these in humans have been hampered by several obstacles that include inaccessibility of the placenta, the complexity of its venous effluent, and the need for radioisotopes or invasive techniques that are unsuitable for human research.

Measurement of uterine artery blood flow velocity has been used to estimate resistance to uteroplacental blood flow (see Chap. 16, p. 364). Vascular resistance is estimated by comparing arterial systolic and diastolic velocity waveforms. By the completion of placentation, impedance to uterine artery blood flow is markedly decreased. However, with abnormal placentation, abnormally high resistance persists (Ghidini and Locatelli, 2008). Earlier studies were done to assess this by measuring peak systolic:diastolic velocity ratios from uterine and umbilical arteries in preeclamptic pregnancies. The results were interpreted as showing that in some cases, but certainly not all, there was increased resistance (Fleischer and colleagues, 1986; Trudinger and Cook, 1990). Another Doppler waveform—uterine artery "notching"—has been reported to be associated with subsequent increased risks for preeclampsia or growth-restricted infants (Groom and coworkers, 2009).

Matijevic and Johnson (1999) measured resistance in *uterine spiral arteries*. Impedance was higher in peripheral than in central vessels. This has been termed a "ring-like" distribution. Mean resistance was higher in all women with preeclampsia compared with that in normotensive controls. Ong and colleagues (2003) used magnetic resonance imaging and other techniques to assess placental perfusion ex vivo in myometrial arteries removed from women with preeclampsia or fetal-growth restriction. They confirmed that in both conditions myometrial arteries exhibited endothelium-dependent vasodilatory response. Moreover, other pregnancy conditions such as fetal-growth restriction are also associated with increased resistance (Urban and co-workers, 2007).

Despite the above findings, evidence for compromised uteroplacental circulation is found in only a minority of

women who go on to develop preeclampsia. Indeed, when preeclampsia develops during the third trimester, only a third of women with severe disease have abnormal uterine artery velocimetry (Li and colleagues, 2005). And in a study of 50 women with HELLP syndrome, only a third had abnormal uterine artery waveforms (Bush and associates, 2001). In general, the extent of abnormal waveforms correlates with severity of fetal involvement (Ghidini and Locatelli, 2008; Groom and colleagues, 2009).

PREDICTION AND PREVENTION

Prediction

Measurement in early pregnancy—or across pregnancy—of a variety of biological, biochemical, and biophysical markers implicated in the pathophysiology of preeclampsia has been proposed to predict its development. Attempts have been made to identify early markers of faulty placentation, impaired placental perfusion, endothelial cell activation and dysfunction, and activation of coagulation. For the most, these have resulted in testing strategies with poor sensitivity and with poor positive-predictive value for preeclampsia (Conde-Agudelo and colleagues, 2009; Lindheimer and associates, 2008b; Sibai, 2003). Currently there are no screening tests that are reliable, valid, and economical. There are, however, combinations of tests, some yet to be adequately evaluated, that may be promising (Levine and Lindheimer, 2009; Poon and co-workers, 2009). A major goal of the Maternal-Fetal Medicine Units Network (MFMU) is to identify such techniques.

The list of predictive factors evaluated during the last three decades is legion. Some are listed in Table 34-5, which is by no means all inclusive. Conde-Agudelo and associates (2009) have recently provided a thorough review of many of these testing strategies.

Placental Perfusion/Vascular Resistance-Related Tests

Most of these are cumbersome and time consuming.

Provocative Pressor Tests. There are three tests extensively evaluated to assess blood pressure increase in response to a stimulus. The "roll-over test" measures the hypertensive response in women at 28 to 32 weeks who are resting in the left lateral decubitus position and then "roll over" to assume a supine position. The *isometric exercise test* employs the same principle by squeezing a handball. The *angiotensin II infusion test* is performed by giving incrementally increasing doses intravenously, and the hypertensive response is quantified. In their updated meta-analysis, Conde-Agudelo and associates (2009) found sensitivities of all three tests to range from 55 to 70 percent with specificities of approximately 85 percent.

Uterine Artery Doppler Velocimetry. Faulty trophoblastic invasion of the spiral arteries, which is depicted in Figure 34-2, results in diminished placental perfusion and upstream increased uterine artery resistance. Increased uterine artery velocimetry determined by Doppler ultrasound—in the first or middle trimester—should provide indirect evidence of this process and thus serve as a predictive test for preeclampsia (Gebb and associates, 2009a, b; Groom and co-workers, 2009). As described on page 724 and in Chapter 16 (p. 364), increased flow resistance results in an abnormal waveform represented by an increased diastolic notch. A number of flow velocity waveforms—alone or in combination—have been investigated for preeclampsia prediction. At this time, none is suitable for clinical use (Conde-Agudelo and associates, 2009).

Pulse Wave Analysis. Like the uterine artery, finger arterial pulse "stiffness" is an indicator of cardiovascular risk. Investigators have evaluated its usefulness in preeclampsia prediction (Vollebregt and colleagues, 2009).

TABLE 34-5. Predictive Tests for Development of the Preeclampsia Syndrome

Testing Related To:	Examples
Placental perfusion/ vascular resistance	Roll-over test, isometric handgrip or cold pressor test, angiotensin-II infusion, midtrimester mean arterial pressure, platelet angiotensin-II binding, renin, 24-hour ambulatory blood pressure monitoring, uterine artery or fetal transcranial Doppler velocimetry
Fetal-placental unit endocrine dysfunction	Human chorionic gonadotropin (hCG), alpha-fetoprotein (AFP), estriol, pregnancy-associated protein A (PAPP A), inhibin A, activin A, placental protein 13, corticotropin-releasing hormone
Renal dysfunction	Serum uric acid, microalbuminuria, urinary calcium or kallikrein, microtransferrinuria, *N*-acetyl-β-glucosaminidase
Endothelial dysfunction/ oxidant stress	Platelet count and activation, fibronectin, endothelial adhesion molecules, prostaglandin, thromboxane, C-reactive protein, cytokines, endothelin, neurokinin B, homocysteine, lipids, antiphospholipid antibodies, plasminogen activator-inhibitor (PAI), leptin, p-selectin, angiogenic factors to include placental growth factor (PlGF), vascular endothelial growth factor (VEGF), fms-like tyrosine kinase receptor-1 (sFlt-1), endoglin
Others/miscellaneous	Antithrombin-III(AT-3), atrial natriuretic peptide (ANP), β_2-microglobulin, genetic markers, free fetal DNA, serum proteonomic markers

Adapted from Conde-Agudelo and associates (2009).

Fetal-Placental Unit Endocrine Dysfunction

A number of serum analytes that have been proposed to help predict preeclampsia are shown in Table 34-5. Newer ones are continuously added (Jeyabalan, 2009; Kanasaki, 2008; Kenny, 2009, and all their associates). Many of these gained widespread use in the 1980s to identify fetal malformations and were also found to be associated with other pregnancy abnormalities such as neural-tube defects and aneuploidy (see Chap. 13, p. 292). Although touted as such, in general, none of these tests has been shown to be clinically beneficial for hypertension prediction.

Renal Dysfunction-Related Tests

Some of the earliest studies to find predictive tests were related to preeclampsia-induced renal dysfunction.

Serum Uric Acid. One of the earliest laboratory manifestations of preeclampsia is hyperuricemia (Powers and associates, 2006). It likely results from reduced uric acid clearance from diminished glomerular filtration, increased tubular reabsorption, and decreased secretion (Lindheimer and colleagues, 2008a). It is used by some to define preeclampsia, but Cnossen and associates (2006) reported that its sensitivity ranged from 0 to 55 percent and specificity from 77 to 95 percent.

Microalbuminuria. A number of investigators have evaluated the potential value of microalbuminuria as a predictive test for preeclampsia. As reviewed by Conde-Agudelo and associates (2009), sensitivities ranging from 7 to 90 percent and specificities between 29 and 97 percent indicate a poor clinical predictive value. A recent study by Poon and colleagues (2008) likewise found unacceptable sensitivity and specificity for urine albumin:creatinine ratios.

Endothelial Dysfunction and Oxidant Stress-Related Tests

As discussed on page 713, overwhelming evidence indicates that endothelial activation is a major participant in the pathophysiology of the preeclampsia syndrome. As a result, compounds such as those listed in Table 34-5 are found in circulating blood of affected women, and some have been assessed for their predictive value.

Fibronectins. These high-molecular-weight glycoproteins serve a variety of cellular functions that include adhesion and morphology, migration, phagocytosis, and hemostasis (Chavarria and co-workers, 2002). Fibronectins are released from endothelial cells and extracellular matrix following endothelial injury. More than 20 years ago, Stubbs and colleagues (1984) reported that plasma concentrations were elevated in women with preeclampsia. Following their recent systematic review, Leeflang and associates (2007) concluded that neither cellular nor total fibronectin was clinically useful to predict preeclampsia.

Coagulation Activation. Thrombocytopenia and platelet dysfunction are integral features of preeclampsia as discussed on page 717. Platelet activation causes increased destruction and decreased concentrations. Mean platelet volume increases because of young platelet age (Kenny and colleagues, 2009). Although markers of coagulation activation are increased, the substantive overlap with levels in normotensive pregnant women prevents their predictive use.

Oxidative Stress. Increased levels of lipid peroxides coupled with decreased antioxidant activity have raised the possibility that markers of oxidative stress might predict preeclampsia (Walsh, 1994). For example, malondialdehyde is a marker of lipid peroxidation. Other markers are a variety of pro-oxidants or potentiators of pro-oxidants, including iron, transferrin, and ferritin; blood lipids, including triglycerides, free fatty acids, and lipoproteins; and antioxidants, including ascorbic acid and vitamin E (Bainbridge, 2005; Hubel, 1996; Powers, 2000, and all their colleagues). They are not predictive, but treatment to prevent preeclampsia with some of these has been studied as discussed on page 727.

Hyperhomocysteinemia causes oxidative stress and endothelial cell dysfunction and is found in preeclampsia. Although women with elevated serum homocysteine levels at midpregnancy had a three- to fourfold risk of preeclampsia, these tests have not shown to be clinically useful predictors (D'Anna, 2004; Mignini, 2005; Zeeman, 2003, and all their colleagues).

Angiogenic Factors. As discussed on page 714, evidence has accrued that an imbalance between proangiogenic and antiangiogenic factors is related to the pathogenesis of preeclampsia. Serum levels of proangiogenic factors, such as vascular endothelial growth factor (VEGF) and placental growth factor (PlGF), begin to decrease before clinical preeclampsia develops. And, recall as shown in Figure 34-4 that at the same time, levels of some antiangiogenic factors such as soluble fms-like tyrosine kinase 1 (sFlt-1) and soluble endoglin (sEng) are increased (Maynard and colleagues, 2008). Because of these findings, measurement of their plasma levels may serve as predictive tests for preeclampsia.

Conde-Agudelo and associates (2009) recently reviewed the predictive accuracy of some of these factors for severe preeclampsia. Sensitivities for all cases of preeclampsia ranged from 59 to 100 percent and specificity from 43 to 100 percent. The predictive accuracy was higher for early-onset preeclampsia.

These preliminary results suggest a clinical role for preeclampsia prediction. However, until better substantiated, their clinical usefulness is not recommended (Widmer and colleagues, 2007). Automated assays are being evaluated (Sunderji and associates, 2009). The World Health Organization began a multicenter trial in 2008 to evaluate these factors with plans to enroll 12,000 women.

Free Fetal DNA

Using polymerase chain reaction, free fetal DNA can be detected in maternal plasma (Lo and colleagues, 1997). Holzgreve and associates (1998) reported that fetal-maternal cell trafficking is increased in pregnancies complicated by preeclampsia. It is hypothesized that free DNA is released by accelerated apoptosis of cytotrophoblasts (DiFederico and colleagues, 1999). From their review, Conde-Agudelo and associates (2009) concluded that free fetal DNA quantification is not useful for prediction purposes.

TABLE 34-6. Some Methods to Prevent Preeclampsia That Have Been Evaluated in Randomized Trials

Dietary manipulation—low-salt diet, calcium supplementation, fish oil supplementation
Cardiovascular drugs—diuretics, antihypertensive drugs
Antioxidants—ascorbic acid (vitamin C), α-tocopherol (vitamin E)
Antithrombotic drugs—low-dose aspirin, aspirin/dipyridamole, aspirin + heparin, aspirin + ketanserin

Modified from Sibai and Cunningham (2009).

Prevention

A variety of strategies used to prevent or modify the severity of preeclampsia have been evaluated. Some are listed in Table 34-6. In general, none of these has been found to be clinically efficacious.

Dietary Manipulation

A favorite of many theorists and faddists for centuries, dietary "treatment" for preeclampsia has produced some interesting abuses as chronicled by Chesley (1978).

Low-Salt Diet. One of the earliest research efforts to prevent preeclampsia was salt restriction (De Snoo, 1937). This interdiction was followed by years of inappropriate diuretic therapy, after which these practices were discarded. Ironically, it was not until relatively recently that the first randomized trial was done by Knuist and colleagues (1998), who showed that a sodium-restricted diet was ineffective in preventing preeclampsia in 361 women.

Calcium Supplementation. Studies performed in the 1980s outside the United States showed that women with low dietary calcium intake were at significantly increased risk for gestational hypertension (Belizan and Villar, 1980; López-Jaramillo and associates, 1989; Marya and colleagues, 1987). An impressive number of trials have since been performed including one by the National Institute of Child Health and Human Development that included more than 4500 nulliparous women (Levine and colleagues, 1997). In aggregate, these trials have shown that unless women are calcium deficient, supplementation has no salutary effects (Sibai and Cunningham, 2009).

Fish Oil Supplementation. Cardioprotective fatty acids found in some fatty fishes are plentiful in diets of Scandinavians and American Eskimos. The most common dietary sources are EPA—eicosapentaenoic acid—and ALA—alpha-linoleic acid. With proclamations that supplementation with these fatty acids would prevent inflammatory-mediated atherogenesis, it was not a quantum leap to posit that they might prevent preeclampsia syndrome. Unfortunately, randomized trials conducted thus far have shown no such benefits (Makrides, 2006; Olafsdottir, 2006; Olsen, 2000, and all their colleagues).

Antihypertensive Drugs

Because of the putative effects of sodium restriction, it was not surprising that diuretic therapy became popular with the introduction of chlorothiazide in 1957 (Finnerty and colleagues, 1958; Flowers and co-workers, 1962). In their recent meta-analysis, Churchill and colleagues (2007) summarized nine randomized trials that included more than 7000 pregnant women. They found that women given diuretics had a decreased incidence of edema and hypertension, but not of preeclampsia.

Because women with chronic hypertension are at high risk for preeclampsia, several randomized trials—only a few placebo-controlled—have been done to evaluate various antihypertensive drugs to reduce the incidence of superimposed preeclampsia. A critical analysis of these trials failed to demonstrate such a reduction (Sibai and Cunningham, 2009).

Antioxidants

There are inferential data that an imbalance between oxidant and antioxidant activity may have an important role in the pathogenesis of preeclampsia (see p. 726). Two naturally occurring antioxidants—vitamins C and E—may decrease such oxidation. Moreover, women who developed preeclampsia were found to have reduced plasma levels of these two vitamins (Raijmakers and associates, 2004). Thus, dietary supplementation was proposed as a method to improve the oxidative capability of women at risk for preeclampsia.

There have now been a number of quality randomized studies to evaluate this possibility in women at high risk for preeclampsia (Poston, 2006; Rumbold, 2006; Villar, 2007, and all their co-workers). Most recently, Roberts (2009) reported the Maternal-Fetal Medicine Units Network trial that included almost 10,000 low-risk nulliparas. None of these studies showed reduction of preeclampsia in women given antioxidant vitamins compared with those given placebo.

Antithrombotic Agents

There are ample theoretical reasons that antithrombotic agents might reduce the incidence of preeclampsia. As discussed on page 713, the syndrome is characterized by vasospasm, endothelial cell dysfunction, and activation of platelets and the coagulation-hemostasis system. Moreover, prostaglandin imbalance(s) may be operative, and other sequelae of preeclampsia include placental infarction and spiral artery thrombosis.

Low-Dose Aspirin. In oral doses of 50 to 150 mg daily, aspirin effectively inhibits platelet thromboxane A2 biosynthesis with minimal effects on vascular prostacyclin production (Wallenburg and associates, 1986). But results from clinical trials have shown limited benefits. For example, results shown in Table 34-7 are from the Maternal-Fetal Medicine Units Network, and none of the outcomes was significantly improved. The Paris Collaborative Group performed a meta-analysis of the efficacy and safety of antiplatelet agents—predominantly aspirin—to

TABLE 34-7. Maternal-Fetal Medicine Units Network Trial of Low-Dose Aspirin in Women at High Risk for Preeclampsia

		Preeclampsia (Percent)[a]	
Risk Factors	**No.**	**Aspirin**	**Placebo**
Normotensive, no proteinuria	1613	14.5	17.7
Proteinuria plus hypertension	119	31.7	22.0
Proteinuria only	48	25.0	33.3
Hypertension only	723	24.8	25.0
Insulin-dependent diabetes	462	18.3	21.6
Chronic hypertension	763	26.0	24.6
Multifetal gestation	678	11.5	15.9
Previous preeclampsia	600	16.7	19.0

[a]No statistical difference for any comparison between groups.
Data from Caritis and associates (1998).

prevent preeclampsia (Askie and colleagues, 2007). They included 31 randomized trials involving 32,217 women. For women assigned to receive antiplatelet agents, the relative risk of preeclampsia was decreased significantly by 10 percent for development of preeclampsia, superimposed preeclampsia, preterm delivery, or any pregnancy with an adverse outcome. The number-needed-to-treat (NNT), however, was high. Because of these marginal benefits, it seems reasonable to individualize use of low-dose aspirin to prevent recurrent preeclampsia (Sibai and Cunningham, 2009).

Low-Dose Aspirin plus Heparin. Because of the high prevalence of placental thrombotic lesions found with severe preeclampsia, there have been several observational trials to evaluate heparin treatment for affected women. Sergis and associates (2006) reviewed effects of prophylaxis with low-molecular-weight heparin plus low-dose aspirin on pregnancy outcomes in women with a history of severe early-onset preeclampsia and low-birthweight infants. They reported better pregnancy outcomes in women given low-molecular-weight heparin plus low-dose aspirin compared with those given low-dose aspirin alone. At this time, it is not possible to make recommendations from these observational data.

MANAGEMENT

Pregnancy complicated by gestational hypertension is managed according to severity, gestational age, and presence of preeclampsia. Tenets of management, as emphasized earlier, also take into consideration endothelial cell injury and multi-organ dysfunction caused by the preeclampsia syndrome.

Preeclampsia cannot always be diagnosed definitively. Thus, given the explosive nature of the disorder, both the American College of Obstetricians and Gynecologists (2002a) and the National High Blood Pressure Education Program (NHBPEP) Working Group (2000) recommend more frequent prenatal visits, even if preeclampsia is only "suspected." *Increases in systolic and diastolic blood pressure can be either normal physiological changes or signs of developing pathology.* Increased surveillance permits more prompt recognition of ominous changes in blood pressure, critical laboratory findings, and development of clinical signs and symptoms.

The basic management objectives for any pregnancy complicated by preeclampsia are:

1. Termination of pregnancy with the least possible trauma to mother and fetus
2. Birth of an infant who subsequently thrives
3. Complete restoration of health to the mother.

In many women with preeclampsia, especially those at or near term, all three objectives are served equally well by induction of labor. *One of the most important clinical questions for successful management is precise knowledge of fetal age.*

Early Diagnosis of Preeclampsia

Traditionally, the frequency of prenatal visits is increased during the third trimester, and this aids early detection of preeclampsia. Women without overt hypertension, but in whom early developing preeclampsia is suspected during routine prenatal visits, are seen more frequently. The protocol used successfully for many years at Parkland Hospital for women with new-onset diastolic blood pressures $>$ 80 mm Hg but $<$ 90 mm Hg or with sudden abnormal weight gain of more than 2 pounds per week includes return visits minimally at 7-day intervals, and preferably at 3- to 4-day intervals. Outpatient surveillance is continued unless overt hypertension, proteinuria, headache, visual disturbances, or epigastric discomfort supervene. Women with overt new-onset hypertension—either diastolic pressures 90 mm Hg or greater or systolic pressures 140 mm Hg or greater—are admitted for 2 to 3 days to determine if the increase is due to preeclampsia and if so, to evaluate its severity. Women with persistent severe disease are observed closely, and many are delivered. Conversely, women with apparently mild disease can often be managed as outpatients, although we have a low threshold for continued hospitalization in the nullipara.

Evaluation

Hospitalization is considered at least initially for women with new-onset hypertension, especially if there is persistent or worsening hypertension or development of proteinuria. A systematic evaluation is instituted to include the following:

- Detailed examination followed by daily scrutiny for clinical findings such as headache, visual disturbances, epigastric pain, and rapid weight gain
- Weight determined daily
- Analysis for proteinuria on admittance and at least every 2 days thereafter
- Blood pressure readings in the sitting position with an appropriate-size cuff every 4 hours, except between 2400 and 0600 unless previous readings had become elevated
- Measurements of plasma or serum creatinine and liver transaminase levels, and hemogram to include platelet quantification. The frequency of testing is determined by the severity of hypertension. Some recommend measurement of serum uric acid and lactic acid dehydrogenase levels as well as coagulation studies, but studies have called into question the value of these tests (Conde-Agudelo, 2009; Cnossen, 2006; Thangaratinam, 2006, and all their colleagues).
- Evaluation of fetal size and well-being and amnionic fluid volume either clinically or using sonography.

Goals of such management include early identification of worsening preeclampsia and development of a management scheme that includes a plan for timely delivery. If any of these observations lead to a diagnosis of severe preeclampsia as previously defined by the criteria in Table 34-2, further management is subsequently described.

Reduced physical activity throughout much of the day is likely beneficial. Absolute bed rest is not necessary. Ample protein and calories should be included in the diet, and sodium and fluid intake should not be limited or forced. Further management depends on: (1) severity of preeclampsia, (2) gestational age, and (3) condition of the cervix.

Fortunately, many cases are sufficiently mild and near enough to term that they can be managed conservatively until labor commences spontaneously or until the cervix becomes favorable for labor induction. Complete abatement of all signs and symptoms, however, is uncommon until after delivery. *Almost certainly, the underlying disease persists until after delivery!*

Consideration for Delivery

Termination of pregnancy is the only cure for preeclampsia. Headache, visual disturbances, or epigastric pain is indicative that convulsions may be imminent, and oliguria is another ominous sign. Severe preeclampsia demands anticonvulsant and usually antihypertensive therapy followed by delivery. Treatment is identical to that described subsequently for eclampsia. The prime objectives are to forestall convulsions, to prevent intracranial hemorrhage and serious damage to other vital organs, and to deliver a healthy infant.

When the fetus is preterm, the tendency is to temporize in the hope that a few more weeks in utero will reduce the risk of neonatal death or serious morbidity from prematurity. As discussed, such a policy certainly is justified in milder cases. Assessments of fetal well-being and placental function are performed, especially when the fetus is immature. Most recommend frequent performance of various tests to assess fetal well-being as described by the American College of Obstetricians and Gynecologists (1999). These include the *nonstress test* or the *biophysical profile* (see Chap. 15, pp. 337 and 341). Measurement of the lecithin-sphingomyelin (L/S) ratio in amnionic fluid may provide evidence of lung maturity (see Chap. 29, p. 606).

With moderate or severe preeclampsia that does not improve after hospitalization, delivery is usually advisable for the welfare of both mother and fetus. Labor induction is carried out, usually with preinduction cervical ripening with a prostaglandin or osmotic dilator (see Chap. 22, p. 501). Whenever it appears that induction almost certainly will not succeed, or attempts have failed, cesarean delivery is indicated for more severe cases.

For a woman near term, with a soft, partially effaced cervix, even milder degrees of preeclampsia probably carry more risk to the mother and her fetus-infant than does induction of labor. However, Barton and colleagues (2009) have recently quantified excessive neonatal morbidity in women delivered before 38 weeks despite having stable mild nonproteinuric gestational hypertension.

Elective Cesarean Delivery

Once severe preeclampsia is diagnosed, labor induction and vaginal delivery have traditionally been considered ideal. Temporization with an immature fetus is considered subsequently. Several concerns, including an unfavorable cervix, a perceived sense of urgency because of the severity of preeclampsia, and the need to coordinate neonatal intensive care, have led some to advocate cesarean delivery. Alexander and colleagues (1999) reviewed 278 singleton liveborns weighing 750 to 1500 g delivered of women with severe preeclampsia at Parkland Hospital. In half of the women, labor was induced, and the remainder underwent cesarean delivery without labor. Induction was successful in accomplishing vaginal delivery in a third, and it was not harmful to the very-low-birthweight infants. Alanis and associates (2008) reported similar observations. In their recent systematic review, Le Ray and co-workers (2009) confirmed these conclusions.

Hospitalization versus Outpatient Management

For women with mild to moderate stable hypertension—whether or not preeclampsia has been confirmed—continued surveillance in the hospital, at home for some reliable patients, or through a day-care unit is carried out. At least intuitively, reduced physical activity throughout much of the day seems beneficial. A number of observational studies and randomized trials have addressed the benefits of inpatient care and outpatient management.

Somewhat related, Abenhaim and colleagues (2008) reported a retrospective cohort study of 677 women hospitalized for bed rest because of threatened preterm delivery. When outcomes of these women were compared with those of the general

obstetrical population, bed rest was associated with a significantly reduced risk of developing preeclampsia—RR 0.27 (CI 0.16–0.48). In a review of two small randomized trials totaling 106 women at high risk for preeclampsia, prophylactic bed rest 4 to 6 hours daily at home was successful in significantly lowering the incidence of preeclampsia but not gestational hypertension (Meher and Duely, 2006).

These and other observations support the claim that restricted activity alters the underlying pathophysiology of the preeclampsia syndrome. As for "complete bed rest," this is likely unachievable because of the severe restrictions it places on the otherwise well woman, and it also predisposes to thromboembolism (Knight and co-workers, 2007).

High-Risk Pregnancy Unit

An inpatient antepartum unit was established in 1973 at Parkland Hospital by Dr. Peggy Whalley in large part to provide care for women with hypertensive disorders. Initial results from this unit were reported by Hauth (1976) and Gilstrap (1978) and their colleagues. Most women hospitalized have a beneficial response characterized by disappearance or improvement of hypertension. ***These women are not "cured," and nearly 90 percent have recurrent hypertension before or during labor.*** By the end of 2006, more than 9000 nulliparous women with mild to moderate early-onset hypertension during pregnancy had been managed successfully in this unit. Provider costs—*not* charges—for this relatively simple physical facility, modest nursing care, no drugs other than iron and folate supplements, and few essential laboratory tests are minimal compared with the cost of neonatal intensive care for a preterm infant.

Home Healthcare

Many clinicians believe that further hospitalization is not warranted if hypertension abates within a few days, and this has legitimized third-party payers to deny hospital reimbursement. Consequently, most women with mild to moderate hypertension are managed at home. Outpatient management may continue as long as the disease does not worsen and if fetal jeopardy is not suspected. Sedentary activity throughout the greater part of the day is recommended. These women are instructed in detail to report symptoms. Home blood pressure and urine protein monitoring or frequent evaluations by a visiting nurse may prove beneficial. Lo and co-workers (2002) cautioned about the use of certain automated home blood pressure monitors that may fail to detect severe hypertension.

In an observational study by Barton and colleagues (2002), 1182 nulliparous women with mild gestational hypertension—20 percent had proteinuria—were managed with home health care. Their mean gestational ages were 32 to 33 weeks at enrollment and 36 to 37 weeks at the time of delivery. Severe preeclampsia developed in approximately 20 percent, about 3 percent developed HELLP syndrome, and two women had eclampsia. Perinatal outcomes were generally good. In approximately 20 percent, there was fetal-growth restriction, and the perinatal mortality rate was 4.2 per 1000.

Several prospective studies have been designed to compare continued hospitalization with either home healthcare or a day-care unit. In a pilot study from Parkland Hospital, Horsager and associates (1995) randomly assigned 72 nulliparas with new-onset hypertension from 27 to 37 weeks either to continued hospitalization or to outpatient care. In all of these women, proteinuria had receded to less than 500 mg per day when randomized. Outpatient management included daily blood pressure monitoring by the patient or her family. Weight and spot urine protein determinations were evaluated three times weekly. A home health nurse visited twice weekly, and the women were seen weekly in the clinic. Perinatal outcomes were similar in each group. The only significant difference was that women in the home care group developed severe preeclampsia significantly more frequently than hospitalized women—42 versus 25 percent.

A larger randomized trial reported by Crowther and co-workers (1992) included 218 women with mild gestational nonproteinuric hypertension. After evaluation, half remained hospitalized, whereas the other half was managed as outpatients. As shown in **Table 34-8**, the mean duration of hospitalization was 22.2 days for women with inpatient management compared with only 6.5 days in the home care group. Preterm delivery before 34 and before 37 weeks was increased twofold in the outpatient group, but maternal and infant outcomes otherwise were similar.

Day-Care Unit

Another approach, now common in European countries, is day care. This approach has been evaluated by several investigators. In the study by Tuffnell and associates (1992), 54 women with hypertension after 26 weeks were assigned to either day care or routine management (Table 34-8). Hospitalizations, progression to overt preeclampsia, and labor inductions were significantly increased in the routine management group. Turnbull and co-workers (2004) enrolled 395 women who were randomly assigned to either day care or inpatient management (Table 34-8). Almost 95 percent had mild to moderate hypertension—288 without proteinuria and 86 with ≥ 1+ proteinuria. Fetal outcomes overall were good, there were no neonatal deaths, and none of the women developed eclampsia or HELLP syndrome. Surprisingly, costs for either scheme were not significantly different. Perhaps not surprisingly, general satisfaction favored day care.

Antepartum Hospitalization versus Outpatient Care

From the above, it can be seen that either inpatient or close outpatient management is appropriate for the woman with mild de novo hypertension, with or without nonsevere preeclampsia. Most of these studies were carried out in academic centers with dedicated management teams. That said, the key to success is close follow-up and a conscientious patient.

Antihypertensive Therapy for Mild to Moderate Hypertension

The use of antihypertensive drugs in attempts to prolong pregnancy or modify perinatal outcomes in pregnancies complicated by various types and severities of hypertensive disorders

has been of considerable interest. Treatment for women with chronic hypertension complicating pregnancy is discussed in detail in Chapter 45 (p. 988).

Drug treatment for early mild preeclampsia has been disappointing as shown in representative randomized trials listed in Table 34-9. Sibai and colleagues (1987a) evaluated the effectiveness of labetalol and hospitalization compared with hospitalization alone in 200 nulliparous women with gestational hypertension from 26 to 35 weeks. Although women given labetalol had significantly lower mean blood pressures, there

were no differences between the groups in terms of mean pregnancy prolongation, gestational age at delivery, or birthweight. The cesarean delivery rates were similar, as were the number of infants admitted to special-care nurseries. *Growth-restricted infants were significantly twice as frequent in women given labetalol—19 versus 9 percent.*

The three other studies listed in Table 34-9 were performed to compare labetalol or the calcium-channel blockers, nifedipine and isradipine, with placebo. In none of these studies were any benefits of antihypertensive treatment shown. Von Dadelszen and Magee (2002) updated their previous meta-analysis and again concluded that treatment-induced decreases in maternal blood pressure may adversely affect fetal growth.

Abalos and colleagues (2007) reviewed randomized trials of active antihypertensive therapy compared with either no treatment or placebo given to women with mild to moderate gestational hypertension. These reviewers included 46 trials enrolling 4282 women and reported that, except for a halving of the risk for developing severe hypertension, active antihypertensive therapy had no beneficial effects. In contrast to the findings by von Dadelszen and Magee (2002) cited above, they reported that fetal-growth restriction *was not increased* in treated women. Similarly, it is controversial whether β-blocking agents cause fetal-growth restriction if given across pregnancy for chronic hypertension (August and Lindheimer, 2009; Umans and colleagues, 2009). Thus, any salutary or adverse effects of antihypertensive therapy seem minimal at most.

Delayed Delivery

Delayed Delivery with Early-Onset Severe Preeclampsia

For many years, it was the practice that all women with severe preeclampsia were delivered without delay. During the past 20 years, however, another approach for women with severe preeclampsia remote from term has been advocated by several investigators worldwide. This calls for "conservative" or "expectant" management with the aim of improving neonatal outcome without compromising maternal safety. Aspects of such management always include careful daily—and usually more frequent—inpatient monitoring of the woman and fetus, with or without antihypertensive drugs.

Theoretically, antihypertensive therapy has potential application when severe preeclampsia develops before neonatal survival is likely. Such management is controversial, and it may be dangerous. In one of the first studies, Sibai and the Memphis group (1985) attempted to prolong pregnancy because of fetal immaturity in 60 women with severe preeclampsia between 18 and 27 weeks. The results were disastrous. *The perinatal mortality rate was 87 percent. Although no mothers died, 13 suffered placental abruption, 10 had eclampsia, 3 developed renal failure, 2 had hypertensive encephalopathy, and one each had an intracerebral hemorrhage and a ruptured hepatic hematoma.*

Because of these catastrophic outcomes, the Memphis group redefined their study criteria and performed a randomized trial of expectant versus aggressive management of 95 women who had severe preeclampsia but with more advanced gestations of 28 to 32 weeks (Sibai and associates, 1994). *Women with HELLP syndrome were excluded from this trial.* Aggressive management included glucocorticoid administration for fetal lung maturation followed by delivery in 48 hours. Expectantly managed women were observed at bed rest and given either labetalol or nifedipine orally to control severe hypertension. In this study, pregnancy was prolonged for a mean of 15.4 days in the expectant management group. An overall improvement in neonatal outcomes was also reported.

Following these experiences, expectant management became more commonly practiced, but with the caveat that women with HELLP syndrome or growth-restricted fetuses were usually excluded. But in a subsequent follow-up observational study, the Memphis group compared outcomes in 133 preeclamptic women with and 136 without HELLP syndrome who presented between 24 and 36 weeks (Abramovici and co-workers, 1999). Women were subdivided into three study groups: The first group included those with hemolysis, elevated liver enzymes, *and* low platelets—*complete HELLP syndrome*. The second group included women with *partial HELLP syndrome*—defined as either one or two but not three of these laboratory findings. The third group included women who had severe preeclampsia without HELLP syndrome laboratory findings. Perinatal outcomes were similar in each group, and importantly, outcomes were not improved with procrastination. Despite this, the investigators concluded that women with partial HELLP syndrome, as well as those with severe preeclampsia alone, could be managed expectantly.

Sibai and Barton (2007) recently reviewed most reports since the early 1990s of expectant management of severe preeclampsia. Outcomes reported from seven studies published since 2000 are shown in **Table 34-10**. A total of more than 1200 women were included, and although the average time gained ranged from 5 to 10 days, their morbidity rates were formidable. As shown, serious complications included placental abruption, HELLP syndrome, pulmonary edema, renal failure, and eclampsia. Moreover, perinatal mortality rates averaged from 39 to 133 per 1000. Fetal-growth restriction was common, and in the study from The Netherlands by Ganzevoort and associates (2005a, b), it was an astounding 94 percent. It has been shown that perinatal mortality rates are disproportionately high in these growth-restricted infants, but maternal outcomes were not appreciably different from pregnancies in women without growth-restricted fetuses (Haddad and coworkers, 2007; Shear and colleagues, 2005).

Barber and associates (2009) conducted a 10-year review of 3408 women with severe preeclampsia from 24 to 32 weeks who had been entered into the California vital statistics database. They found that increasing lengths of antepartum hospital stays were associated with slight but significantly increased rates of maternal and neonatal morbidity.

Expectant Management of Midtrimester Severe Preeclampsia

A number of small studies have focused on expectant management of severe preeclampsia syndrome *before 28 weeks*. In their recent review, Bombrys and colleagues (2008) found eight such studies that included nearly 200 women with severe preeclampsia with an onset from less than 24 and up to 26 completed

weeks. Maternal complications were common, and there were no infant survivors in those presenting before 23 weeks. Thus, the authors recommended pregnancy termination for these women. For those at 23 weeks, the perinatal survival rate was 18 percent, but long-term perinatal morbidity is yet unknown. For women with pregnancies at 24 to 26 weeks, perinatal survival approached 60 percent, and it averaged almost 90 percent for those at 26 weeks.

Results from five studies published since 2000 of women with severe midtrimester preeclampsia who were managed expectantly are shown in Table 34-11. As can be seen, there are extraordinarily high maternal and perinatal morbidity and mortality rates in these extremely preterm pregnancies. Because of these results, at this time, there are inadequate contemporaneous comparative studies attesting to the perinatal benefits of such expectant treatment versus early delivery in the face of serious maternal complications that approach 50 percent.

Glucocorticoids for Lung Maturation

In attempts to enhance fetal lung maturation, glucocorticoids have been administered to women with severe hypertension who are remote from term. Treatment does not seem to worsen maternal hypertension, and a decrease in the incidence of respiratory distress and improved fetal survival has been cited. That said, there is only one randomized trial of corticosteroids given to hypertensive women for fetal lung maturation (Amorim and associates, 1999). This trial included 218 women with severe preeclampsia between 26 and 34 weeks who were randomly

assigned to betamethasone or placebo administration. Neonatal complications, including respiratory distress, intraventricular hemorrhage, and death, were decreased significantly when betamethasone was given compared with placebo. However, there were two maternal deaths and 18 stillbirths**.** We add these findings to buttress our unenthusiastic acceptance of attempts to prolong gestation in many of these women (Bloom and Leveno, 2003; Leveno and Cunningham, 2009).

Corticosteroids to Ameliorate HELLP Syndrome

More than 25 years ago, Thiagarajah and colleagues (1984) suggested that glucocorticoids might also play a role in treatment of the laboratory abnormalities associated with the HELLP syndrome. Subsequently, Tompkins (1999) and O'Brien (2002) and their associates reported less than salutary effects. Martin and coworkers (2003) reviewed outcomes of almost 500 such women at their institution. From 1994 to 2000, 90 percent of women with HELLP syndrome were treated. Their outcomes were more favorable than the retrospective cohort from 1985 to 1991, during which time only 16 percent were treated with corticosteroids. Their randomized trial, although comparing two corticosteroids, did not include a nontreated group (Isler and co-workers, 2001).

Since these observational studies, there have been at least two prospective randomized trials designed to address this question. Fonseca and colleagues (2005) randomized 132 women with HELLP syndrome to either dexamethasone or placebo administration. Outcomes assessed included duration of hospitalization, recovery time of abnormal laboratory test results, recovery of clinical parameters, and complications that included acute renal failure, pulmonary edema, eclampsia, and death. None of these was significantly different between the two groups. In a similar blinded study, Katz and co-workers (2008) randomized 105 postpartum women with HELLP syndrome to treatment with dexamethasone or placebo. They analyzed outcomes similar to the Fonseca study and found no advantage to dexamethasone. Shown in **Figure 34-16** are recovery times for platelet counts and serum aspartate transferase (AST) levels. These recoveries are almost identical in the two groups. For these reasons, we do not recommend corticosteroid treatment for thrombocytopenia.

Risks versus Benefits of Delayed Delivery

Taken in toto, these studies require comment about repeated claims that expectant management of severe preeclampsia is beneficial. Undoubtedly, the overriding reason to terminate pregnancies with severe preeclampsia is maternal safety. There are no data to suggest that expectant management is beneficial for the mother. Indeed, it seems obvious that a delay to prolong gestation in women with severe preeclampsia may have serious maternal consequences such as those shown in Table 34-10. Notably, placental abruption develops in approximately 20 percent and pulmonary edema in about 4 percent. Moreover, there are substantive risks for eclampsia, cerebrovascular hemorrhage, and maternal death. These observations are especially pertinent when considered along with the absence of convincing evidence that perinatal outcomes are markedly improved by the average prolongation of pregnancy of about 1 week. If undertaken, shown in **Table 34-12** are some criteria

TABLE 34-12. Some Indications for Delivery with Early-Onset Severe Preeclampsia

Maternal
Persistent severe headache or visual changes; eclampsia
Shortness of breath; chest tightness with rales and/or S_aO_2 < 94 percent breathing room air; pulmonary edema
Uncontrolled severe hypertension despite treatment
Oliguria < 500 mL/24 hr or serum creatinine ≥ 1.5 mg/dL
Persistent platelet counts < 100,000/μL
Suspected abruption, progressive labor, and/or ruptured membranes
Fetal
Severe growth restriction—< 5th percentile for EGA
Persistent severe oligohydramnios—AFI < 5 cm
Biophysical profile ≤ 4 done 6 hr apart
Reversed end-diastolic umbilical artery flow
Fetal death

AFI = amnionic fluid index; EGA = estimated gestational age; S_aO_2 = oxygen saturation.
From Sibai and Barton (2007).

recommended by Sibai and Barton (2007) that should promote consideration for delivery.

Eclampsia

Preeclampsia complicated by generalized tonic-clonic convulsions increases appreciably the risk to both mother and fetus. In an earlier study, Mattar and Sibai (2000) described outcomes in 399 consecutive women with eclampsia from 1977 through 1998. Major maternal complications included placental abruption—10 percent, neurological deficits—7 percent, aspiration pneumonia—7 percent, pulmonary edema—5 percent, cardiopulmonary arrest—4 percent, and acute renal failure—4 percent. Moreover, 1 percent of these women died.

European maternity units also report excessive maternal and perinatal morbidity and mortality rates with eclampsia. In a report from Scandinavia encompassing a 2-year period ending in 2000, Andersgaard and associates (2006) described 232 women with eclampsia. Although there was but a single maternal death, a third of the women experienced major complications that included HELLP syndrome, renal failure, pulmonary edema, pulmonary embolism, and stroke. The United Kingdom Obstetric Surveillance System (UKOSS) updated audit by Knight (2007) described maternal outcomes in 214 eclamptic women. There were no maternal deaths, and although outcomes were improved since the previous audit, five women experienced cerebral hemorrhage. In The Netherlands during 2 years ending in 2006, there were three maternal deaths among 222 eclamptic women (Zwart and colleagues, 2008). From Dublin, Akkawi and co-workers (2009) reported four maternal deaths among 247 eclamptic women. Thus, in developed countries, the maternal mortality rate is about 1 percent in women with eclampsia—in perspective, this is 1000-fold increased over the national maternal death rates for these countries.

Almost without exception, preeclampsia precedes the onset of eclamptic convulsions. Depending on whether convulsions appear before, during, or after labor, eclampsia is designated as antepartum, intrapartum, or postpartum. Eclampsia is most common in the last trimester and becomes increasingly more frequent as term approaches. In more recent years, there has been an increasing shift in the incidence of eclampsia toward the postpartum period. This is presumably related to improved access to prenatal care, earlier detection of preeclampsia, and prophylactic use of magnesium sulfate (Chames and colleagues, 2002). Importantly, other diagnoses should be considered in women with the onset of convulsions more than 48 hours postpartum or in women with focal neurological deficits, prolonged coma, or atypical eclampsia (Sibai, 2005).

Immediate Management of Seizure

Eclamptic seizures may be violent. During seizures, the woman must be protected, especially her airway. So forceful are the muscular movements that the woman may throw herself out of her bed, and if not protected, her tongue is bitten by the violent action of the jaws (**Fig. 34-17**). This phase, in which the muscles alternately contract and relax, may last approximately a minute. Gradually, the muscular movements become smaller and less frequent, and finally the woman lies motionless. After a seizure, the woman is postictal, but in some, a coma of variable duration ensues. When the convulsions are infrequent, the woman usually recovers some degree of consciousness after each attack. As the woman arouses, a semiconscious combative state may ensue. In severe cases, coma persists from one convulsion to another, and death may result. In rare instances, a single convulsion may be followed by coma from which the woman may never emerge. However, as a rule, death does not occur until after frequent convulsions. Finally and also rarely, convulsions continue unabated—*status epilepticus*—and require deep sedation and even general anesthesia.

FIGURE 34-17 Hematoma of tongue from laceration during an eclamptic convulsion. Thrombocytopenia may have contributed to the bleeding.

Respirations after an eclamptic convulsion are usually increased in rate and may reach 50 or more per minute in response to hypercarbia, lactic acidemia, and transient hypoxia. Cyanosis may be observed in severe cases. High fever is a grave sign because it probably results from cerebrovascular hemorrhage.

Proteinuria is usually present and frequently pronounced. Urine output may be diminished appreciably, and occasionally anuria develops. There may be hemoglobinuria, but hemoglobinemia is observed rarely. Often, as shown in **Figure 34-18**, peripheral and facial edema is pronounced—at times, massive—but it may also be absent.

As with severe preeclampsia, after delivery, an increase in urinary output is usually an early sign of improvement. If there is renal dysfunction, serum creatinine levels should be monitored. Proteinuria and edema ordinarily disappear within a week postpartum (see Fig. 34-18). In most cases, blood pressure returns to normal within a few days to 2 weeks after delivery. As subsequently discussed, the longer hypertension persists postpartum, and the more severe it is, the more likely the patient also has chronic vascular disease.

In antepartum eclampsia, labor may begin spontaneously shortly after convulsions ensue and may progress rapidly. If the convulsion occurs during labor, contractions may increase in frequency and intensity, and the duration of labor may be

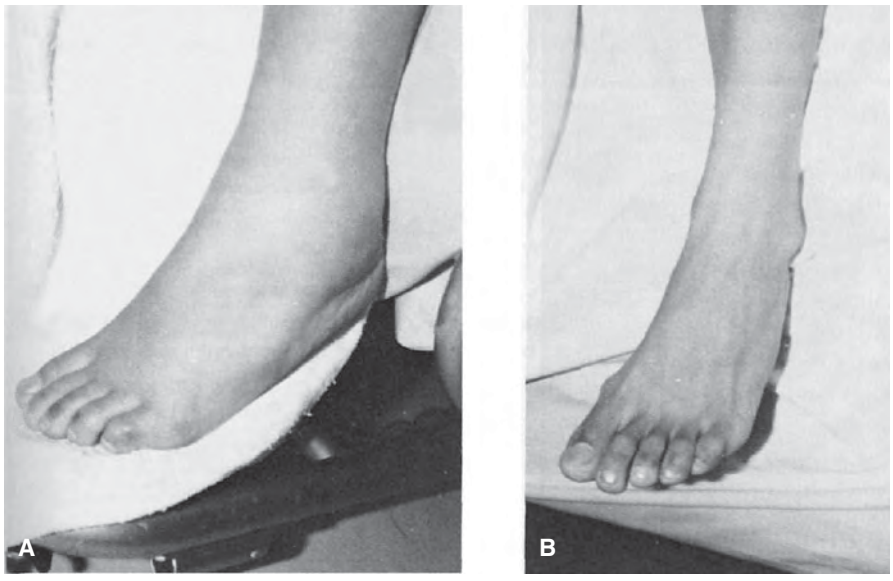

FIGURE 34-18 A. Severe edema in a young nulliparous woman with antepartum eclampsia. **B.** The same woman 3 days after delivery. The remarkable clearance of pedal edema, accompanied by diuresis and a 28-pound weight loss, was spontaneous and unprovoked by diuretic therapy.(From Cunningham and Pritchard, 1984, with permission.)

shortened. Because of maternal hypoxemia and lactic acidemia caused by convulsions, it is not unusual for fetal bradycardia to follow a seizure (**Fig. 34-19**). Bradycardia usually recovers within 3 to 5 minutes. However, if it persists more than approximately 10 minutes, then another cause such as placental abruption or imminent delivery must be considered.

Pulmonary edema may follow eclamptic convulsions. This usually is caused by aspiration pneumonitis from gastric content inhalation during vomiting that frequently accompanies convulsions. In some women, pulmonary edema may be caused by ventricular failure from increased afterload that may result from severe hypertension and vigorous intravenous fluid administration. Such pulmonary edema from ventricular failure is more common in morbidly obese women and in those with previously unappreciated chronic hypertension.

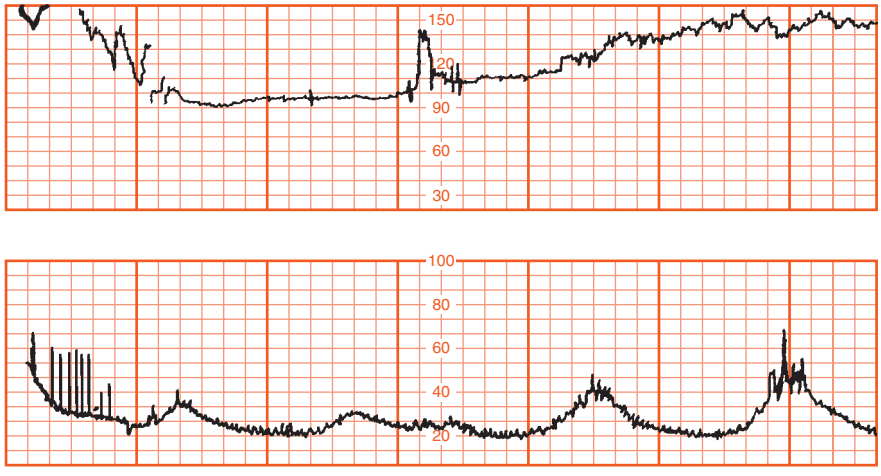

FIGURE 34-19 Fetal bradycardia following an intrapartum eclamptic convulsion. Bradycardia resolved and beat-to-beat variability returned approximately 5 minutes following the seizure.

Occasionally, sudden death occurs synchronously with an eclamptic convulsion, or it follows shortly thereafter. Most often in these cases, death results from a massive cerebral hemorrhage (see Fig. 34-11). Hemiplegia may result from sublethal hemorrhage. Cerebral hemorrhages are more likely in older women with underlying chronic hypertension as discussed on page 721. Rarely, they may be due to a ruptured cerebral berry aneurysm or arteriovenous malformation (Witlin and coworkers, 1997a).

In approximately 10 percent of women, some degree of blindness follows a seizure. Blindness seldom develops spontaneously with preeclampsia. Two causes of blindness or impaired vision are varying degrees of retinal detachment or occipital lobe ischemia and edema (see p. 723). In both instances, the prognosis for return to normal function is good and is usually complete within a week postpartum (Cunningham and associates, 1995). Approximately 5 percent of women have substantively altered consciousness, including persistent coma, following a seizure. This is due to extensive cerebral edema, and transtentorial herniation may cause death as discussed on page 724 (Cunningham and Twickler, 2000).

Rarely, eclampsia is followed by psychosis, and the woman becomes violent. This usually lasts for several days to 2 weeks, but the prognosis for return to normal function is good, provided there was no preexisting mental illness. It is presumed to be similar to postpartum psychosis discussed in detail in Chapter 55 (p. 1179). Antipsychotic medications in carefully titrated doses have proved effective in the few cases of posteclampsia psychosis treated at Parkland Hospital.

Differential Diagnosis

Generally, eclampsia is more likely to be diagnosed too frequently rather than overlooked. Epilepsy, encephalitis, meningitis, cerebral tumor, cysticercosis, and ruptured cerebral aneurysm during late pregnancy and the puerperium may simulate eclampsia. **Until other such causes are excluded, however, all pregnant women with convulsions should be considered to have eclampsia.**

Management of Eclampsia

As reviewed by Chesley (1978), it has been long recognized in American obstetrics that magnesium sulfate is highly effective in preventing convulsions in

women with preeclampsia and in stopping them in those with eclampsia. He cited observational data by Pritchard and colleagues (1955, 1975) from Parkland Hospital and from his own institution, Kings County Hospital in Brooklyn. At that time, most eclampsia regimens used in the United States adhered to a similar philosophy still in use today, and the tenets of which include the following:

1. Control of convulsions using an intravenously administered loading dose of magnesium sulfate. This is followed by a continuous infusion of magnesium sulfate
2. Intermittent administration of an antihypertensive medication to lower blood pressure whenever it is considered dangerously high
3. Avoidance of diuretics unless there is obvious pulmonary edema, limitation of intravenous fluid administration unless fluid loss is excessive, and avoidance of hyperosmotic agents
4. Delivery of the fetus to achieve a "cure."

Magnesium Sulfate to Control Convulsions

In more severe cases of preeclampsia, as well as in eclampsia, magnesium sulfate administered parenterally is an effective anticonvulsant that avoids producing central nervous system depression in either the mother or the infant. It may be given intravenously by continuous infusion or intramuscularly by intermittent injection (**Table 34-13**). The dosages for severe preeclampsia are the same as for eclampsia. Because labor and delivery is a more likely time for convulsions to develop, women with preeclampsia-eclampsia usually are given magnesium sulfate during labor and for 24 hours postpartum.

Magnesium sulfate is almost universally administered intravenously, and in most units, the intramuscular route has been abandoned. Of concern, magnesium sulfate solutions, although inexpensive to prepare, are not readily available in all parts of the developing world. And even when the solutions are available, the technology to infuse them may not be. Therefore, it should not be forgotten that the drug can be administered intramuscularly and that this route is as effective as intravenous administration. In a recent report from India, Chowdhury and colleagues (2009) showed that the two regimens were equivalent in preventing recurrent convulsions and maternal deaths in 630 women with eclampsia.

Magnesium sulfate is not given to treat hypertension. Based on a number of studies cited subsequently, as well as extensive clinical observations, magnesium most likely exerts a specific anticonvulsant action on the cerebral cortex. Typically, the mother stops convulsing after the initial 4-g loading dose. By an hour or two, she regains consciousness sufficiently to be oriented to place and time.

The magnesium sulfate dosages presented in Table 34-13 usually result in plasma magnesium levels illustrated in **Figure 34-20**. When magnesium sulfate is given to arrest eclamptic seizures, 10 to 15 percent of women have a subsequent convulsion. If so, an additional 2-g dose of magnesium sulfate in a 20-percent solution is slowly administered intravenously. In a small woman, this additional 2-g dose may be used once, but it can be given twice if needed in a larger woman. In only five of 245 women with eclampsia at Parkland Hospital was it necessary to use supplementary medication to control convulsions (Pritchard and associates, 1984). An intravenous barbiturate such as amobarbital or thiopental is given slowly. Midazolam or lorazepam may be given in a small single dose because

TABLE 34-13. Magnesium Sulfate Dosage Schedule Dosage Schedule for Severe Preeclampsia and Eclampsia

Continuous Intravenous Infusion

1. Give 4- to 6-g loading dose of magnesium sulfate diluted in 100 mL of IV fluid administered over 15–20 min
2. Begin 2 g/hr in 100 mL of IV maintenance infusion. Some recommend 1 g/hr
3. Monitor for magnesium toxicity:
   a. Assess deep tendon reflexes periodically
   b. Some measure serum magnesium level at 4–6 hr and adjust infusion to maintain levels between 4 and 7 meq/L (4.8 to 8.4 mg/dL)
   c. Measure serum magnesium levels if serum creatinine ≥ 1.0 mg/dL
4. Magnesium sulfate is discontinued 24 hr after delivery

Intermittent Intramuscular Injections

1. Give 4 g of magnesium sulfate ($MgSO_4 \cdot 7H_2O$ USP) as a 20% solution intravenously at a rate not to exceed 1 g/min
2. Follow promptly with 10 g of 50% magnesium sulfate solution, one-half (5 g) injected deeply in the upper outer quadrant of both buttocks through a 3-inch-long 20-gauge needle. (Addition of 1.0 mL of 2% lidocaine minimizes discomfort.) If convulsions persist after 15 min, give up to 2 g more intravenously as a 20% solution at a rate not to exceed 1 g/min. If the woman is large, up to 4 g may be given slowly
3. Every 4 hr thereafter give 5 g of a 50% solution of magnesium sulfate injected deeply in the upper outer quadrant of alternate buttocks, but only after ensuring that:
   a. The patellar reflex is present,
   b. Respirations are not depressed, and
   c. Urine output the previous 4 hr exceeded 100 mL
4. Magnesium sulfate is discontinued 24 hr after delivery

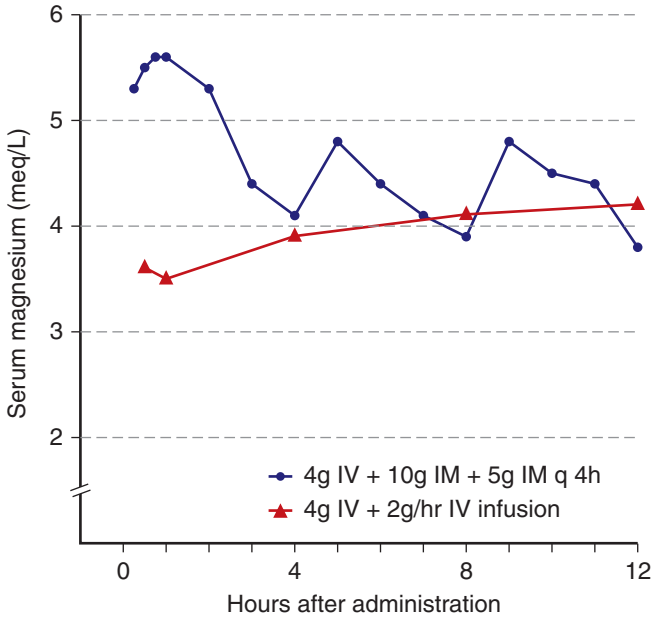

FIGURE 34-20 Comparison of serum magnesium levels in meq/L following a 4-g intravenous loading dose of magnesium sulfate and then maintained by either an intramuscular or continuing infusion. Multiply by 1.2 to convert meq/L to mg/dL. (Data from Sibai and colleagues, 1984.)

prolonged use is associated with a higher mortality rate (Royal College of Obstetricians and Gynaecologists, 2006).

Maintenance magnesium sulfate therapy is continued for 24 hours after delivery. For eclampsia that develops postpartum, magnesium sulfate is administered for 24 hours after the onset of convulsions. Ehrenberg and Mercer (2006) studied abbreviated postpartum magnesium administration in 200 women with *mild* preeclampsia. Of 101 women randomized to 12-hour treatment, seven had worsening preeclampsia, and treatment was extended to 24 hours. None of these 101 women and none of the other cohort of 95 given the 24-hour magnesium infusion developed eclampsia. This abbreviated regimen needs further study before being routinely administered for severe preeclampsia or eclampsia.

Pharmacology and Toxicology. Magnesium sulfate USP is $MgSO_4 \cdot 7H_2O$ and not simple $MgSO_4$. Parenterally administered magnesium is cleared almost totally by renal excretion, and magnesium intoxication is unusual when the glomerular filtration rate is maintained or only slightly decreased. Adequate urine output usually correlates with preserved glomerular filtration rates. That said, magnesium excretion is not urine flow dependent, and urinary volume per unit time does not, per se, predict renal function. Thus, serum creatinine levels must be measured to detect signs of declining glomerular filtration rate.

Eclamptic convulsions are almost always prevented or arrested by plasma magnesium levels maintained at 4 to 7 meq/L, 4.8 to 8.4 mg/dL, or 2.0 to 3.5 mmol/L. Although laboratories typically report *total* magnesium levels, free or *ionized* magnesium is the active moiety for suppressing neuronal excitability. Taber and associates (2002) found that there is a poor correlation between total and ionized levels. Further studies are necessary to determine if either measurement provides a superior method for surveillance. As shown in Figure 34-20, after a 4-g intravenous loading dose, magnesium levels observed with the intramuscular regimen and those observed with the maintenance infusion of 2 g per hour are similar. In our experience with the infusion, a number of women require 3 g/hr to maintain effective plasma levels of magnesium. That said, most do not recommend routine magnesium level measurements (American College of Obstetricians and Gynecologists, 2002a; Royal College of Obstetricians and Gynaecologists, 2006).

Patellar reflexes disappear when the plasma magnesium level reaches 10 meq/L—about 12 mg/dL—presumably because of a curariform action. This sign serves to warn of impending magnesium toxicity. When plasma levels rise above 10 meq/L, breathing becomes weakened, and at 12 meq/L or more, respiratory paralysis and respiratory arrest follow. Somjen and colleagues (1966) induced marked hypermagnesemia in themselves by intravenous infusion and achieved plasma levels up to 15 meq/L. Predictably, at such high plasma levels, respiratory depression developed that necessitated mechanical ventilation, but depression of the sensorium was not dramatic as long as hypoxia was prevented.

Treatment with calcium gluconate or calcium chloride, 1 g intravenously, along with withholding further magnesium sulfate, usually reverses mild to moderate respiratory depression. One of these agents should be readily available. Unfortunately, the effects of intravenously administered calcium may be short-lived if there is a steady-state toxic level. For severe respiratory depression and arrest, prompt tracheal intubation and mechanical ventilation are lifesaving. Direct toxic effects on the myocardium from high levels of magnesium are uncommon. It appears that the cardiac dysfunction associated with magnesium is due to respiratory arrest and hypoxia. With appropriate ventilation, cardiac action is satisfactory even when plasma levels are exceedingly high (McCubbin and co-workers, 1981).

Because magnesium is cleared almost exclusively by renal excretion, the dosages described will become excessive if glomerular filtration is decreased substantively. The initial 4-g loading dose of magnesium sulfate can be safely administered regardless of renal function. It is important to administer the standard loading dose and not to reduce it under the mistaken conception that diminished renal function requires it. This is because after distribution, a loading dose achieves the desired therapeutic level, and the infusion maintains the steady-state level. *Thus, only the maintenance infusion rate should be altered with diminished glomerular filtration rate.* Renal function is estimated by measuring plasma creatinine. Whenever plasma creatinine levels are > 1.0 mg/mL, serum magnesium levels are used to adjust the infusion rate.

Acute cardiovascular effects of parenteral magnesium in women with severe preeclampsia have been studied using data obtained by pulmonary and radial artery catheterization. After a 4-g intravenous dose administered over 15 minutes, mean arterial blood pressure fell slightly, accompanied by a 13-percent increase in cardiac index (Cotton and colleagues, 1986b). Thus, magnesium decreased systemic vascular resistance and mean arterial pressure, and at the same time increased cardiac output without evidence of myocardial depression. These findings were

coincidental with transient nausea and flushing, and the cardiovascular effects persisted for only 15 minutes despite continued magnesium infusion.

Thurnau and associates (1987) showed that there was a small but highly significant increase in total magnesium concentration in the cerebrospinal fluid with magnesium therapy. The magnitude of the increase was directly proportional to the corresponding serum concentration.

Magnesium is anticonvulsant and neuroprotective in a number of animal models. Some proposed mechanisms of action include: (1) reduced presynaptic release of the neurotransmitter glutamate, (2) blockade of glutamatergic *N*-methyl-D-aspartate (NMDA) receptors, (3) potentiation of adenosine action, (4) improved mitochondrial calcium buffering, and (5) blockage of calcium entry via voltage-gated channels (Arango and Mejia-Mantilla, 2006). Because hippocampal seizures can be blocked by magnesium, this implicates the NMDA receptor in eclamptic convulsions (Hallak and associates, 1998). These studies also confirm that magnesium has a central anticonvulsant effect.

Uterine Effects. Relatively high serum magnesium concentrations depress myometrial contractility both in vivo and in vitro. With the regimen described and the plasma levels that result, no evidence of myometrial depression has been observed beyond a transient decrease in activity during and immediately after the initial intravenous loading dose. Leveno and colleagues (1998) compared outcomes in 480 nulliparous women given phenytoin for preeclampsia with outcomes in 425 preeclamptic women given magnesium sulfate. Magnesium did not significantly alter the need for oxytocin stimulation of labor, admission-to-delivery intervals, or route of delivery. Similar results have been reported by others (Atkinson, 1995; Szal, 1999; Witlin, 1997b, and all their colleagues).

The mechanisms by which magnesium might inhibit uterine contractility are not established. However, these mechanisms are generally assumed to depend on its effects on intracellular calcium as discussed in detail in Chapter 6 (p. 148). Inhibition of uterine contractility is magnesium dose dependent, and serum levels of at least 8 to 10 meq/L are necessary to inhibit uterine contractions (Watt-Morse and colleagues, 1995). This likely explains why there are few if any uterine effects seen clinically when magnesium sulfate is given for preeclampsia. And as discussed in Chapter 36 (p. 824), magnesium is also not considered by many to be an effective tocolytic agent.

Fetal Effects. Maternal magnesium administered parenterally promptly crosses the placenta to achieve equilibrium in fetal serum and less so in amnionic fluid (Hallak and co-workers, 1993). Levels in amnionic fluid increase with duration of maternal infusion (Gortzak-Uzen and associates, 2005). Neonatal depression occurs only if there is *severe* hypermagnesemia at delivery. Neonatal compromise after therapy with magnesium sulfate is usually not problematic (Cunningham and Pritchard, 1984; Hallak and associates, 1999a). Whether magnesium sulfate affects the fetal heart rate pattern—specifically beat-to-beat variability—is controversial. In a randomized investigation, Hallak and colleagues (1999b) compared an infusion of magnesium sulfate with saline and reported that magnesium was associated with a small and clinically insignificant decrease in heart rate variability.

Observational studies have suggested a protective effect of magnesium against the development of cerebral palsy in very-low-birthweight infants (Nelson and Grether, 1995; Schendel and colleagues, 1996). At least five randomized trials have also assessed neuroprotective fetal effects. Moreover, Doyle and associates (2009) conducted a meta-analysis of five randomized trials that enrolled a total of 6145 infants born to women who were likely to give birth before 37 weeks. These women were randomly allocated to receive treatment with magnesium sulfate or placebo to prevent preeclampsia or preterm labor or to provide neuroprotection. Rates of substantive gross motor dysfunction were significantly decreased in infants exposed to therapeutic magnesium—0.61(CI 0.44–0.85). These findings are discussed in detail in Chapters 29 (p. 614) and 36 (p. 824).

Clinical Efficacy of Magnesium Sulfate Therapy. The multinational Eclampsia Trial Collaborative Group study (1995) involved 1687 women with eclampsia who were randomly allocated to different anticonvulsant regimens. In one cohort, 453 women were randomly assigned to be given magnesium sulfate and compared with 452 given diazepam. In a second cohort, 388 eclamptic women were randomly assigned to be given magnesium sulfate and compared with 387 women given phenytoin. The results of these and other comparative studies that each enrolled at least 50 women are summarized in **Table 34-14**. In aggregate, magnesium sulfate therapy was associated with a significantly lower incidence of recurrent seizures compared with women given an alternative anticonvulsant—9.7 versus 23 percent. Importantly, the maternal death rate of 3.1 percent with magnesium sulfate was significantly lower than that of 4.9 percent for the other regimens.

Management of Severe Hypertension

Dangerous hypertension can cause cerebrovascular hemorrhage, hypertensive encephalopathy and can trigger eclamptic convulsions in women with preeclampsia. Other complications include hypertensive afterload congestive heart failure and placental abruption.

Accordingly, the National High Blood Pressure Education Program Working Group (2000) specifically recommended that treatment include lowering systolic pressures to ≤ 160 mm Hg. Moreover, Martin and associates (2005) provided provocative observations that highlight the importance of treating systolic hypertension. They described 28 selected women with severe preeclampsia who suffered an associated stroke. Most of these were hemorrhagic—93 percent—and all women had systolic pressures > 160 mm Hg before suffering their stroke. By contrast, only 20 percent of these same women had diastolic pressures > 110 mm Hg. It seems likely that at least half of serious hemorrhagic strokes associated with preeclampsia are in women with chronic hypertension (Cunningham, 2005). Chronic hypertension results in development of *Charcot-Bouchard aneurysms* in the deeply penetrating arteries of the lenticulostriate branch of the middle cerebral artery. These supply the basal ganglia, putamen, thalamus, and adjacent deep white matter, as well as the pons and deep cerebellum. These aneurysmal

Data adapted from Leveno and Cunningham (2009) and Sibai and Cunningham (2009).

weakenings predispose these small arteries to rupture with sudden hypertension.

Because of these observations, our policy has been to treat women whose systolic blood pressures reach ≥ 160 mm Hg or whose diastolic pressures reach ≥ 110 mm Hg.

Antihypertensive Agents. There are several drugs available for rapid lowering of dangerously elevated blood pressure in women with the gestational hypertensive disorders. The three most commonly employed in North America and Europe are hydralazine, labetalol, and nifedipine. For years, parenteral hydralazine was the only one of the three available. However, when parenteral labetalol was later introduced, it was considered by most to be equally effective for obstetrical use. Orally administered nifedipine then became available, and this has gained popularity as first-line treatment for severe gestational hypertension.

Hydralazine. This is still a commonly used antihypertensive agent in the United States for treatment of women with severe gestational hypertension. Hydralazine is administered intravenously with a 5-mg initial dose, and this is followed by 5- to 10-mg doses at 15- to 20-minute intervals until a satisfactory response is achieved (American College of Obstetricians and Gynecologists, 2002a). Some limit the total dose to 30 mg per treatment cycle (Sibai, 2003). The target response antepartum or intrapartum is a decrease in diastolic blood pressure to 90 to 100 mm Hg, but not lower, lest placental perfusion be compromised. Hydralazine so administered has proven remarkably effective in the prevention of cerebral hemorrhage. Its onset of action can be as rapid as 10 minutes. Although repeated administration every 15 to 20 minutes may theoretically lead to undesirable hypotension, this has not been our experience.

At both Parkland Hospital and the University of Alabama at Birmingham Hospital, between 5 and 10 percent of all pregnant women with intrapartum hypertensive disorders are given a parenteral antihypertensive agent. Most often, we use hydralazine as described. We do not limit the total dose, and seldom has a second antihypertensive agent been needed. We estimate that at least 5000 women have been so treated at Parkland during the past 40 years. Although less popular in Europe, hydralazine is used in some centers according to the Royal College of Obstetricians and Gynaecologists (2006). A dissenting opinion for first-line intrapartum use of hydralazine was voiced by the Vancouver group after their first meta-analysis (Magee and colleagues, 2003). They reached a similar conclusion after a more recent systematic review (Magee and co-workers, 2009). At the same time, however, Umans and associates (2009) concluded that objective outcomes data did not support the use of one drug over another.

As with any antihypertensive agent, the tendency to give a larger initial dose of hydralazine when the blood pressure is higher must be avoided. The response to even 5- to 10-mg doses cannot be predicted by the level of hypertension. Thus, our protocol is to always administer 5 mg as the initial dose. An adverse response to exceeding this initial dose is shown in **Figure 34-21**. This woman had chronic hypertension complicated by severe superimposed preeclampsia, and hydralazine was injected more frequently than recommended. Her blood pressure decreased in less than 1 hour from 240–270/130–150 mm Hg to 110/80 mm Hg. Fetal heart rate decelerations characteristic of uteroplacental insufficiency were evident when the pressure fell to 110/80 mm Hg. These decelerations persisted until her blood pressure was increased with rapid crystalloid infusion. In some cases, this fetal response to diminished uterine perfusion may be confused with placental abruption and may result in unnecessary emergent cesarean delivery.

Labetalol. Another effective antihypertensive agent commonly used in the United States is intravenous labetalol—an α_1- and nonselective β-blocker. Some prefer its use over hydralazine because of fewer side effects (Sibai, 2003). At Parkland Hospital, we give 10 mg intravenously initially. If the blood pressure has not decreased to the desirable level in 10 minutes, then 20 mg is given. The next 10-minute incremental dose is 40 mg and is

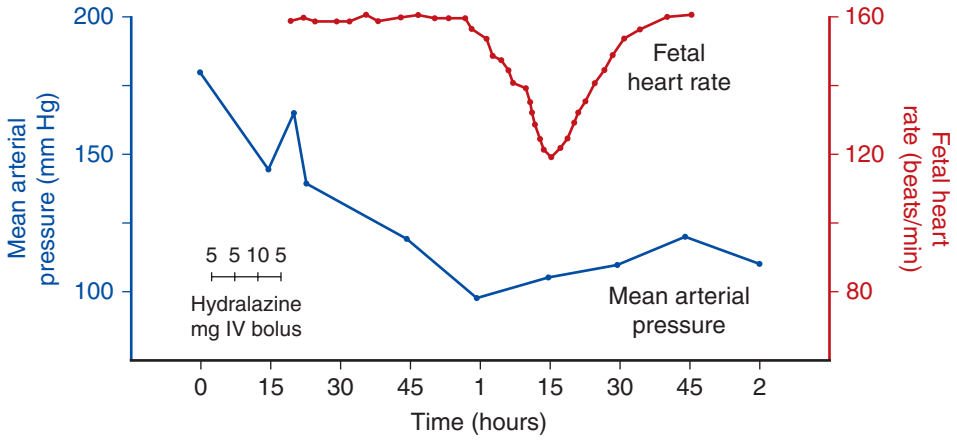

FIGURE 34-21 Effects of acute blood pressure decrease on fetal status. Hydralazine was given at 5-minute intervals instead of 15-minute intervals. The mean arterial pressure decreased from 180 to 90 mm Hg within 1 hour and was associated with fetal bradycardia. Rapid crystalloid infusion raised the mean pressure to 115 mm Hg and the fetus recovered.

followed by another 40 mg if needed. If a salutary response is not achieved, then an 80-mg dose is given. Sibai (2003) recommends 20 to 40 mg every 10 to 15 minutes as needed for a maximum dose of 220 mg per treatment cycle. The NHBPEP Working Group (2000) and the American College of Obstetricians and Gynecologists (2002a) recommend starting with a 20-mg intravenous bolus. If not effective within 10 minutes, this is followed by 40 mg, then 80 mg every 10 minutes but not to exceed a 220-mg total dose per episode treated.

Hydralazine versus Labetalol. Comparative studies of these two antihypertensive agents show equivalent results. In one, Mabie and colleagues (1987) compared intravenous hydralazine with labetalol for blood pressure control in 60 peripartum women. Labetalol lowered blood pressure more rapidly, and associated tachycardia was minimal, but hydralazine lowered mean arterial pressures to safe levels more effectively. In another trial, Vigil-De Gracia and associates (2007) randomized 200 severely hypertensive intrapartum women to be given either: (1) intravenous hydralazine—5 mg, which could be given every 20 minutes and repeated to a maximum of five doses, or (2) intravenous labetalol—20 mg initially, followed by 40 mg in 20 minutes and then 80 mg every 20 minutes if needed up to a maximum 300-mg dose. Maternal and neonatal outcomes were similar. Hydralazine caused significantly more maternal tachycardia and palpitations, whereas labetalol more frequently caused maternal hypotension and bradycardia. Other than maternal tachycardia with hydralazine and occasional maternal bradycardia with labetalol, we have not encountered arrhythmias with either drug.

Nifedipine. This calcium-channel blocking agent has become popular because of its efficacy for control of acute pregnancy-related hypertension. The NHBPEP Working Group (2000) and the Royal College of Obstetricians and Gynaecologists (2006) recommend a 10-mg initial oral dose to be repeated in 30 minutes if necessary. Nifedipine given sublingually is no longer recommended. Randomized trials that compared nifedipine with labetalol found neither drug definitively superior to the other (Scardo and associates, 1999; Vermillion and co-workers, 1999).

Other Antihypertensive Agents. A few other generally available antihypertensive agents have been tested in clinical trials but are not widely used. Belfort and associates (1990) administered the calcium antagonist, *verapamil*, by intravenous infusion at 5 to 10 mg per hour. Mean arterial pressure was lowered by 20 percent. Belfort and co-workers (1996, 2003) reported that *nimodipine* given either by continuous infusion or orally was effective to lower blood pressure in women with severe preeclampsia. Bolte and colleagues (1998, 2001) reported good results in preeclamptic women given intravenous *ketanserin*, a selective serotonergic ($5HT_{2A}$) receptor blocker. *Nitroprusside* or *nitroglycerine* is recommended by some if there is not optimal response to first-line agents (National High Blood Pressure Education Program Working Group, 2000). With these latter two agents, fetal cyanide toxicity may develop after 4 hours. We have not had the need for either due to our consistent success with first-line treatment using hydralazine, labetalol, or a combination of the two given in succession, but never simultaneously.

There are experimental antihypertensive drugs that may become useful for preeclampsia treatment. Two of these are *calcitonin gene related peptide (CGRP),* which is a 37-amino acid potent vasodilator, and *endogenous digitalis-like factors*, also called *cardiotonic steroids* (Bagrov and Shapiro, 2008; Márquez-Rodas and colleagues, 2006).

Diuretics. Potent diuresis can further compromise placental perfusion. Immediate effects include depletion of intravascular volume, which most often is already reduced compared with that of normal pregnancy (see p. 717). Therefore, before delivery, diuretics are not used to lower blood pressure (Zeeman and co-workers, 2009a; Zondervan and associates, 1988). We limit antepartum use of furosemide or similar drugs solely to treatment of pulmonary edema.

Fluid Therapy

Lactated Ringer solution is administered routinely at the rate of 60 mL to no more than 125 mL per hour unless there is unusual fluid loss from vomiting, diarrhea, or diaphoresis, or more

likely, there is excessive blood loss with delivery. Oliguria is common with severe preeclampsia. Thus, coupled with the knowledge that maternal blood volume is likely constricted compared with that of normal pregnancy, it is tempting to administer intravenous fluids more vigorously. However, controlled, conservative fluid administration is preferred for the typical woman with eclampsia who already has excessive extracellular fluid that is inappropriately distributed between intravascular and extravascular spaces. As discussed on page 716, infusion of large fluid volumes enhances the maldistribution of extravascular fluid and thereby appreciably increases the risk of pulmonary and cerebral edema (Sciscione, 2003; Sibai, 1987b; Zinaman, 1985, and all their co-workers).

Pulmonary Edema. Women with severe preeclampsia-eclampsia who develop pulmonary edema most often do so postpartum (Cunningham and colleagues, 1986; Zinaman and associates, 1985). First, aspiration of gastric contents, which may be the result of convulsions, anesthesia, or oversedation, should be excluded. As discussed in Chapter 42 (p. 929), there are three common causes of pulmonary edema in women with severe preeclampsia syndrome—pulmonary capillary permeability edema, cardiogenic edema, or a combination of the two.

Most women with severe preeclampsia will have some mild pulmonary congestion from permeability edema. This is caused by normal pregnancy changes magnified by the preeclampsia syndrome as discussed in Chapter 5 (p. 121). Importantly, plasma oncotic pressure decreases appreciably in normal term pregnancy because of decreased serum albumin concentration, and oncotic pressure falls even more with preeclampsia (Zinaman and associates, 1985). And both increased extravascular fluid oncotic pressure and increased capillary permeability have been described in women with preeclampsia (Brown and colleagues, 1989; Øian and associates, 1986).

Invasive Hemodynamic Monitoring. Knowledge concerning cardiovascular and hemodynamic pathophysiological alterations associated with severe preeclampsia-eclampsia has accrued from studies done using invasive monitoring and a flow-directed pulmonary artery catheter (see Figs. 34-5 and 34-6). A few reviews have addressed such monitoring in obstetrics (Clark and Cotton, 1988; Nolan and colleagues, 1992). Two conditions frequently cited as indications are preeclampsia associated with either oliguria or pulmonary edema. Somewhat ironically, it is usually vigorous treatment of the former that results in most cases of the latter. The American College of Obstetricians and Gynecologists (2002a) recommends such monitoring be reserved for severely preeclamptic women with accompanying severe cardiac disease, renal disease, or both or in cases of refractory hypertension, oliguria, and pulmonary edema.

Plasma Volume Expansion

Because the preeclampsia syndrome is associated with hemoconcentration directly proportional to syndrome severity, attempts to expand blood volume seem reasonable, at least intuitively (Ganzevoort and associates, 2004). This reasoning has led some to infuse various fluids, starch polymers, albumin concentrates, or combinations thereof in attempts to expand blood volume.

There are, however, observational studies that describe serious complications—especially pulmonary edema—with volume expansion. For example, López-Llera and colleagues (1982) reported that vigorous volume expansion in more than 700 eclamptic women was associated with a high incidence of pulmonary edema. Benedetti and associates (1985) described pulmonary edema in 7 of 10 women with severe preeclampsia who were given colloid therapy. Moreover, Sibai and co-workers (1987b) cited excessive colloid and crystalloid infusions as causing most of their reported 37 cases of pulmonary edema associated with severe preeclampsia-eclampsia. In general, these studies were not controlled or even comparative (Habek and colleagues, 2006).

The Amsterdam randomized study reported by Ganzevoort and co-workers (2005a, b) was a well-designed investigation done to evaluate volume expansion. A total of 216 women with severe preeclampsia were enrolled between 24 and 34 weeks' gestation. They also included women whose preeclampsia was complicated by HELLP syndrome, eclampsia, or fetal-growth restriction. All women were given magnesium sulfate to prevent eclampsia, betamethasone to promote pulmonary maturity, ketanserine to control dangerous hypertension, and normal saline infusions restricted to only deliver medications. In the group randomly assigned to volume expansion, each woman was given 250 mL of 6-percent hydroxyethyl starch infused over 4 hours twice daily. Their maternal and perinatal outcomes were compared with a control group and are shown in **Table 34-15**. None of these outcomes was significantly different between the two groups. Importantly, serious maternal morbidity and a substantive perinatal mortality rate accompanied their "expectant" management (see Table 34-10).

Prevention of Eclampsia

There have been a number of randomized trials designed to test the efficacy of seizure prophylaxis for women with gestational hypertension, with or without proteinuria, and thus preeclampsia. In most of these, magnesium sulfate was compared with either another anticonvulsant or with a placebo. *In all studies, magnesium sulfate was reported to be superior to the comparator agent to prevent eclampsia.* Four of the larger studies are summarized in **Table 34-16**. Lucas and colleagues (1995) reported that magnesium sulfate therapy was superior to phenytoin to prevent eclamptic seizures in women with gestational hypertension including those with all severities of preeclampsia. Belfort and associates (2003) compared magnesium sulfate and nimodipine—a calcium-channel blocker with specific cerebral vasodilator activity—for eclampsia prevention. In this unblinded randomized trial involving 1650 women with severe preeclampsia, the rate of eclampsia was more than threefold higher for women allocated to the nimodipine group—2.6 versus 0.8 percent compared with the group given magnesium sulfate.

The largest comparative study was the *MAGnesium Sulfate for Prevention of Eclampsia* (MAGPIE Trial Collaboration Group, 2002). More than 10,000 women with severe preeclampsia from 33 countries were randomly allocated to treatment

TABLE 34-15. Maternal and Perinatal Outcomes in a Randomized Trial of Plasma Volume Expansion versus Saline Infusion in 216 Women with Severe Preeclampsia between 24 and 34 Weeks

Outcomes	Control Group[a] (n = 105)	Treatment Group[a] (n = 111)
Maternal Outcomes (percent)		
Eclampsia (after enrollment)	1.9	1.8
HELLP (after enrollment)	19.0	17.0
Pulmonary edema	2.9	4.5
Placental abruption	3.8	1.0
Hepatic hematoma	1.0	0.0
Encephalopathy	2.9	1.8
Perinatal Outcomes		
Fetal deaths (percent)	7	12
Prolongation pregnancy (mean)	11.6 days	6.7 days
EGA at death (mean)	26.7 weeks	26.3 weeks
Birthweight (mean)	625 g	640 g
Live births (percent)	93	88
Prolongation pregnancy (mean)	10.5 days	7.4 days
EGA at delivery (mean)	31.6 weeks	31.4 weeks
Assisted ventilation (percent)	40	45
RDS (percent)	30	35
Chronic lung disease (percent)	7.6	8.1
Neonatal death (percent)	7.6	8.1
Perinatal mortality rate	142/1000	207/1000

[b]Magpie Trial Collaboration Group (2002).

with magnesium sulfate or placebo. Women given magnesium had a 58-percent significantly lower risk of eclampsia than those given placebo. Women given placebo and who developed eclampsia were treated with magnesium sulfate. Smyth and colleagues (2009) provided follow-up data of infants born to these mothers given magnesium sulfate. At about 18 months, child behavior did not differ in those exposed to versus those not exposed to magnesium sulfate.

Who Should Be Given Magnesium Sulfate?

Magnesium will prevent more seizures in women with correspondingly worse disease. Severity is difficult to quantify, and thus it is difficult to decide which individual woman might benefit most from prophylaxis. *In the United States, the consensus is that women judged to have severe preeclampsia should be given magnesium sulfate prophylaxis.* This is also the recommendation of the American College of Obstetricians and Gynecologists (2002a). As discussed, criteria that establish "severity" are not totally uniform, and many use those promulgated by the NHBPEP Working Group (2000), which are listed in Table 34-1. For women with "nonsevere" disease—again variably defined—the guidelines are even less clear-cut.

In many other countries, and principally following dissemination of the Magpie Trial Collaboration Group (2002) study results, magnesium sulfate is now recommended for women with severe preeclampsia. In some, however, debate continues concerning whether therapy should be reserved for women who have an eclamptic seizure. We are of the opinion that eclamptic seizures are dangerous for reasons discussed on page 735. Maternal mortality rates of up to 5 percent have been reported even in recent studies (Andersgaard, 2006; Benhamou, 2009; Schutte, 2008; Zwart, 2008, and all their colleagues). Moreover, there are substantively increased perinatal mortality rates in both industrialized countries as well as underdeveloped ones (Basso, 2006; Chowdhury, 2009; Knight, 2007; Schutte, 2008; Zwart, 2008, and all their associates). Finally, the possibility of adverse long-term neuropsychological sequelae of eclampsia described by Aukes (2007, 2009) and Postma (2009) and their colleagues, which is discussed on page 749, have raised additional concerns that eclamptic seizures perhaps are not "benign."

Parkland Hospital Study of Selective versus Universal Magnesium Sulfate Prophylaxis

Debate in the United States currently centers around which women with nonsevere gestational hypertension should be given magnesium sulfate prophylaxis. An opportunity to address these questions was afforded by a change in magnesium sulfate prophylaxis protocol for women delivering at Parkland Hospital beginning in 2000. Prior to this time, Lucas and colleagues (1995) had found the risk of eclampsia without magnesium prophylaxis to be 1 in 100 or less in women with *mild preeclampsia*. Up until 2000, all women with gestational hypertension were given maintenance magnesium prophylaxis intramuscularly as first described by Pritchard in 1955. After 2000, we instituted a standardized protocol for intravenously administered magnesium sulfate. At the same time, we also changed our practice of universal seizure prophylaxis for all women with gestational hypertension to one of selective prophylaxis given only to women who met our criteria for severe gestational hypertension. These criteria shown in **Table 34-17** included women with ≥ 2+ proteinuria measured by dipstick in a catheterized urine specimen.

TABLE 34-17. Selective versus Universal Magnesium Sulfate Prophylaxis: Parkland Hospital Criteria to Define Severity of Gestational Hypertension

In a woman with new-onset proteinuric hypertension, at least one of the following criteria is required:

- Systolic BP ≥ 160 or diastolic BP ≥ 110 mm Hg
- Proteinuria ≥ 2+ as measured by dipstick in a catheterized urine specimen
- Serum creatinine > 1.2 mg/dL
- Platelet count < 100,000/μL
- Aspartate transaminase (AST) elevated two times above upper limit of normal range
- Persistent headache or scotomata
- Persistent midepigastric or right-upper quadrant pain

BP = blood pressure.
Criteria based on those from National High Blood Pressure Education Program Working Group (2000) and American College of Obstetricians and Gynecologists (2002a) and cited by Alexander and associates (2006).

Following this protocol change, 60 percent of 6431 women with gestational hypertension during a 41/2-year period were given magnesium sulfate prophylaxis. Of the 40 percent with nonsevere hypertension who were not treated, 27 women developed eclamptic seizures—1 in 92. The seizure rate was only 1 in 358 for 3935 women with criteria for severe disease who were given magnesium sulfate and thus were treatment failures. To assess morbidity, outcomes in 87 eclamptic women were compared with those in all 6431 noneclamptic hypertensive women. Although most maternal outcomes were similar, as shown in **Table 34-18**, almost a fourth of women with eclampsia who underwent emergent cesarean delivery required general anesthesia. This is of great concern because eclamptic women have laryngotracheal edema and are at a higher risk for failed intubation, gastric acid aspiration, and death (American College of Obstetricians and Gynecologists, 2002b). Neonatal outcomes were also of concern because the composite morbidity defined in Table 34-18 was significantly increased tenfold in eclamptic compared with noneclamptic women—12 versus 1 percent, respectively.

Thus, if one uses the Parkland criteria for nonsevere gestational hypertension, about 1 of 100 such women who are not given magnesium sulfate prophylaxis can be expected to have an eclamptic seizure. A fourth of these women likely will require emergent cesarean delivery with attendant maternal and perinatal morbidity and mortality from general anesthesia. From this, it appears that the major question regarding management of nonsevere gestational hypertension remains: Is it acceptable to avoid unnecessary treatment of 99 women to risk eclampsia in one?

TABLE 34-18. Selected Pregnancy Outcomes in 6518 Women with Gestational Hypertension According to Whether They Developed Eclampsia

Pregnancy Outcomes	Eclampsia No. (%)	Gestational Hypertension[a] No. (%)	*p* value
Number	87	6431	
Maternal			
Cesarean delivery	32 (37)	2423 (38)	0.86
Placental abruption	1 (1)	72 (1)	0.98
General anesthesia[b]	20 (23)	270 (4)	< 0.001
Neonatal			
Composite morbidity[c]	10 (12)	240 (1)	0.04

[a]Includes women who had preeclampsia.
[b]Emergent cesarean delivery.
[c]One or more: cord artery pH < 7.0; 5-minute Apgar score < 4; perinatal death; or unanticipated admission of term infant to an intensive care nursery.
Data from Alexander and colleagues (2006).

Delivery

To avoid maternal risks from cesarean delivery, steps to effect vaginal delivery are used initially in women with eclampsia. Following a seizure, labor often ensues spontaneously or can be induced successfully even in women remote from term (Alanis and associates, 2008). An immediate cure does not promptly follow delivery by any route, but serious morbidity is less common during the puerperium in women delivered vaginally.

Blood Loss at Delivery

Hemoconcentration or lack of normal pregnancy-induced hypervolemia is an almost predictable feature of severe preeclampsia-eclampsia as quantified by Zeeman and associates (2009) and shown in Figure 34-6. **These women, who consequently lack normal pregnancy hypervolemia, are much less tolerant of even normal blood loss than are normotensive pregnant women.** It is of great importance to recognize that an appreciable fall in blood pressure soon after delivery most often means excessive blood loss and not sudden resolution of vasospasm and endothelial damage. When oliguria follows delivery, the hematocrit should be evaluated frequently to help detect excessive blood loss. If identified, hemorrhage should be treated appropriately by careful blood transfusion.

Analgesia and Anesthesia

During the past 20 years, the use of conduction analgesia for women with preeclampsia syndrome has proven ideal. Initial problems with this method included hypotension and diminished uterine perfusion caused by sympathetic blockade in these women with attenuated hypervolemia. Development of techniques that used slow induction of epidural analgesia with dilute solutions of anesthetic agents were reported to counter the need for rapid infusion of large volumes of crystalloid or colloid to correct maternal hypotension and usually averts pulmonary edema (Hogg and colleagues, 1999; Wallace and co-workers, 1995). Moreover, epidural blockade avoids stimulation caused by tracheal intubation, which can cause sudden severe hypertension. Such blood pressure increases, in turn, can cause pulmonary edema, cerebral edema, or intracranial hemorrhage (Lavies and co-workers, 1989). Finally, tracheal intubation may be particularly difficult and thus hazardous in women with airway edema due to preeclampsia (American College of Obstetricians and Gynecologists, 2002b).

At least two randomized studies have been performed to evaluate these methods of analgesia and anesthesia. Wallace and colleagues (1995) studied 80 women with severe preeclampsia at a mean gestational age of 34.8 weeks who were to undergo cesarean delivery. They had not been given labor epidural analgesia and were randomized to receive general anesthesia, epidural analgesia, or combined spinal-epidural analgesia. Their mean preoperative blood pressure approximated 170/110 mm Hg, and all had proteinuria. Anesthetic and obstetrical management included antihypertensive drug therapy and limited intravenous fluids. Perinatal outcomes in each group were similar. Maternal hypotension resulting from regional analgesia was managed with judicious intravenous fluid administration. Similarly, maternal blood pressure was managed to avert severe hypertension in women undergoing general anesthesia (Fig. 34-22). There were no serious maternal or fetal complications attributable to any of the three anesthetic methods. It was concluded that all three are acceptable for use in women with pregnancies complicated by severe preeclampsia if steps are taken to ensure a careful approach to either method. A similar conclusion was reached by Dyer and colleagues (2003) following their randomized study of spinal analgesia versus general anesthesia in 70 women with preeclampsia and a nonreassuring fetal heart rate tracing. Dyer and associates (2008) later showed that decreased vascular resistance and mean arterial blood pressure induced by

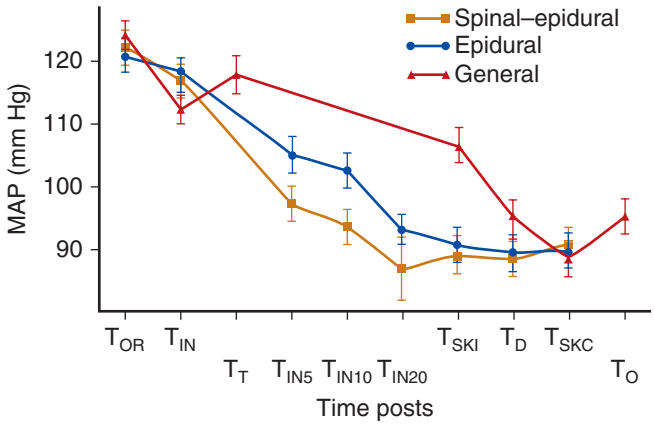

FIGURE 34-22 Blood pressure effects of general anesthesia versus epidural or spinal–epidural analgesia for cesarean delivery in 80 women with severe preeclampsia. MAP = mean arterial pressure. Time posts (T): OR = operating room; IN = induction of anesthesia; T = tracheal intubation; IN5 = induction + 5 min; IN10 = induction + 10 min; IN20 = induction + 20 min; SKI = skin incision; D = delivery; SKC = skin closure; O = extubation. (From Wallace and associates, 1995, with permission.)

epidural blockade were effectively counteracted by phenylephrine infusion to maintain cardiac output.

In a study from the University of Alabama at Birmingham, Head and co-workers (2002) randomly assigned 116 women with severe preeclampsia to receive either epidural or patient-controlled intravenous meperidine analgesia during labor. A standardized protocol limited intravenous fluids to 100 mL/hour. More women—9 percent—from the group assigned to epidural analgesia required ephedrine for hypotension. As expected, pain relief was superior in the epidural group but otherwise, maternal and neonatal complications were similar between groups. One woman in each group developed pulmonary edema.

In the past, some believed that epidural analgesia was an important factor in the intrapartum *treatment* of women with preeclampsia (Gutsche and Cheek, 1993). Lucas and associates (2001) studied 738 laboring women at Parkland Hospital who were 36 weeks or more and who had gestational hypertension of varying severity. Patients were randomly assigned to receive either epidural analgesia or patient-controlled intravenous meperidine analgesia. Maternal and infant outcomes were similar in the two study groups. As shown in **Table 34-19**, although epidural analgesia resulted in a greater decrement of mean maternal arterial pressure compared with meperidine, it was not superior in preventing recurrent severe hypertension later in labor. Thus, labor epidural analgesia should not be misconstrued to be a therapy for hypertension.

For these reasons, judicious fluid administration in severely preeclamptic women who receive regional analgesia is key in their management. Newsome and associates (1986) showed that epidural blockade in women with severe preeclampsia caused elevation of pulmonary capillary wedge pressures. It is clear that aggressive volume replacement in these women increases their risk for pulmonary edema, especially in the first 72 hours postpartum (Clark and colleagues, 1985; Cotton and co-workers, 1986a). When pulmonary edema develops, there is also concern for development of cerebral edema. Finally, Heller and associates (1983) demonstrated that most cases of pharyngolaryngeal edema were related to aggressive volume therapy.

Persistent Severe Postpartum Hypertension

The potential problem of antihypertensive agents causing serious compromise of uteroplacental perfusion and thus of fetal well-being is obviated by delivery. Postpartum, if difficulty arises in controlling severe hypertension or if intravenous hydralazine or labetalol are being used repeatedly, then oral regimens can be given. Examples include labetalol or another β-blocker, nifedipine or another calcium-channel blocker, and possible addition of a thiazide diuretic. Persistent or refractory hypertension is likely due to mobilization of interstitial edema fluid and redistribution into the intravenous compartment, underlying chronic hypertension, or usually both (Tan and deSwiet, 2002). In women with chronic hypertension and left-ventricular hypertrophy, severe postpartum hypertension can cause pulmonary edema from cardiac failure (Cunningham and colleagues, 1986; Sibai and co-workers, 1987a).

Furosemide

Because persistence of severe hypertension corresponds to the onset and length of diuresis and extracellular fluid mobilization,

TABLE 34-19. Comparison of Cardiovascular Effects of Epidural versus Patient-Controlled Meperidine Analgesia During Labor in Women with Gestational Hypertension

	Labor Analgesia		
Hemodynamic Change	Epidural (n = 372)	Meperidine (n = 366)	*p* value
Mean arterial pressure change (mean)	−25 mm Hg	−15 mm Hg	< 0.001
Ephedrine for hypotension	11%	0	< 0.001
Severe hypertension after analgesia (BP ≥ 160/110 mm Hg)	< 1%	1%	NS

NS = not significant.
Data from Lucas and associates (2001).

it seems logical that furosemide-augmented diuresis might serve to hasten blood pressure control. To study this, Ascarelli and associates (2005) designed a randomized trial that included 264 postpartum preeclamptic women. After onset of spontaneous diuresis, patients were randomly assigned to 20-mg oral furosemide given daily versus no therapy. Compared with women with mild disease, those with severe preeclampsia had a lower mean systolic blood pressure at 2 days—142 versus 153 mm Hg—and less often required antihypertensive therapy during the remainder of hospitalization—14 versus 26 percent, respectively.

We have used a simple method to estimate excessive extracellular/interstitial fluid. The *postpartum weight* is compared with the last recorded recent *prenatal weight*, either from the last clinic visit or upon admission for delivery. On average, soon after delivery, maternal weight should be reduced by at least 10 to 15 pounds depending on birthweight, amnionic fluid volume, placental weight, and blood loss. Because of various interventions, especially intravenous crystalloid infusions given during operative vaginal or cesarean delivery, women with severe preeclampsia often have a postpartum weight *in excess of their last prenatal weight*. If this weight increase is associated with severe persistent postpartum hypertension, diuresis with intravenous furosemide is usually helpful.

Plasma Exchange

Martin and colleagues (1995) have described an atypical syndrome in which severe preeclampsia-eclampsia persists despite delivery. These investigators described 18 such women who they encountered over a 10-year period. They advocate single or multiple plasma exchange for these women. In some cases, 3 L of plasma was exchanged three times—a 36- to 45-donor unit exposure for each patient—before a response was forthcoming. Others have described plasma exchange performed in postpartum women with HELLP syndrome (Förster and associates, 2002; Obeidat and colleagues, 2002). In all of these cases, however, the distinction between HELLP syndrome and thrombotic thrombocytopenic purpura or hemolytic uremic syndrome was not clear. As further discussed in Chapter 51 (p. 1095), in our experiences with more than 50,000 women with gestational hypertension among nearly 400,000 pregnancies cared for at Parkland Hospital through 2009, we have encountered very few women with persistent postpartum hypertension, thrombocytopenia, and renal dysfunction who were diagnosed as having a thrombotic microangiopathy (Dashe and co-workers, 1998). As concluded by Martin and colleagues (2008) after their review of 166 pregnancies complicated by thrombotic thrombocytopenic purpura, a rapid diagnostic test such as that for ADAMTS-13 enzyme activity might be helpful to differentiate most of these.

Postpartum Angiopathy. Another cause of persistent hypertension, seizures, and central nervous system findings is termed postpartum angiopathy. Also known as the *reversible cerebral vasoconstriction syndrome*, it is more common in women, and is associated with a myriad of different precipitating events, with pregnancy and the puerperium being just one of these (Singhal and co-workers, 2009). In some cases, vasoconstriction may be so severe as to cause cerebral ischemia and areas of infarction. The appropriate management is not known at this time.

LONG-TERM CONSEQUENCES

Women with hypertension identified during pregnancy should be evaluated during the first several months postpartum. They are counseled about long-term risks. As discussed earlier, the longer hypertension identified during pregnancy persists postpartum, the greater the likelihood that the woman has chronic hypertension. The Working Group concluded that hypertension attributable to pregnancy should resolve within 12 weeks of delivery (National High Blood Pressure Education Program, 2000). Persistence beyond this time is considered to be chronic hypertension (see Chap. 45, p. 983). The Magpie Trial Follow-Up Collaborative Group (2007) reported that 20 percent of 3375 preeclamptic women seen at a median of 26 months postpartum had hypertension. But even if hypertension does not persist in the short term, there is now convincing evidence that the risk for long-term cardiovascular morbidity is significantly increased in preeclamptic women as subsequently discussed.

Counseling for Future Pregnancies

Women who have had either gestational hypertension or preeclampsia are at higher risk to develop hypertensive and metabolic complications in future pregnancies. Generally, the earlier preeclampsia is diagnosed during the index pregnancy, the greater the likelihood of recurrence. For example, Sibai and colleagues (1986, 1991) found that nulliparous women diagnosed with preeclampsia before 30 weeks have a recurrence risk as high as 40 percent during a subsequent pregnancy.

In a study of 511 Icelandic women with gestational hypertension during their first pregnancy, Hjartardottir and co-workers (2006) reported an astonishing 70-percent recurrence risk for hypertension in the second pregnancy. Although most of these women had recurrent gestational hypertension, 5 percent had preeclampsia and 16 percent had chronic hypertension. The 151 women with preeclampsia in the first pregnancy had an overall 58-percent recurrence rate—over half had gestational hypertension and about a fourth each had either preeclampsia or chronic hypertensive disease. In a much larger study from the Denmark Birth Registry, Lykke and co-workers (2009b) analyzed singleton births in more than 535,000 women who had a first and second delivery from 1978 to 2007. Women whose first pregnancy was complicated by preeclampsia between 32 and 36 weeks had a significant twofold increased incidence of preeclampsia in their second pregnancy 25 versus 14 percent—compared with women who were normotensive during the first pregnancy. They also found that preterm delivery and fetal-growth restriction in the first pregnancy slightly, albeit significantly, increased the risk for preeclampsia in the second pregnancy.

Women with HELLP syndrome have a substantive risk for recurrence in subsequent pregnancies. In an earlier study, Sibai and colleagues (1995) found this to be approximately 5 percent, but this same group later described a 26-percent recurrence risk (Habli and co-workers, 2009). The true recurrence risk likely

lies between these two extremes. Even if HELLP syndrome does not recur with subsequent recurrent preeclampsia, there is a high incidence of preterm delivery, fetal-growth restriction, placental abruption, and cesarean delivery (Habli and associates, 2009; Hnat and colleagues, 2002).

Some women with early-onset severe preeclampsia are found to have underlying thrombophilias (see p. 718). These disorders may also complicate subsequent pregnancies. For example, Facchinetti and associates (2009) reported a twofold increased risk for recurrent preeclampsia in women with a thrombophilia and preeclampsia compared with preeclamptic women without thrombophilia identified. In addition, these inherited disorders also affect overall long-term health (see Chap. 47, p. 1014).

Long-Term Sequelae

Cardiovascular and Neurovascular Morbidity

With the advent of national databases, several long-term studies confirm that any hypertension during pregnancy is a marker for increased rates of later cardiovascular-related morbidity and mortality. In a case-control study from Iceland, Arnadottir and colleagues (2005) analyzed outcomes for 325 women who had hypertension complicating pregnancy and who were delivered from 1931 through 1947. At a median follow-up of 50 years, 60 percent of hypertensive women compared with only 53 percent of controls had died. Compared with 629 normotensive pregnant controls, the prevalences of *ischemic heart disease*—24 versus 15 percent, and *stroke*—9.5 versus 6.5 percent, were significantly increased in the women who had had hypertension during pregnancy. In a Swedish population study of more than 400,000 nulliparous women delivered between 1973 and 1982, Wikström and co-workers (2005) also found an increased incidence of ischemic heart disease in women with prior pregnancy-associated hypertension.

Lykke and associates (2009a) cited findings from a Danish registry of more than 780,000 nulliparous women having a singleton delivery from 1978 to 2007. After a mean follow-up of almost 15 years, the incidence of *chronic hypertension* was significantly increased 5.2-fold in those who had gestational hypertension, 3.5-fold after mild preeclampsia, and 6.4-fold after severe preeclampsia. After two hypertensive pregnancies, there was a 5.9-fold increase in the incidence of chronic hypertension. Importantly, these investigators also reported a significant 3.5-fold increased risk for *type 2 diabetes*.

Bellamy and co-workers (2007) recently performed a systematic review and meta-analysis of long-term risks for cardiovascular disease in women with preeclampsia. As shown in **Figure 34-23**, the risks in later life were increased for hypertension, ischemic heart disease, stroke, venous thromboembolism, as well as all-cause mortality. As emphasized by Harskamp and associates (2007), a number of cofactors or comorbidities are related to acquisition of these long-term adverse outcomes associated with pregnancy hypertension. These include but are not limited to the metabolic syndrome, diabetes, obesity, dyslipidemia, and atherosclerosis. These conclusions are underscored by the

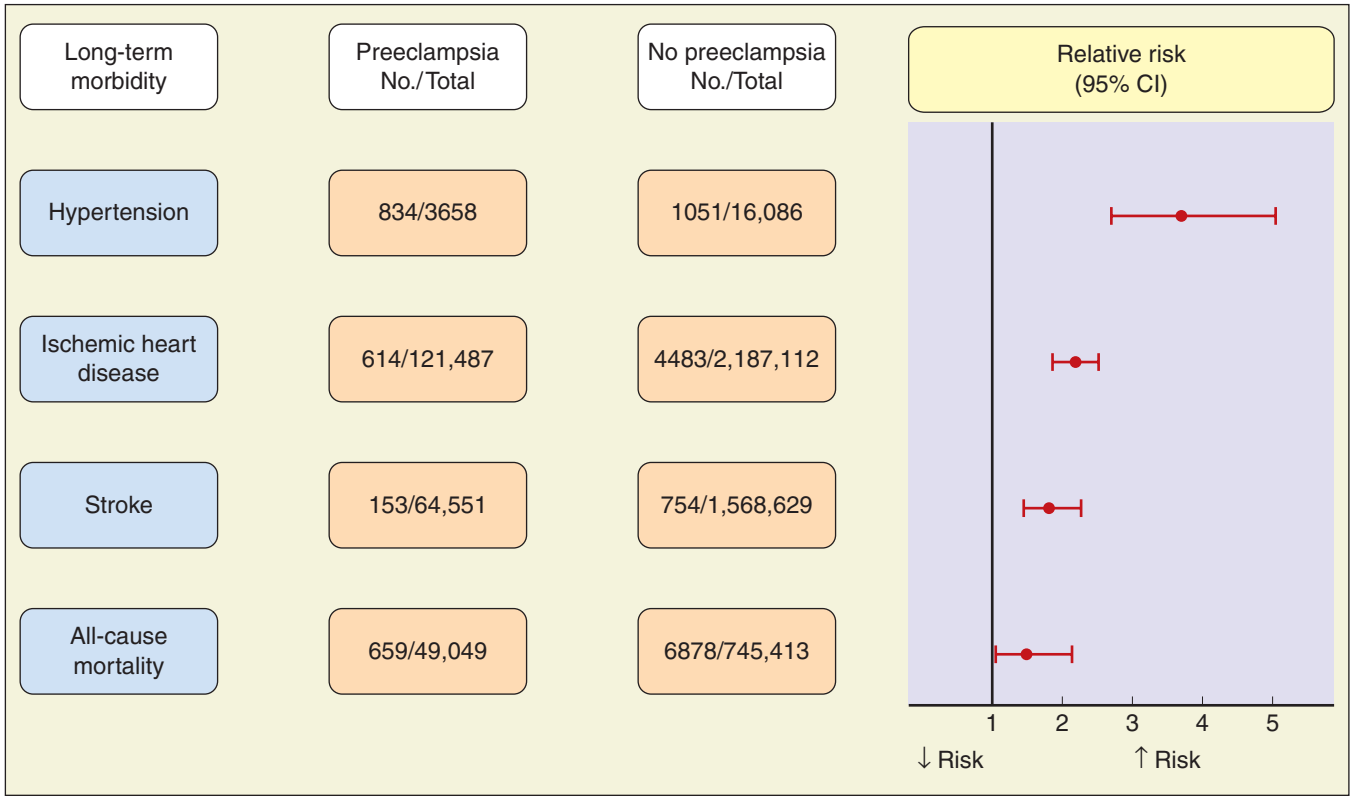

FIGURE 34-23 Long-term cardiovascular consequences of preeclampsia. All differences $p \leq .001$ except p = 0.03 for all-cause mortality. (Data from Bellamy and colleagues, 2007.)

findings of Berends and colleagues (2008), who confirmed shared constitutional risks for long-term vascular related risks in preeclamptic women as well as in their parents. Similar preliminary observations were recently reported by Smith and associates (2009) in an ongoing investigation.

Renal Sequelae

In a 40-year study of Norwegian birth and end-stage renal disease linked registries, Vikse and associates (2008) found that although the absolute risk of renal failure was small, preeclampsia was associated with a fourfold increased risk. Women with recurrent preeclampsia had an even greater risk. These data need to be considered in light of the findings that 15 to 20 percent of women with preeclampsia who undergo renal biopsy have evidence of chronic renal disease (Chesley, 1978). In another long-term follow-up study, Spaan and co-workers (2009) compared formerly preeclamptic women with a cohort of women who were normotensive at delivery. At 20 years following delivery, preeclamptic women were significantly more likely to be chronically hypertensive—55 versus 7 percent—compared with control women. They also had higher peripheral vascular and renal vascular resistance and decreased renal blood flow. These data do not permit conclusions of cause versus effect.

Neurological Sequelae

Until recently, it was commonly held that eclamptic seizures have no significant long-term sequelae. Findings have now accrued, however, that this is not always the case. Recall that almost all eclamptic women have multifocal areas of perivascular edema, as discussed on page 722. Approximately one fourth also have areas of cerebral infarctions. Recent preliminary data are compatible with long-term persistence of brain white matter lesions incurred at the time of eclamptic convulsions (Aukes and colleagues, 2009). When studied with MR imaging at a mean of 7.1 years, 40 percent of formerly eclamptic women had more and larger aggregate white matter lesions compared with only 17 percent of normotensive control women. The clinical relevance of these observations is not yet known. In studies designed to assess this, Aukes and colleagues (2007) reported that formerly eclamptic women had subjectively impaired cognitive functioning. They later reported preliminary evidence that women with multiple seizures had impaired sustained attention compared with contemporaneous normotensive controls (Postma and coworkers, 2009). Because there were no studies done before these women suffered from eclampsia, the investigators appropriately concluded that only limited conclusions are warranted.

CHAPTER 35

Obstetrical Hemorrhage

OVERVIEW, IMPLICATIONS, AND CLASSIFICATION 757
CAUSES OF OBSTETRICAL HEMORRHAGE 761
CONSUMPTIVE COAGULOPATHY 785
MANAGEMENT OF HEMORRHAGE 791
SURGICAL MANAGEMENT OF HEMORRHAGE 795

Obstetrics is "bloody business." Although medical advances have dramatically reduced the dangers of childbirth, death from hemorrhage still remains a leading cause of maternal mortality. Hemorrhage was a direct cause of more than 17 percent of 4200 pregnancy-related maternal deaths in the United States as ascertained from the Pregnancy Mortality Surveillance System of the Centers for Disease Control and Prevention (Gerberding, 2003). Hemorrhage was the major factor for maternal deaths in the United Kingdom reported in the Confidential Enquiry into Maternal and Child Health (2008). In a private-sector report from the Hospital Corporation of America, Clark and co-workers (2008) reported that 12 percent of maternal deaths were caused by obstetrical hemorrhage. Finally, in many developed countries, hemorrhage is a leading reason for admission of pregnant women to intensive care units (Gilbert, 2003; Hazelgrove, 2001; Zeeman, 2003; Zwart, 2008, and all their associates).

In countries with fewer resources, the contribution of hemorrhage to maternal mortality rates is even more striking (Jegasothy, 2002; Rahman and co-workers, 2002). Indeed, hemorrhage is the single most important cause of maternal death worldwide. Obstetrical hemorrhage accounts for almost half of all postpartum deaths in developing countries (Lalonde and colleagues, 2006; McCormick and associates, 2002).

A number of reports exemplify the great improvement in mortality rates from hemorrhage with modernization of American obstetrics. Maternal deaths from hemorrhage in Massachusetts declined tenfold from the mid-1950s to the mid-1980s (Sachs and co-workers, 1987). Similarly, at Grady Memorial Hospital in Atlanta, maternal mortality rates from hemorrhage decreased from 13 percent between 1949 and 1971 to 6 percent between 1972 and 2000 (Ho and associates, 2002).

OVERVIEW, IMPLICATIONS, AND CLASSIFICATION

Some causes of severe obstetrical hemorrhage and their contribution to maternal mortality are shown in **Figure 35-1**. Fatal hemorrhage is most likely in circumstances in which blood or components are not available immediately. Moreover, Singla and associates (2001) reported that women who are Jehovah's Witnesses have a 44-fold increased risk of maternal death because of hemorrhage. Establishment and maintenance of facilities that allow prompt administration of blood are absolute requirements for acceptable obstetrical care.

Generally speaking, obstetrical hemorrhage may be *antepartum*—such as with placenta previa or placental abruption, or more commonly it is *postpartum*—from uterine atony or genital tract lacerations.

Incidence and Predisposing Conditions

The exact incidence of obstetrical hemorrhage is not known because of its imprecise definition as well as difficulty in its recognition and thus its diagnosis. One indicator is the number of women transfused, and this has likely decreased because of prevailing conservative attitudes towards blood replacement. For example, in older studies, the incidence of postpartum hemorrhage was cited to be 3.9 percent in women delivered vaginally and 6 to 8 percent in those undergoing cesarean delivery (Combs and associates, 1991a, b; Naef and colleagues, 1994). In a recent 24-center investigation from Argentina and

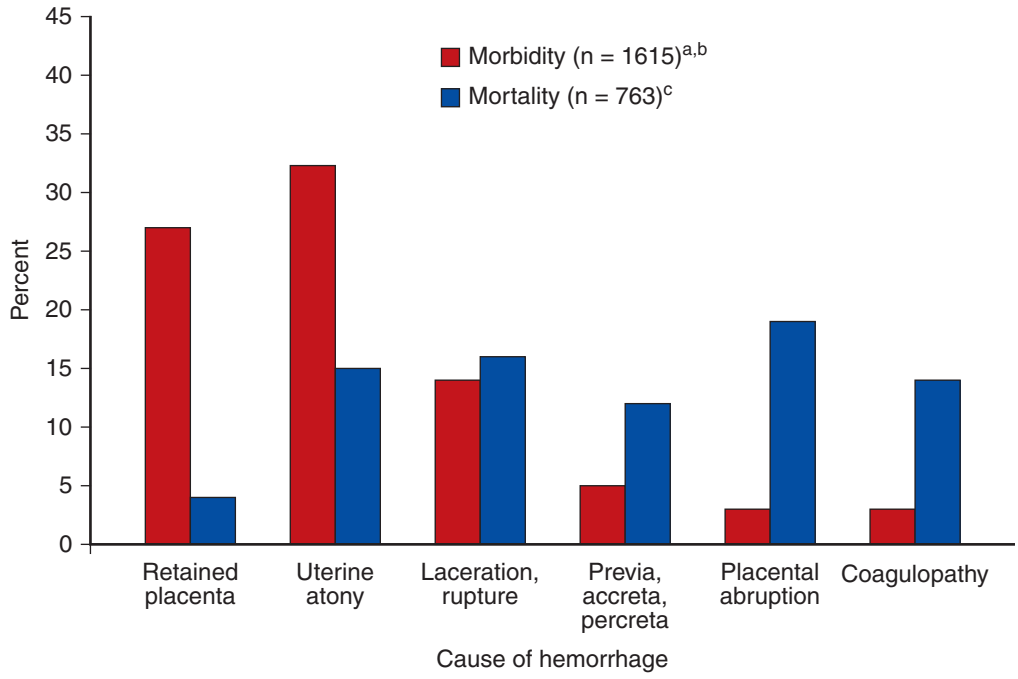

FIGURE 35-1 Incidences of some causes of obstetrical hemorrhage and their contribution to maternal death from hemorrhage. Percentages are approximations because of different classification schemata used. (Data from Al-Zirqi, 2008[a]; Chichakli, 1999[c]; Zwart, 2008[b], and all their colleagues.)

Uruguay, Sosa and colleagues (2009) used especially made plastic sheets to collect blood shed at delivery. They reported that 10.8 percent of women lost more than 500 mL, and 1.9 percent lost greater than 1000 mL. In another recent population-based study of more than 66,000 women delivered at Parkland Hospital from 2002 to 2006, Alexander and colleagues (2009) reported that 2.3 percent were given blood transfusions for hypovolemia. Half of these had undergone cesarean delivery, and this is related to the substantively increased maternal mortality and severe morbidity rate with cesarean compared with vaginal delivery (Alexander, 2009; Clark, 2008; Pallasmaa, 2008, and all their colleagues).

When these prospective audits are compared with evaluations using discharge statistics, it is apparent that hemorrhage is underreported. Recently, Berg and colleagues (2009) from the Centers for Disease Control and Prevention sampled nearly 185,000 hospitalizations for delivery in the National Hospital Discharge Summary database representing more than 40 million deliveries in the United States from 1993–1997 and 2001–2005. For these two epochs, the incidence of postpartum hemorrhage by ICD-9-CM codes was 2.0 and 2.6 percent, respectively. The rate for transfusions in these women between 1991 and 2003 increased from 3 per 1000 deliveries to 5 per 1000. These incidences are far below those reported in the studies above.

Table 35-1 lists the many clinical circumstances in which risk of hemorrhage is appreciably increased. It is apparent that serious hemorrhage may occur at any time throughout pregnancy and the puerperium. Although the timing of bleeding is widely used to classify obstetrical hemorrhage, the term *third-trimester* bleeding is imprecise, and its use is not recommended.

One factor not generally considered as "predisposing" to exsanguination is the lack of adequate obstetrical and anesthetic services. According to the 2002 Confidential Enquiry into Maternal and Child Health (CEMACH), however, most maternal deaths from hemorrhage in the United Kingdom were associated with substandard care. Moreover, from Japan, Nagaya and associates (2000) concluded that many hemorrhage-related maternal deaths were preventable and were associated with inadequate facilities. Zwart and co-workers (2008) provided similar observation from the Netherlands.

Antepartum Hemorrhage

Slight vaginal bleeding is common during active labor. This "bloody show" is the consequence of effacement and dilatation of the cervix, with tearing of small vessels. Uterine bleeding, however, coming from above the cervix, is cause for concern. It may follow some separation of a placenta implanted in the immediate vicinity of the cervical canal—*placenta previa.* It may come from separation of a placenta located elsewhere in the uterine cavity—*placental abruption.* Rarely, there may be velamentous insertion of the umbilical cord, and involved placental vessels may overlie the cervix—*vasa previa* (see Figs. 27-6 and 27-7, p. 583). In such cases, hemorrhage may follow laceration of these vessels at the time of membrane rupture.

The source of uterine bleeding is not always identified. In that circumstance, antepartum bleeding typically begins with few, if any, symptoms and then stops. At delivery no anatomical cause is identified. In many of these cases, bleeding likely is the consequence of slight marginal placental separation. *A pregnancy with such bleeding remains at increased risk for a poor*

TABLE 35-1. Causes and Predisposing Factors of Obstetrical Hemorrhage

Abnormal Placentation
- Placenta previa
- Placental abruption
- Placenta accreta/increta/percreta
- Ectopic pregnancy
- Hydatidiform mole

Trauma During Labor and Delivery
- Episiotomy
- Complicated vaginal delivery
- Low- or midforceps delivery
- Cesarean delivery or hysterectomy
- Uterine rupture-risk increased by:
  - Previously scarred uterus
  - High parity
  - Hyperstimulation
  - Obstructed labor
  - Intrauterine manipulation
  - Midforceps rotation

Small Maternal Blood Volume
- Small women
- Pregnancy hypervolemia not yet maximal
- Pregnancy hypervolemia constricted
  - Severe preeclampsia
  - Eclampsia
- Sepsis syndrome
- Chronic renal insufficiency

Other Factors
- Obesity
- Previous postpartum hemorrhage

Uterine Atony
- Overdistended uterus
  - Large fetus
  - Multiple fetuses
  - Hydramnios
  - Distension with clots
- Labor induction
- Anesthesia or analgesia
  - Halogenated agents
  - Conduction analgesia with hypotension
- Exhausted myometrium
  - Rapid labor
  - Prolonged labor
  - Oxytocin or prostaglandin stimulation
  - Chorioamnionitis
- Previous uterine atony

Coagulation Defects—Intensify Other Causes
- Massive transfusions
- Placental abruption
- Sepsis syndrome
- Severe preeclampsia and eclampsia
- Anticoagulant treatment
- Congenital coagulopathies
- Amnionic fluid embolism
- Prolonged retention of dead fetus
- Saline-induced abortion

outcome even though the bleeding soon stops and placenta previa appears to have been excluded by sonography. Lipitz and colleagues (1991) studied 65 consecutive women with uterine bleeding between 14 and 26 weeks and found that a fourth had placental abruption or previa. Total fetal loss rates including abortions and perinatal deaths were 32 percent. Leung and colleagues (2001) found that unexplained antepartum hemorrhage before 34 weeks was associated with a 62-percent risk of delivery within 1 week when associated with uterine contractions and with a 13-percent risk even in the absence of contractions. In pregnancies with hemorrhage after 26 weeks not explained by placental abruption or previa, Ajayi and associates (1992) reported adverse outcomes in a third. For this reason, delivery should be considered in any woman at term with unexplained vaginal bleeding.

Postpartum Hemorrhage

Postpartum hemorrhage describes an event rather than a diagnosis, and when encountered, its etiology must be determined. Common causes include bleeding from the placental implantation site, trauma to the genital tract and adjacent structures, or both (Table 35-2).

Definition

Traditionally, postpartum hemorrhage has been defined as the loss of 500 mL of blood or more after completion of the third stage of labor. This is problematic because half of all women delivered vaginally shed that amount of blood or more when losses are measured quantitatively (Fig. 35-2). Pritchard and associates (1962) used precise methods and found that approximately 5 percent of women delivering vaginally lost more than 1000 mL of blood. **They also reported that estimated blood loss is commonly only approximately half the actual loss.** Because of this, estimated blood loss in excess of 500 mL should call attention to mothers who are bleeding excessively. Toledo and colleagues (2007) have shown that calibrated drape markings improve estimation accuracy. Still, as shown by the study of Sosa and associates (2009) cited above, even this technique underestimates blood loss when compared with more precise methods described by Pritchard and colleagues (1962).

The blood volume of a pregnant woman with normal pregnancy-induced hypervolemia usually increases by 30 to 60 percent. This amounts to 1500 to 2000 mL for an average-sized woman (Pritchard, 1965). The equation that determines this is

TABLE 35-2. Predisposing Factors and Causes of Immediate Postpartum Hemorrhage

Bleeding from Placental Implantation Site
- Hypotonic myometrium—uterine atony
  - Some general anesthetics—halogenated hydrocarbons
  - Poorly perfused myometrium—hypotension
    - Hemorrhage
    - Conduction analgesia
  - Overdistended uterus: large fetus, twins, hydramnios
  - Prolonged labor
  - Very rapid labor
  - Induced or augmented labor
  - High parity
  - Uterine atony in previous pregnancy
  - Chorioamnionitis
- Retained placental tissue
  - Avulsed lobule, succenturiate lobe
  - Abnormally adhered: accreta, increta, percreta

Trauma to the Genital Tract
- Large episiotomy, including extensions
- Lacerations of perineum, vagina, or cervix
- Ruptured uterus

Coagulation Defects
- Intensify all of the above

shown in Table 35-3. This computation was constructed by studying blood volumes and blood losses in more than 100 women using chromium-51 labeled erythrocytes. A normally pregnant woman tolerates, without any remarkable decrease in postpartum hematocrit, a blood loss at delivery that approaches the volume of blood that she added during pregnancy. Thus, if blood loss is less than the amount added by pregnancy, the hematocrit stays the same acutely and during the first several days. It eventually increases as normal plasma volume shrinks postpartum.

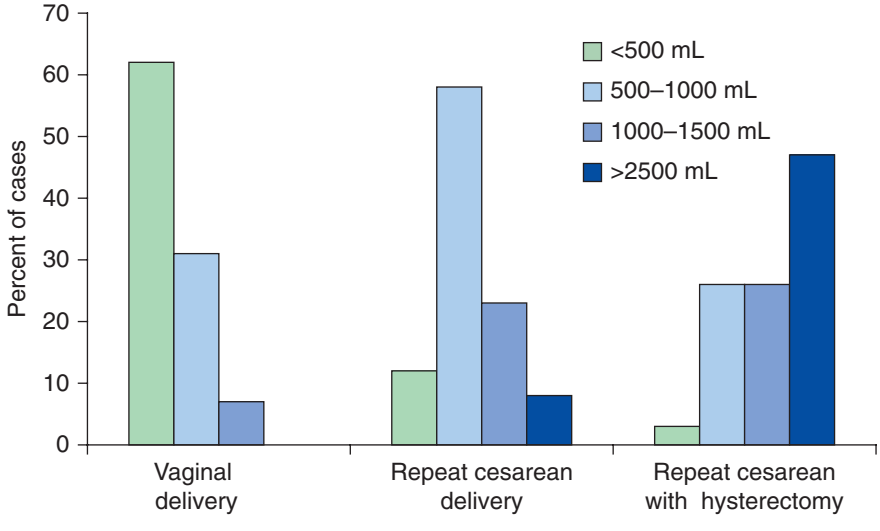

FIGURE 35-2 Blood loss associated with vaginal delivery, repeat cesarean delivery, and repeat cesarean delivery plus hysterectomy. (Data from Pritchard and associates, 1962.)

Any time the postpartum hematocrit is lower than one obtained on admission for delivery, blood loss can be estimated as the sum of the calculated pregnancy hypervolemia plus 500 mL for each 3 volumes percent drop in the hematocrit. In the study by Combs and colleagues (1991b), the mean postpartum hematocrit declined from 2.6 to 4.3 volumes percent. Only a third of women had no decline or had an actual increase. The same investigators found that women undergoing cesarean delivery had a mean decrease in hematocrit of 4.2 volumes percent—only 20 percent had no decline (Combs and co-workers, 1991a).

Late Postpartum Hemorrhage. Bleeding after the first 24 hours is designated *late postpartum hemorrhage* and is discussed in Chapter 30 (p. 648).

Hemostasis at the Placental Site

Near term, it is estimated that at least 600 mL/min of blood flows through the intervillous space (see Chap. 5, p. 108). This flow is carried by the spiral arteries—which average 120 in number—and their accompanying veins. With separation of the placenta, these vessels are avulsed (see Chap. 3, p. 46). Hemostasis at the placental implantation site is achieved first by contraction of the myometrium that compresses this formidable number of relatively large vessels (Fig. 2-14, p. 25). This is followed by subsequent clotting and obliteration of their lumens. Thus, adhered pieces of placenta or large blood clots that prevent effective myometrial contraction can impair hemostasis at the implantation site.

It is therefore readily apparent that fatal postpartum hemorrhage can result from uterine atony despite normal coagulation. Conversely, if the myometrium within and adjacent to the denuded implantation site contracts vigorously, fatal hemorrhage *from the placental implantation site* is unlikely even in circumstances when coagulation may be severely impaired.

Clinical Characteristics

Postpartum bleeding may begin before or after placental separation. Instead of sudden massive hemorrhage, there usually is steady bleeding. At any given instant, it appears to be only moderate, but may persist until serious hypovolemia develops. Especially with hemorrhage after placental delivery, constant seepage can lead to enormous blood loss.

The effects of hemorrhage depend to a considerable degree on the nonpregnant blood volume and the corresponding magnitude of pregnancy-induced hypervolemia. A treacherous feature of postpartum hemorrhage is the failure of the pulse and blood pressure to undergo more than moderate alterations until large amounts of blood have been lost. The normotensive woman initially may actually become somewhat hypertensive in response to hemorrhage. Moreover, the already hypertensive woman may be interpreted to be normotensive although remarkably hypov-

TABLE 35-3. Calculation of Maternal Total Blood Volume

Nonpregnant blood volume:

$$\frac{[\text{Height (inches)} \times 50] + [\text{Weight (pounds)} \times 25]}{2} = \text{Blood volume (mL)}$$

Pregnant blood volume:

- Varies from 30 to 60 percent of calculated nonpregnant volume
- Increases across gestational age and plateaus at approximately 34 weeks
- Usually larger with low normal-range hematocrit (~30) and smaller with high normal-range hematocrit (~38)
- Average increase is 40 to 80 percent with multifetal gestation
- Average increase is less with preeclampsia—volumes vary inversely with severity

Postpartum blood volume with serious hemorrhage

Assume acute return to nonpregnant total volume—with fluid resuscitation—because pregnancy hypervolemia will not be attained again

Modified from Leveno and colleagues (2003).

olemic. Accordingly, hypovolemia may not be recognized until very late.

The woman with severe preeclampsia or eclampsia does not have normally expanded blood volume. Zeeman and colleagues (2009) documented a mean increase above nonpregnant volume of only 10 percent in 29 eclamptic women at delivery. Thus, these women are very sensitive to, or even intolerant of, what may be considered normal blood loss (see Chap. 34, p. 717). **When excessive hemorrhage is suspected in the woman with severe preeclampsia, efforts should be made immediately to identify those clinical and laboratory findings that would prompt vigorous crystalloid and blood administration to resuscitate hypovolemia.**

In some women after delivery, blood may not escape vaginally but instead may collect within the uterine cavity, which can become distended by 1000 mL or more of blood. In some, the attendant may massage a roll of abdominal fat mistaken for the postpartum uterus. Thus, observation of the uterus postpartum must not be left to an inexperienced person (see Chap. 17, p. 398).

Diagnosis

Except possibly when intrauterine and intravaginal accumulation of blood is not recognized, or in some instances of uterine rupture with intraperitoneal bleeding, the diagnosis of postpartum hemorrhage should be obvious. The differentiation between bleeding from uterine atony and that from genital tract lacerations is tentatively determined by predisposing risk factors and the condition of the uterus (see Table 35-2). If bleeding persists despite a firm, well-contracted uterus, the cause of the hemorrhage most likely is from lacerations. Bright red blood also suggests arterial blood from lacerations. *To confirm that lacerations are a cause of bleeding, careful inspection of the vagina, cervix, and uterus is essential.*

Sometimes bleeding may be caused by both atony and trauma, especially after major operative delivery. If easily accessible, such as with conduction analgesia, inspection of the cervix and vagina should be performed after every delivery to identify hemorrhage from lacerations. Palpation of the uterine cavity and inspection of the cervix and entire vagina is essential after internal podalic version and breech extraction. The same is true when unusual bleeding is identified during the second stage of labor.

CAUSES OF OBSTETRICAL HEMORRHAGE

Placental Abruption

Placental separation from its implantation site before delivery has been variously called *placental abruption*, *abruptio placentae*, and in Great Britain, *accidental hemorrhage*. The Latin term *abruptio placentae* means "rending asunder of the placenta" and denotes a sudden accident, which is a clinical characteristic of most cases. The cumbersome term *premature separation of the normally implanted placenta* is most descriptive. It differentiates the placenta that separates prematurely but is implanted some distance beyond the cervical internal os from one that is implanted over the cervical internal os—that is, *placenta previa*.

The bleeding of placental abruption typically insinuates itself between the membranes and uterus, ultimately escaping through the cervix, causing *external hemorrhage* (Fig. 35-3). Less often, the blood does not escape externally but is retained between the detached placenta and the uterus, leading to *concealed hemorrhage* (Fig. 35-3). As shown in Figures 35-4 and 35-5, placental abruption may be *total* or *partial*. Concealed hemorrhage carries much greater maternal and fetal hazards. This is not only because of possible consumptive coagulopathy, but also because the extent of the hemorrhage is not readily appreciated, and the diagnosis typically is delayed (Chang and co-workers, 2001).

Significance and Frequency

Abruption severity often depends on how quickly the woman is seen following symptom onset. With delay, the likelihood of extensive separation causing fetal death is increased remarkably.

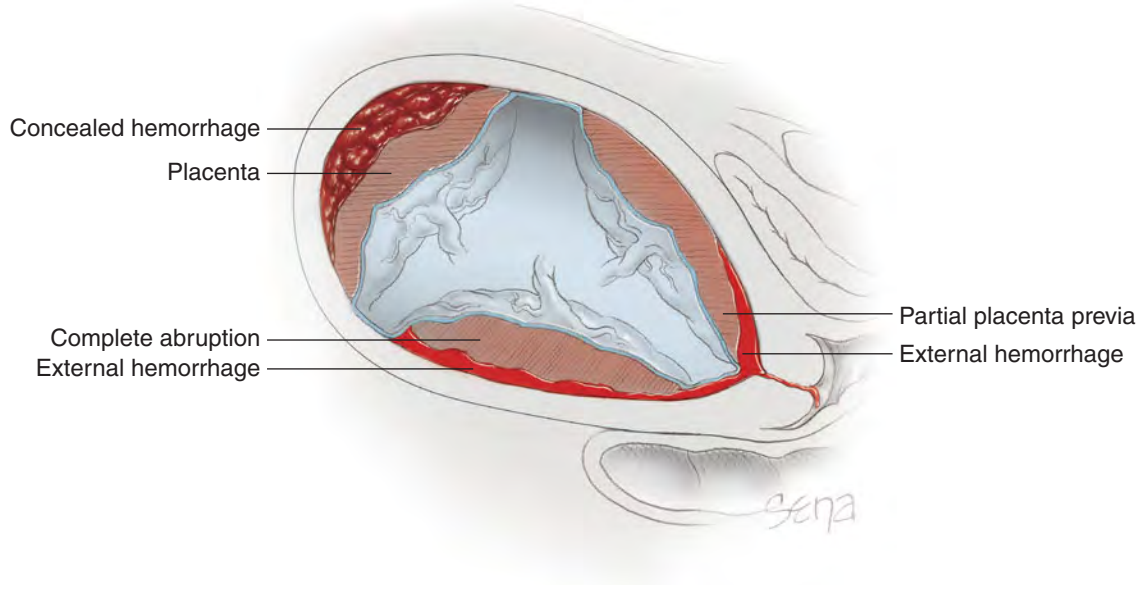

FIGURE 35-3 Hemorrhage from extensive placental abruption. **External hemorrhage:** the placenta has detached peripherally, and the membranes between the placenta and cervical canal are detached from the underlying decidua. This allows blood egress through the vagina. **Concealed hemorrhage:** the periphery of the placenta and the membranes are still adhered and blood remains within the uterus. **Partial placenta previa:** there is placental separation and external hemorrhage.

The frequency with which placental abruption is diagnosed varies because of different criteria, but the reported frequency averages 1 in 200 deliveries. In the 15-million delivery database of the National Center for Health Statistics, Salihu and associates (2005) reported an incidence in singleton births of 1 in 160. Using birth certificate data for the United States for 2003, the incidence of placental abruption was found to be 1 in 190 deliveries (Martin and co-workers, 2005). At Parkland Hospital from 1988 through 2006, the incidence of placental abruption in more than 280,000 deliveries has been approximately 1 in 290 (Fig. 35-6).

At least at Parkland Hospital, both incidence and severity have decreased over time. Applying the criterion of placental separation so extensive as to kill the fetus, the incidence was 1 in 420 deliveries from 1956 through 1967 (Pritchard and Brekken, 1967). As the number of high-parity women giving birth decreased and as availability of prenatal care and emergency transportation improved, the frequency of abruption causing fetal death dropped to approximately 1 in 830 deliveries from 1974 through 1989 (Pritchard and colleagues, 1991). Between 1996 and 2003, it decreased further to approximately 1 in 1600.

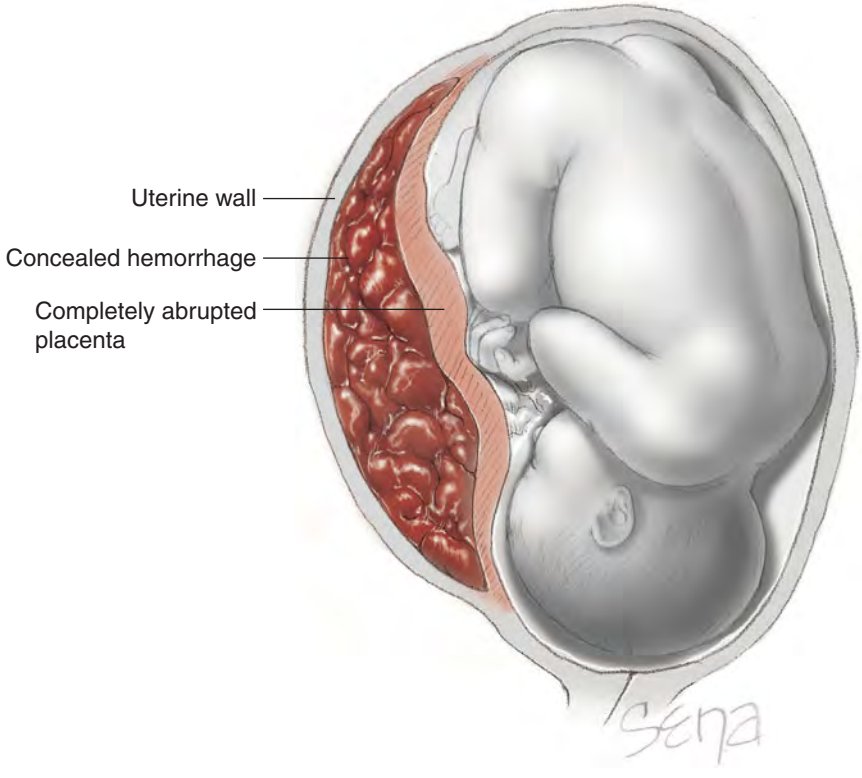

FIGURE 35-4 Total placental abruption with concealed hemorrhage and fetal death.

Perinatal Morbidity and Mortality

Although the rates of fetal death from abruption have declined, they remain especially prominent as stillbirth rates from other causes have decreased. For example, since the early 1990s, 10 to 12 percent of all third-trimester stillbirths at Parkland Hospital have been the consequence of placental abruption. This is similar to the rate reported by Fretts and Usher (1997) for the Royal Victoria Hospital in Montreal

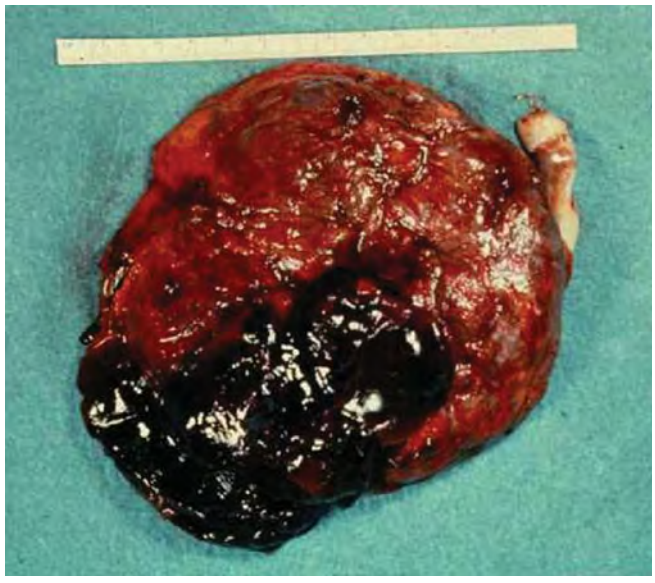

FIGURE 35–5 Partial placental abruption with adhered clot.

during the 18-year period ending in 1995 (see Chap. 29, p. 630).

Excessive perinatal mortality rates from placental abruption have been documented in several reports. Salihu and colleagues (2005) analyzed more than 15 million singletons in the United States between 1995 and 1998. They reported that the perinatal mortality rate associated with placental abruption was 119 per 1000 births compared with 8 per 1000 for those without this complication. Importantly, they emphasized that the high perinatal mortality rate was not due solely to placental abruption, but also to the associated increased incidence of preterm delivery and fetal-growth restriction. Nath and co-workers (2008), however, reported that preterm birth was the overriding association with these low-birthweight perinates.

There are also increased serious adverse sequelae in infants who survive. In the study by Abdella and associates (1984), approximately 15 percent of 182 surviving infants were identified to have significant neurological deficits within the first year of life. Similarly, Matsuda and co-workers (2003) reported that approximately 20 percent of 39 survivors delivered between 26 and 36 weeks developed cerebral palsy compared with only 1 percent of gestational age–matched controls.

Etiology and Associated Factors

The primary cause of placental abruption is unknown, but several associated conditions are listed in **Table 35-4**.

Age, Parity, Race, and Familial Factors. As is shown in Figure 35-6, the incidence of abruption increases with *maternal age*. In the First- and Second-Trimester Evaluation of Risk (FASTER) trial, women older than 40 years were 2.3 times more likely to experience abruption compared with those 35 years or younger (Cleary-Goldman and co-workers, 2005). Although Pritchard and colleagues (1991) reported the incidence to be higher in women of *great parity*, Toohey and associates (1995) did not find this. *Race* or ethnicity appears to be important. Of the almost 170,000 deliveries reported by Pritchard and co-workers (1991) from Parkland Hospital, abruption was more common in African-American and Caucasian women (1 in 200) than in Asian (1 in 300) or Latin-American women (1 in 450). A familial association was recently reported by Rasmussen and Irgens (2009), who analyzed outcomes in the Norwegian population-based registry that included almost 378,000 sisters with more than 767,000 pregnancies. If a woman had a severe abruption, then the risk for her sister was doubled, and the

TABLE 35-4. Risk Factors for Placental Abruption

Risk Factor	Relative Risk
Increased age and parity	1.3–1.5
Preeclampsia	2.1–4.0
Chronic hypertension	1.8–3.0
Preterm ruptured membranes	2.4–4.9
Multifetal gestation	2.1
Low birthweight	14.0
Hydramnios	2.0
Cigarette smoking	1.4–1.9
Thrombophilias	3–7
Cocaine use	NA
Prior abruption	10–25
Uterine leiomyoma	NA

NA = not available.
Adapted from Cunningham and Hollier (1997); risk data from Ananth (1999a,b, 2001b), Eskes (2001), Kramer (1997), Kupferminc (1999), Nath (2008), and all their associates.

heritability risk was estimated to be 16 percent. There was no increase in their sisters-in-law's risk.

Hypertension. By far the most common condition associated with placental abruption is some type of *hypertension*—gestational hypertension, preeclampsia, chronic hypertension, or combinations of these. In the Parkland Hospital report of 408 women with placental abruption and fetal demise, hypertension was apparent in approximately half of the women once the depleted intravascular compartment was adequately refilled (Pritchard and co-workers, 1991). Half of these women—a fourth of all 408—had chronic hypertension. Looked at another way, Sibai and co-workers (1998) reported for the Maternal–Fetal Medicine Units Network that 1.5 percent of pregnant women with chronic hypertension suffered placental abruption. Ananth and associates (2007) reported a 2.4-fold increased incidence of abruption with chronic hypertension, and this was increased further if there was superimposed preeclampsia or fetal-growth restriction. Zetterstrom and colleagues (2005) reported a twofold increased incidence of abruption in women with chronic hypertension compared with normotensive women—an incidence of 1.1 versus 0.5 percent.

The severity of hypertension does not necessarily correlate with the incidence of abruption (Witlin and colleagues, 1999; Zetterstrom and co-workers, 2005). Also, observations from the Magpie Trial Collaborative Group (2002) suggest that women with preeclampsia may have a reduced risk of abruption when treated with magnesium sulfate.

Prematurely Ruptured Membranes and Preterm Delivery. There is no doubt that there is an increased incidence of abruption when the membranes rupture before term. Major and colleagues (1995) reported that 5 percent of 756 women with ruptured membranes between 20 and 36 weeks developed an abruption. Kramer and co-workers (1997) found an incidence of 3.1 percent in all women if membranes were ruptured for longer than 24 hours. Ananth and associates (2004) studied data from the 1988 National Maternal and Infant Health Survey and reported a threefold risk of abruption with prematurely ruptured membranes. This risk was further increased with infection. This same group has suggested that inflammation and infection may be the primary cause of placental abruption (Nath and co-workers, 2007). They also reported a strong association with low birthweight principally due to perterm delivery, but not growth restriction (2008).

Smoking. Early studies from the Collaborative Perinatal Project linked *cigarette smoking* with an increased risk for abruption (Misra and Ananth, 1999; Naeye, 1980). In a meta-analysis of 1.6 million pregnancies, Ananth and colleagues (1999a, b) found a twofold risk for abruption in smokers. This was increased to five- to eightfold if smokers had chronic hypertension, severe preeclampsia, or both. Similar findings have been reported by Mortensen (2001), Hogberg (2007), Kaminsky (2007), and all their associates.

Cocaine. Women who used cocaine have an alarming frequency of placental abruption. In the report from Bingol and colleagues (1987) of 50 women who abused cocaine during pregnancy, there were eight stillbirths caused by placental abruption. In their systematic review of 15 studies of cocaine-using women, Addis and associates (2001) reported that placental abruption was more common in women who used cocaine than in those who did not.

Thrombophilias. Over the past decade, a number of inherited or acquired *thrombophilias* have been associated with thromboembolic disorders during pregnancy. Some of these disorders—for example factor V Leiden or prothrombin gene mutation—are associated with placental abruption and infarction as well as preeclampsia. These have been reviewed recently by Kenny and colleagues (2009) and are discussed further in Chapter 47 (p. 1014).

Traumatic Abruption. In some cases of external trauma, usually associated with motor vehicle accidents or physical violence, placental separation may follow. In earlier studies from Parkland Hospital, only approximately 2 percent of placental abruptions causing fetal death were due to trauma (see Chap. 42, p. 938). However, as placental abruption incidence has declined over the years, traumatic abruptions have become relatively more common. Kettel (1988) and Stafford (1988) and their co-workers have appropriately stressed that abruption can be caused by relatively minor trauma. Moreover, a nonreassuring fetal heart rate tracing is not always immediately associated with evidence of placental separation.

Leiomyomas. These tumors, especially if located behind the placental implantation site, predispose to abruption (see Chap. 40, p. 901). Rice and associates (1989) reported that eight of 14 women with retroplacental leiomyomas developed placental abruption, and four women had stillborns. In contrast, abruption developed in only two of 79 women whose leiomyomas were not retroplacental.

Recurrent Abruption

A woman who has suffered a placental abruption—especially that caused fetal death—has a high recurrence rate. Pritchard

and co-workers (1970) identified this to be 12 percent in a subsequent pregnancy. Importantly, eight of 14 recurrent abruptions caused a second fetal death. Tikkanen and colleagues (2006) looked at this another way and found that of 114 parous women who experienced an abruption, 9 percent had a prior abruption. Furuhashi and colleagues (2002) analyzed subsequent pregnancy outcomes in 27 women with one prior placental abruption. There was a 22-percent recurrence rate, and four of six recurrences were at a gestational age 1 to 3 weeks earlier than the first abruption. In a population-based study of 767,000 pregnancies, Rasmussen and Irgens (2009) reported an odds ratio of 6.5 for recurrent mild abruption and 11.5 for recurrent severe abruption. For women who had two severe placental abruptions, the risk became 50-fold for a third.

Management of a pregnancy subsequent to an abruption is thus difficult because another separation may suddenly recur, even remote from term. In many of these recurrences, fetal well-being is reassuring beforehand. Thus, antepartum fetal testing is usually not predictive (Toivonen and colleagues, 2002).

Pathology

Placental abruption is initiated by hemorrhage into the decidua basalis. The decidua then splits, leaving a thin layer adhered to the myometrium. Consequently, the process in its earliest stages consists of the development of a decidual hematoma that leads to separation, compression, and ultimate destruction of the placenta adjacent to it. Nath and colleagues (2007) found histological evidence of inflammation more commonly in cases of placental abruption than in normal controls. As discussed above, they suggested that inflammation—infection—may be a contributor to causal pathways.

In its early stage, there may be no clinical symptoms, and the separation is discovered upon examination of the freshly delivered placenta. In these cases, there is a circumscribed depression on the placenta's maternal surface. It usually measures a few centimeters in diameter and is covered by dark, clotted blood. Because several minutes are required for these anatomical changes to materialize, a very recently separated placenta may appear to be totally normal at delivery. According to Benirschke and Kaufmann (2000) and also our experiences, the "age" of the retroplacental clot cannot be determined exactly. In the example shown in Figure 35-5, a substantive-sized dark clot is well formed, it has depressed the placental bulk, and it likely is several hours old.

In some instances, a decidual spiral artery ruptures to cause a retroplacental hematoma, which as it expands, disrupts more vessels to separate more placenta (see Fig. 27-3, p. 579). The area of separation rapidly becomes more extensive and reaches the margin of the placenta. Because the uterus is still distended by the products of conception, it is unable to contract sufficiently to compress the torn vessels that supply the placental site. The escaping blood may dissect the membranes from the uterine wall and eventually appear externally or may be completely retained within the uterus (see Figs. 35-3 and 35-4).

Concealed Hemorrhage. Retained or concealed hemorrhage is likely when:

- There is an effusion of blood behind the placenta, but its margins still remain adhered
- The placenta is completely separated, yet the membranes retain their attachment to the uterine wall
- Blood gains access to the amnionic cavity after breaking through the membranes
- The fetal head is so closely applied to the lower uterine segment that blood cannot make its way past.

Most often, however, the membranes are gradually dissected off the uterine wall, and blood sooner or later escapes.

Chronic Placental Abruption. In some women, hemorrhage with retroplacental hematoma formation is somehow arrested completely without delivery. We have been able to document this phenomenon by labeling maternal red cells with chromium-51. In one case, red blood cells were concealed as a 400-mL clot, which was found within the uterus at delivery 3 weeks later. The clot contained no radiochromium, whereas peripheral blood at that time did. The blood in the clot therefore had accumulated before the erythrocytes were labeled.

Some cases of abruption first develop very early in pregnancy. Dugoff and colleagues (2004) observed an association between abnormally elevated maternal serum markers in the first trimester and subsequent abruption. Ananth (2006) and Weiss (2004) and their many associates have correlated first- and second-trimester bleeding with placental abruption in the third trimester.

Fetal-to-Maternal Hemorrhage. Bleeding with placental abruption is almost always maternal. This is logical because the separation is within the maternal decidua. In 78 women with a nontraumatic placental abruption, we found evidence of fetal-to-maternal hemorrhage in 20 percent. In all, the volume of fetal blood was less than 10 mL (Stettler and colleagues, 1992). Conversely, significant fetal bleeding is much more likely with traumatic abruption. *In this circumstance, fetal bleeding results from a tear or fracture in the placenta rather than from the placental separation itself.* Traumatic abruption is considered further in Chapter 42 (p. 938), and an example of a placental tear is shown in Figure 42-9. Pearlman and associates (1990) documented fetal bleeding that averaged 12 mL in a third of women with a traumatic abruption. Stettler and colleagues (1992) reported that there was fetal-to-maternal hemorrhage of 80 to 100 mL in three of eight cases of traumatic placental abruption.

Clinical Diagnosis

The signs and symptoms of placental abruption can vary considerably. For example, external bleeding can be profuse, yet placental separation may not be so extensive as to compromise the fetus. Rarely, there may be no external bleeding, but the placenta may be completely sheared off and the fetus dead as the direct consequence. In one unusual case, a multiparous woman near term presented to Parkland Hospital because of a nosebleed. There was no abdominal or uterine pain or tenderness and no vaginal bleeding, but her fetus was dead. Her blood did not clot, and the plasma fibrinogen level was 25 mg/dL. Labor was induced, and at delivery a total abruption with fresh clots was found.

In a prospective study of 59 women with a placental abruption, Hurd and co-workers (1983) reported vaginal bleeding in 78 percent, uterine tenderness or back pain in 66 percent, and

fetal distress in 60 percent. *In 22 percent, preterm labor was initially diagnosed until subsequent fetal death or distress developed.* Other findings included frequent uterine contractions and persistent uterine hypertonus.

Sonography infrequently confirms the diagnosis of placental abruption at least acutely, because the placenta and fresh clot have similar sonographic appearances. In an early study, Sholl (1987) used sonography and confirmed the clinical diagnosis in only 25 percent of women. In a later study, Glantz and Purnell (2002) reported 24-percent sensitivity in 149 consecutive women who underwent sonography to exclude placental abruption. *Importantly, negative findings with sonographic examination do not exclude placental abruption.*

Differential Diagnosis. With severe placental abruption, the diagnosis generally is obvious. Milder and more common forms of abruption may be difficult to recognize with certainty, and the diagnosis is often made by exclusion. Unfortunately, neither laboratory tests nor diagnostic methods are available to detect lesser degrees of placental separation accurately. Therefore, with vaginal bleeding in a pregnancy with a live fetus, it often becomes necessary to exclude placenta previa and other causes of bleeding by clinical and sonographic evaluation.

Clinically, it has long been taught—perhaps with some justification—that *painful* uterine bleeding signifies placental abruption, whereas *painless* uterine bleeding is indicative of placenta previa. The differential diagnosis is usually not this straightforward, and labor accompanying previa may cause pain suggestive of placental abruption. On the other hand, pain from abruption may mimic normal labor, or it may be painless, especially with a posterior placenta. At times, the cause of the vaginal bleeding remains obscure even after delivery.

Shock. It was once held that the shock sometimes seen with placental abruption was disproportionate to the amount of hemorrhage. Supposedly, placental thromboplastin enters the maternal circulation and incites intravascular coagulation and other features of the amnionic fluid embolism syndrome (see p. 788).This rarely happens, and hypovolemic shock is instead directly due to maternal blood loss. In 141 women with abruption so severe as to kill the fetus, Pritchard and Brekken (1967) proved that blood loss often amounted to at least half of the pregnant blood volume. Conversely, neither hypotension nor anemia is obligatory even with extreme concealed hemorrhage. Oliguria from inadequate renal perfusion that is observed in these circumstances is responsive to vigorous intravenous fluid and blood infusion.

Consumptive Coagulopathy. Placental abruption is one of the most common causes of clinically significant consumptive coagulopathy in obstetrics. In approximately a third of women with an abruption severe enough to kill the fetus, there are measurable changes in coagulation factors. Specifically, clinically significant hypofibrinogenemia—plasma levels less than 150 mg/dL—is found. This is coupled with elevated levels of fibrinogen-fibrin degradation products and/or D-dimers, which are specific degradation products of fibrin. Other coagulation factors are also variably decreased. Consumptive coagulopathy is more likely with a concealed abruption because intrauterine pressure is higher, thus forcing more thromboplastin into the maternal venous system. In those cases in which the fetus survives, severe coagulation defects are seen less commonly. Our experience has been that if serious coagulopathy develops, it is usually evident by the time abruption symptoms appear.

The major mechanism is activation of intravascular coagulation with varying degrees of defibrination (see p. 785). Procoagulants are also consumed in the retroplacental clots, although the amounts recovered are insufficient to account for all of the missing fibrinogen (Pritchard and Brekken, 1967). Moreover, Bonnar and co-workers (1969) have observed, and we have confirmed, that the levels of fibrin degradation products are higher in serum from peripheral blood than in serum from blood contained in the uterine cavity. The reverse would be anticipated in the absence of significant intravascular coagulation.

An important consequence of intravascular coagulation is the activation of plasminogen to plasmin, which lyses fibrin microemboli to maintain microcirculatory patency. With placental abruption severe enough to kill the fetus, there are always pathological levels of fibrinogen–fibrin degradation products and/or D-dimers in maternal serum.

Overt thrombocytopenia may or may not accompany severe hypofibrinogenemia initially, but becomes common after repeated blood transfusions.

Renal Failure. Acute renal failure may be seen with severe placental abruption. It is more common if treatment of hypovolemia is delayed or incomplete. It is unclear if abruption contributes significantly to the increasing incidence of obstetric-related acute kidney injury in this country as recently reported by Kuklina and co-workers (2009). Drakeley and colleagues (2002) described 72 pregnant women with acute renal failure, and a third had suffered an abruption. Fortunately, most cases of acute kidney injury are reversible, however, according to Lindheimer and associates (2007), *acute cortical necrosis,* when it occurs in pregnancy, is usually caused by placental abruption. In older reports, such as the one by Grünfeld and Pertuiset (1987), a third of women with this lesion had suffered an abruption.

Seriously impaired renal perfusion is the consequence of massive hemorrhage. Because preeclampsia frequently coexists with placental abruption, renal vasospasm and hypoperfusion are likely intensified (Hauth and Cunningham, 1999). Even when abruption is complicated by severe intravascular coagulation, prompt and vigorous treatment of hemorrhage with blood and crystalloid solution usually prevents clinically significant renal dysfunction. For unknown reasons, even without preeclampsia, *proteinuria* is initially common, especially with more severe forms of placental abruption. It usually clears soon after delivery.

Sheehan Syndrome. Severe intrapartum or early postpartum hemorrhage rarely is followed by pituitary failure or *Sheehan syndrome.* It is characterized by failure of lactation, amenorrhea, breast atrophy, loss of pubic and axillary hair, hypothyroidism, and adrenal cortical insufficiency. The exact pathogenesis is not well understood, and such endocrine abnormalities develop infrequently even in women who hemorrhage severely. In some but not all instances of Sheehan syndrome, there may be varying degrees of anterior pituitary necrosis and impaired secretion of one or more trophic hormones. It is discussed further in

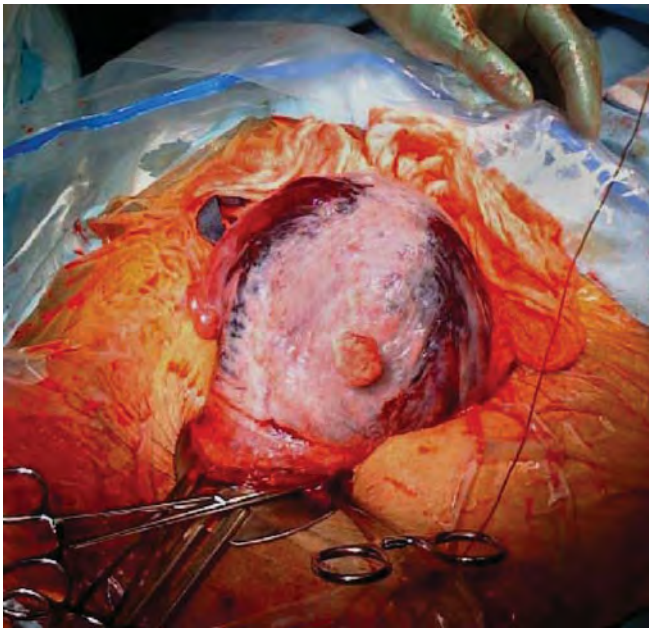

FIGURE 35-7 Couvelaire uterus from total placental abruption after cesarean delivery. Blood markedly infiltrates the myometrium to reach the serosa, especially at the cornua. It gives the myometrium a bluish-purple tone as shown. After the hysterotomy incision was closed, the uterus remained well contracted despite extensive extravasation of blood into the uterine wall. The small serosal leiomyoma seen on the lower anterior uterine surface is an incidental finding. (Courtesy of Dr. Allison Smith).

Chapter 53 (p. 1140), and its diagnosis by magnetic resonance (MR) imaging is shown in Figure 53-5.

Couvelaire Uterus. There may be widespread extravasation of blood into the uterine musculature and beneath the uterine serosa (Fig. 35-7). First described by Couvelaire in the early 1900s as *uteroplacental apoplexy,* it is now termed *Couvelaire uterus.* Such effusions of blood are also occasionally seen beneath the tubal serosa, between the leaves of the broad ligaments, in the substance of the ovaries, and free in the peritoneal cavity. Its precise incidence is unknown because it can be demonstrated conclusively only at laparotomy. These myometrial hemorrhages seldom interfere with myometrial contraction to cause atony, and they are not an indication for hysterectomy.

Management

Treatment for placental abruption varies depending on gestational age and the status of the mother and fetus. With a fetus of viable age, and if vaginal delivery is not imminent, then emergency cesarean delivery is chosen by most clinicians. As discussed on page 791, with massive external bleeding, intensive resuscitation with blood plus crystalloid and prompt delivery to control hemorrhage are lifesaving for the mother and hopefully, for the fetus. If the diagnosis is uncertain and the fetus is alive but without evidence of compromise, then close observation can be practiced in facilities capable of immediate intervention.

Expectant Management in Preterm Pregnancy. Delaying delivery may prove beneficial when the fetus is immature. Bond and associates (1989) expectantly managed 43 women with placental abruption before 35 weeks, and 31 of them were given tocolytic therapy. The mean time to delivery in all 43 was approximately 12 days, and there were no stillborns. Cesarean delivery was performed in 75 percent of cases.

Women with evidence of very early abruption frequently develop oligohydramnios, either with or without premature membrane rupture. In one report by Elliott and associates (1998), four women with an abruption at a mean of 20 weeks also developed oligohydramnios. They were delivered at an average gestational age of 28 weeks.

Lack of ominous decelerations does not guarantee the safety of the intrauterine environment. The placenta may further separate at any instant and seriously compromise or kill the fetus unless delivery is performed immediately. Some of the immediate causes of fetal distress from placental abruption are shown in Figure 35-8. Importantly, for the welfare of the distressed fetus,

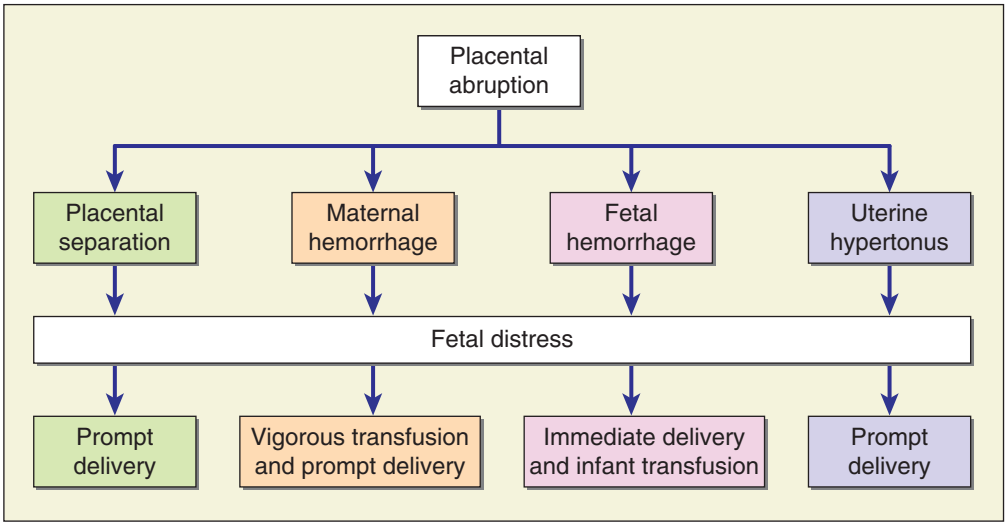

FIGURE 35-8 Various causes of fetal distress from placental abruption and their treatment. Fetal hemorrhage usually is seen only with traumatic abruption and placental tear.

steps should be initiated immediately to correct maternal hypovolemia, anemia, and hypoxia to restore and maintain function of any placenta that is still implanted. Little can be done to favorably modify the other causes that contribute to fetal distress except delivery.

Tocolysis. Some—but certainly not all—advocate tocolysis for the preterm pregnancy complicated by suspected abruption but with no fetal compromise. In an early study, Hurd and associates (1983) reported that abruption went unrecognized for dangerously long periods if tocolysis was initiated. Conversely, Sholl (1987) as well as Combs and co-workers (1992) provided data showing that tocolysis improved outcome in a highly selected group of preterm pregnancies complicated by partial abruption. In another supportive study, Towers and co-workers (1999) administered magnesium sulfate, terbutaline, or both to 95 of 131 women with placental abruption diagnosed before 36 weeks. The perinatal mortality rate of 5 percent in these women did not differ from the nontreated group. The investigators concluded that a randomized clinical trial could be safely conducted. Until then, we are of the view that clinically evident placental abruption should be considered a contraindication to tocolytic therapy.

Cesarean Delivery. Rapid delivery of the fetus who is alive but in distress practically always means cesarean delivery. Kayani and colleagues (2003) studied the relationship between the speed of delivery and neonatal outcome in 33 singleton pregnancies with a clinically overt placental abruption and fetal bradycardia. Of the 22 neurologically intact survivors, 15 were delivered within 20 minutes of the decision to operate. Of the 11 infants who died or developed cerebral palsy, eight were delivered beyond 20 minutes of the decision time. This suggests that the speed of response is an important factor in neonatal outcome.

It is important to note that an electrode applied directly to the fetus may rarely provide misleading information, as in the case illustrated in **Figure 35-9**. At first impression, fetal bradycardia of 80 to 90 beats/min, with some beat-to-beat variability, seemed evident. In this case, however, the fetus was dead, and the maternal pulse rate was identical to that recorded through the fetal scalp electrode. Cesarean delivery at this time would likely have proved dangerous for the mother because she was profoundly hypovolemic and had severe consumptive coagulopathy. Serious coagulation defects are likely to prove especially troublesome with cesarean delivery. The abdominal and uterine incisions are prone to bleed excessively when coagulation is impaired.

Vaginal Delivery. If placental separation is so severe that the fetus has died, then vaginal delivery is usually preferred. Hemostasis at the placental implantation site depends primarily on myometrial contraction. Therefore, with vaginal delivery, stimulation of the myometrium pharmacologically and by uterine massage causes placental site vessels to be compressed and constricted so that serious hemorrhage is avoided even though coagulation defects may be present.

One exception to vaginal delivery includes hemorrhage that is so brisk that it cannot be successfully managed even by vigorous blood replacement. A second is presence of other obstetrical complications that prevent vaginal delivery.

Labor. With extensive placental abruption, the uterus is likely to be persistently hypertonic. The baseline intra-amnionic pressure may be 50 mm Hg or higher, with rhythmic increases up to 75 to 100 mm Hg. Because of persistent hypertonus, it may be difficult at times to determine by palpation whether the uterus is contracting and relaxing to any degree (**Fig. 35-10**).

Amniotomy. Rupture of the membranes as early as possible has long been championed in the management of placental abruption. The rationale for amniotomy is that diminished amnionic fluid volume might allow better spiral artery compression and serve to both decrease bleeding from the implantation site and reduce entry of thromboplastin into the maternal circulation. There is no evidence, however, that either is accomplished by amniotomy. If the fetus is reasonably mature, rupture

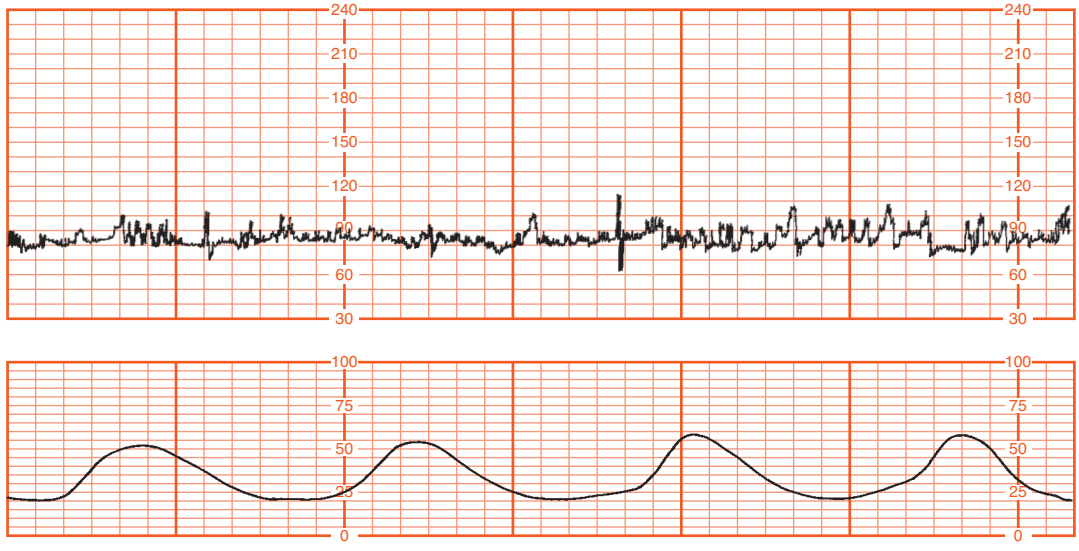

FIGURE 35-9 Placental abruption with dead fetus. Lower panel: Intrauterine pressure monitoring shows tachysystole and increased uterine basal tone. Upper panel: The scalp electrode conducted the maternal ECG signal, which could be mistaken for fetal bradycardia.

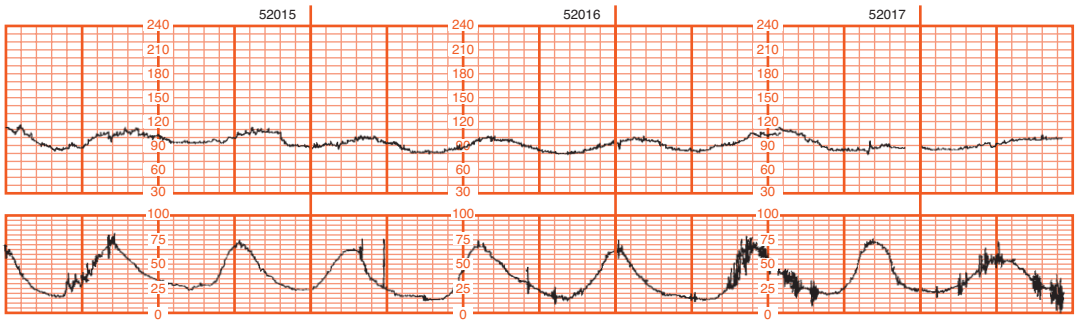

FIGURE 35-10 Lower panel: Placental abruption causing uterine hypertonus with a baseline pressure of 20 to 25 mm Hg and frequent contractions peaking at approximately 75 mm Hg. Upper panel: The fetal heart rate demonstrates baseline bradycardia with repetitive late decelerations.

of the membranes may hasten delivery. If the fetus is immature, the intact sac may be more efficient in promoting cervical dilatation than a small fetal part poorly applied to the cervix.

Oxytocin. Although baseline hypertonus characterizes myometrial function in most cases of severe placental abruption, if no rhythmic uterine contractions are superimposed, and there has been no previous uterine surgery, then oxytocin is given in standard doses. Uterine stimulation to effect vaginal delivery usually provides benefits that override risks. The use of oxytocin has been challenged on the basis that it might enhance the escape of thromboplastin into the maternal circulation and thereby initiate or enhance consumptive coagulopathy or amnionic fluid embolism syndrome. There is no evidence to support this fear (Clark and colleagues, 1995; Pritchard and Brekken, 1967).

Timing of Delivery after Severe Placental Abruption. When the fetus is dead or previable, there is no evidence that establishing an arbitrary time limit for delivery is necessary. Experiences indicate that maternal outcome depends on the diligence with which adequate fluid and blood replacement therapy is pursued, rather than on the interval to delivery. At the University of Virginia Hospital, women with severe placental abruption who were transfused for 18 hours or more before delivery experienced complications that were neither more numerous nor greater in severity than did the group in which delivery was accomplished sooner (Brame and associates, 1968). Our observations from Parkland Hospital described by Pritchard and Brekken (1967) are similar.

Placenta Previa

Placenta previa is used to describe a placenta that is implanted over or very near the internal cervical os. There are several possibilities:

- *Total placenta previa*—the internal os is covered completely by placenta (Fig. 35-11)
- *Partial placenta previa*—the internal os is partially covered by placenta (Fig. 35-12)
- *Marginal placenta previa*—the edge of the placenta is at the margin of the internal os
- *Low-lying placenta*—the placenta is implanted in the lower uterine segment such that the placental edge does not reach the internal os, but is in close proximity to it
- *Vasa previa*—the fetal vessels course through membranes and present at the cervical os (see Chap. 27, p. 583).

The relationships and definitions used for classification in some cases of placenta previa depend on cervical dilatation at the time of assessment. For example, a low-lying placenta at 2-cm dilatation may become a partial placenta previa at 8-cm dilatation because the dilating cervix has uncovered placenta. Conversely, a placenta previa that appears to be total before cervical dilatation may become partial at 4-cm dilatation because the cervix dilates beyond the edge of the placenta (see Fig. 35-12). **Digital palpation in an attempt to ascertain these changing relations between the placental edge and internal os as the cervix dilates usually causes severe hemorrhage!**

With both total and partial placenta previa, a certain degree of spontaneous placental separation is an inevitable consequence of lower uterine segment formation and cervical dilatation. Such separation is usually associated with hemorrhage. And although technically this constitutes a placental abruption, it usually is not termed such.

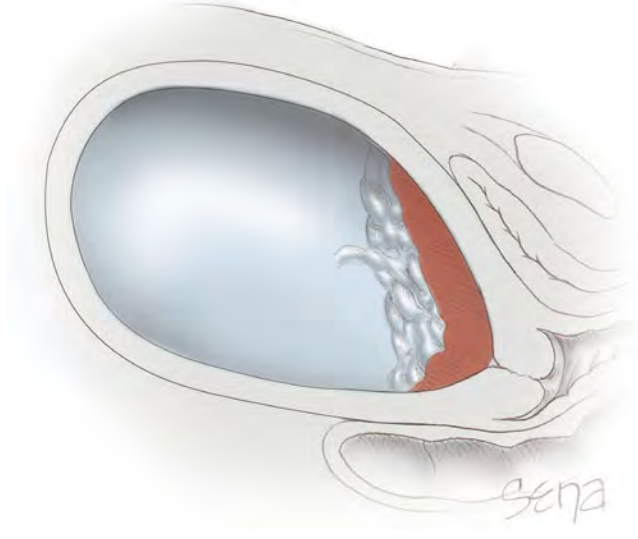

FIGURE 35-11 Total placenta previa showing that copious hemorrhage could be anticipated even with modest cervical dilatation.

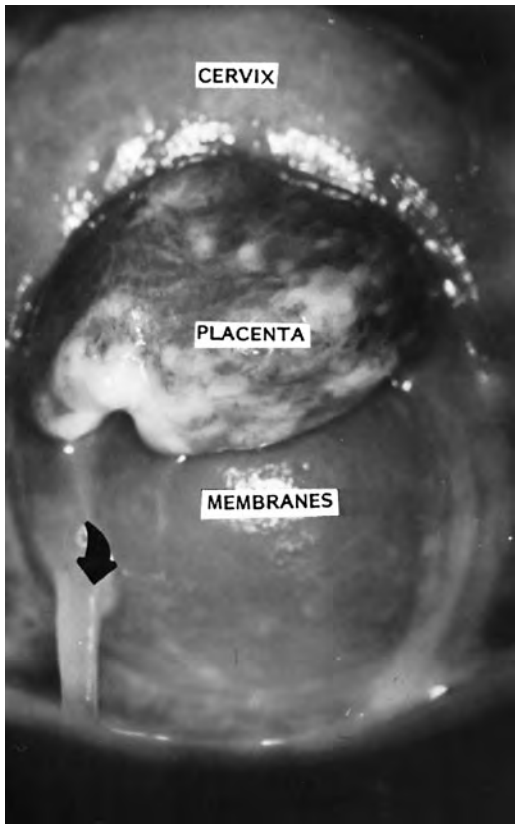

FIGURE 35-12 Partial placenta previa with a 22-week pregnancy. On speculum examination, the cervix appears 3- to 4-cm dilated. The arrow points to mucus dripping from the cervix. Uterine cramping continued, and a 410-g fetus was delivered vaginally the next day with minimal blood loss. (Photograph courtesy of Dr. Rigoberto Santos.)

Incidence

According to 2003 birth certificate data in the United States, placenta previa complicated almost 1 in 300 deliveries (Martin and co-workers, 2005). From Nova Scotia, Crane and associates (1999) found the incidence to be 1 in 300 of almost 93,000 deliveries. At Parkland Hospital, the incidence was 1 in 390 for more than 280,000 deliveries from 1998 through 2006. These prevalences are remarkably similar considering the lack of precision in definition and identification for reasons already discussed.

Associated Factors

Advancing *maternal age* increases the risk of placenta previa. As shown in Figure 35-6, the incidence of previa increased significantly with each advancing maternal age group. It is 1 in 1500 for women 19 years or younger and is 1 in 100 for women older than 35. Increasing maternal age in this country has caused an increased overall incidence of previa from 0.3 percent in 1976 to 0.7 percent in 1997 (Frederiksen and colleagues, 1999). In more than 36,000 women enrolled in the FASTER trial, those older than 35 years had a 1.1-percent risk for previa compared with that of 0.5 percent for women less than 35 (Cleary-Goldman and associates, 2005).

Multiparity is also associated with an increased risk for placenta previa. Babinszki and colleagues (1999) reported that the 2.2-percent incidence in women para 5 or greater was increased significantly compared with that of women with lower parity. Ananth and associates (2003a) reported the rate of placenta previa to be 40 percent higher in *multifetal gestations* compared with singletons.

For unknown reasons, *prior cesarean delivery* increases the risk for placenta previa. In a study of 30,132 women in labor undergoing cesarean delivery, Silver and associates (2006) cited an increased risk of previa in women who had prior cesarean delivery. The incidence was 1.3 percent for those with one prior cesarean delivery and 3.4 percent in women who had six or more cesarean deliveries (see also Chap. 26, p. 574, and Fig. 26-4). Miller and associates (1996) cited a threefold increased risk for previa in women with a prior cesarean delivery in more than 150,000 deliveries at Los Angeles County Women's Hospital. And the risk for previa increases progressively as parity and number of prior cesarean deliveries increases. Gesteland and co-workers (2004) and Gilliam and colleagues (2002) calculated that the likelihood of previa was increased more than eightfold in women with parity greater than four and more than four prior cesareans. Finally, a prior uterine incision with a previa increases the likelihood that *cesarean hysterectomy* will be necessary to control bleeding from a placenta accreta, increta, or percreta (see p. 776). Frederiksen and co-workers (1999) reported a 25-percent hysterectomy rate in women undergoing repeat cesarean delivery with a coexistent previa compared with only 6 percent in those undergoing primary cesarean for placenta previa.

The relative risk of placenta previa was reported by Williams and colleagues (1991) to be increased twofold in women who *smoked cigarettes.* These findings were confirmed by Ananth (2003a), Handler (1994), Usta (2005), and all their associates. It was theorized that carbon monoxide hypoxemia caused compensatory placental hypertrophy. Perhaps related, defective decidual vascularization, the possible result of inflammatory or atrophic changes, is implicated in the development of previa.

Women with otherwise unexplained elevated screening levels of *maternal serum alpha-fetoprotein* (*MSAFP*) are at greater risk for previa. Butler and co-workers (2001) reported that women with a placenta previa who also had increased MSAFP levels of ≥2.0 MoM at 16-week screening were at increased risk for late-pregnancy bleeding and preterm birth. (see also Chap. 13, p. 290).

Clinical Findings

The most characteristic event in placenta previa is painless hemorrhage, which usually does not appear until near the end of the second trimester or after. However, bleeding may begin earlier, and some abortions may result from such an abnormal location of the developing placenta.

With many previas, bleeding begins without warning and without pain in a woman who has had an uneventful prenatal course. Fortunately, the initial bleeding is rarely so profuse as to prove fatal. Usually it ceases, only to recur. In some women, particularly those with a placenta implanted near but not over the cervical os, bleeding does not appear until the onset of labor.

Then, it may vary from slight to profuse and clinically may mimic placental abruption.

The cause of hemorrhage is reemphasized: when the placenta is located over the internal os, the formation of the lower uterine segment and the dilatation of the internal os result inevitably in tearing of placental attachments. The bleeding is augmented by the inherent inability of myometrial fibers of the lower uterine segment to contract and thereby constrict the avulsed vessels.

Hemorrhage from the implantation site in the lower uterine segment may continue after placental delivery because the lower uterine segment contracts poorly. Bleeding may also result from lacerations in the friable cervix and lower uterine segment, especially following manual removal of a somewhat adhered placenta.

Placenta Accreta, Increta, and Percreta. Placenta previa may be associated with *placenta accreta* or one of its more advanced forms, *placenta increta* or *placenta percreta.* Such abnormally firm attachment of the placenta might be anticipated because of poorly developed decidua in the lower uterine segment. Almost 7 percent of 514 cases of previa reported by Frederiksen and associates (1999) had an associated abnormal placental attachment. Biswas and co-workers (1999) performed placental bed biopsies at cesarean delivery in 50 women with a previa and in 50 control women. Although approximately half of specimens from previas showed myometrial spiral arterioles with trophoblastic giant-cell infiltration, only 20 percent from normally implanted placentas had these changes. Placenta accreta and its more severe forms are discussed in detail on page 776.

Coagulation Defects. In our experience, coagulopathy is rare with placenta previa, even when there is extensive separation from the implantation site. Wing and colleagues (1996b) studied 87 antepartum women with bleeding from placenta previa and found no evidence of coagulopathy. Presumably thromboplastin, which incites intravascular coagulation that commonly characterizes placental abruption, readily escapes through the cervical canal rather than being forced into the maternal circulation.

Diagnosis

Placenta previa or abruption should always be suspected in women with uterine bleeding during the latter half of pregnancy. The possibility of placenta previa should not be dismissed until sonographic evaluation has clearly proved its absence. The diagnosis can seldom be established firmly by clinical examination unless a finger is passed through the cervix and the placenta is palpated. **Such digital cervical examination is never permissible unless the woman is in an operating room with all the preparations for immediate cesarean delivery—even the gentlest digital examination can cause torrential hemorrhage.** Furthermore, this type of examination should not be performed unless delivery is planned, for it may cause bleeding that necessitates immediate delivery. This "double set-up" examination is rarely necessary because placental location can almost always be ascertained by sonography.

Sonographic Localization. The simplest, safest, and most accurate method of placental localization is provided by *transabdominal sonography* (Fig. 35-13A). According to Laing (1996), the average accuracy is 96 percent, and rates as high as 98 percent have been obtained. *False-positive results are often a result of bladder distension. Therefore, scans in apparently positive cases should be repeated after emptying the bladder.* An uncommon source of error has been identification of abundant placenta implanted in the uterine fundus but failure to appreciate that the placenta was large and extended downward all the way to the internal cervical os.

The use of *transvaginal sonography* has substantively improved diagnostic accuracy of placenta previa (Figs. 35-13B and 35-14). Although it may appear dangerous to introduce an ultrasound probe into the vagina in suspected cases, the technique has been shown to be safe (Timor-Tritsch and Yunis, 1993).

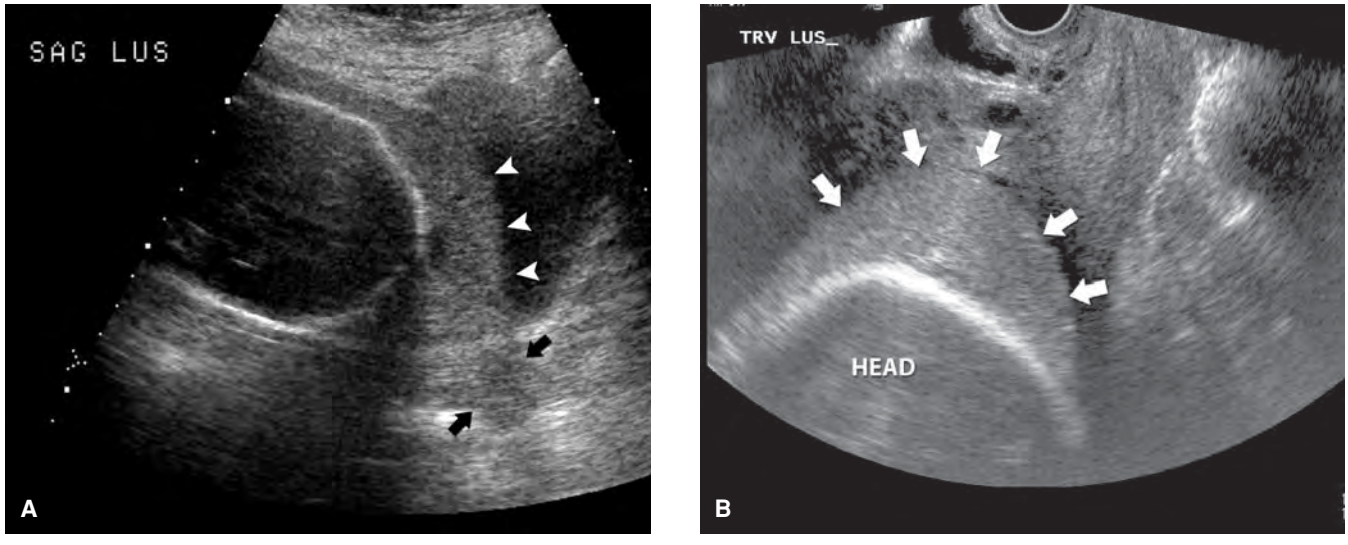

FIGURE 35-13 Total placenta previa. **A.** Transabdominal sonogram of the placenta (*white arrowheads*) behind the bladder covering the cervix (*black arrows*). **B.** Transvaginal sonographic image of the placenta (*arrows*) completely covering the cervix adjacent to the fetal head.

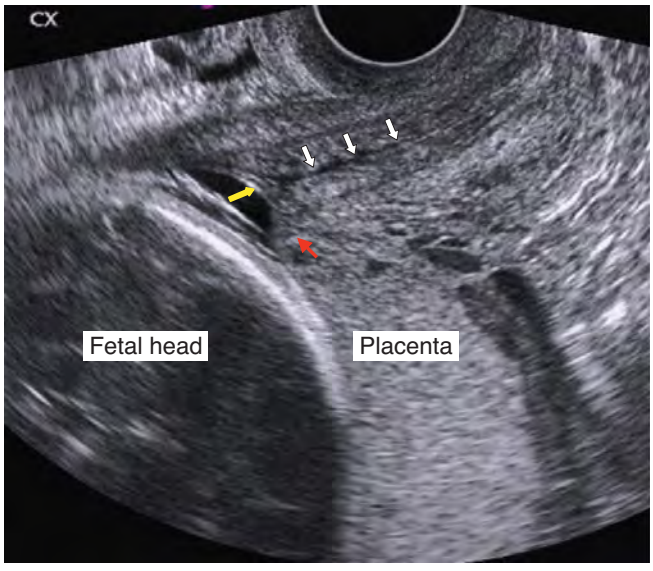

FIGURE 35-14 Partial anterior placenta previa at 36 weeks' gestation. The placental margin (*red arrow*) extends downward toward the cervix. The internal os (*yellow arrow*) and cervical canal (*short white arrows*) are marked to show their relationship to the leading edge of the placenta.

Farine and associates (1988) were able to visualize the internal cervical os in all cases using the transvaginal technique, in contrast to only 70 percent using transabdominal equipment. In studies comparing abdominal with transvaginal imaging, Smith (1997) and Taipale (1998) and their colleagues found the transvaginal technique to be superior.

Transperineal sonography was reported accurate to localize placenta previa by Hertzberg and colleagues (1992). More recently, Rani and associates (2007) demonstrated its accuracy in 75 women in whom placenta previa was visualized using transabdominal sonography. Previa was correctly identified in 69 of the 70 women in which it was confirmed at delivery. The positive-predictive value was 98 percent and negative-predictive value was 100 percent.

Magnetic Resonance (MR) Imaging. A number of investigators have used MR imaging to visualize placental abnormalities, including previa. Although there are many positive attributes to its use, it is unlikely that MR imaging will replace sonographic scanning for routine evaluation in the near future. As discussed on page 779, MR imaging may prove useful for diagnosis of placenta accreta (Palacios Jaraquemada and Bruno, 2005).

Placental "Migration." Since its description by King (1973), the apparent peripatetic nature of the placenta has been well established. Sanderson and Milton (1991) studied 4300 women at 18 to 20 weeks and found that 12 percent of placentas were "low lying." Of those not covering the internal os, previa did not persist and hemorrhage was not encountered. Conversely, of those covering the os at midpregnancy, approximately 40 percent persisted as a previa. Thus, placentas that lie close to the internal os—but not over it—during the second trimester or early third trimester are unlikely to persist as a previa by term.

As shown in **Figure 35-15**, the likelihood that placenta previa persists after being identified sonographically before 28 weeks is greater in women who have had a prior cesarean delivery (Chama, 2004; Dashe, 2002; Laughon, 2005, and all their associates). In the absence of any other abnormality, sonography need not be frequently repeated simply to follow placental position. Restriction of activity is not necessary unless a previa persists beyond 28 weeks or becomes clinically apparent before that time.

The mechanism of apparent placental movement is not completely understood. That said, *migration* is clearly a misnomer because decidual invasion by chorionic villi on either side of the cervical os persists. The apparent movement of the low-lying placenta relative to the internal os probably results from inability to precisely define this relationship in a three-dimensional manner using two-dimensional sonography in early pregnancy. This difficulty is coupled with differential growth of lower and upper myometrial segments as pregnancy progresses. Thus, those placentas that "migrate" most likely never had actual circumferential villus invasion that reached the internal cervical os in the first place.

Management of Placenta Previa

Women with a previa may be considered in one of the following categories:

- The fetus is preterm and there are no other indications for delivery
- The fetus is reasonably mature
- Labor has ensued
- Hemorrhage is so severe as to mandate delivery despite gestational age.

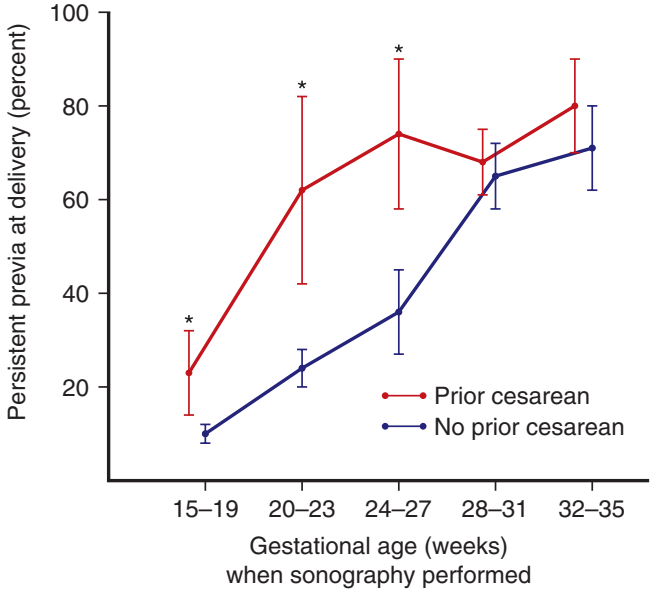

FIGURE 35-15 Percentage of women with persistent placenta previa at delivery according to gestational age at diagnosis and with and without a prior cesarean delivery. Shown as means with error bars that represent 95-percent confidence intervals. (Asterisks note that $p < .05$ comparing women with prior cesarean delivery with multiparous women with no prior cesarean delivery.) (Data from Dashe and colleagues, 2002.)

Management with a preterm fetus, but without persistent active uterine bleeding, consists of close observation. For some women, prolonged hospitalization may be ideal. However, a woman is usually discharged after bleeding has ceased and her fetus judged to be healthy. The woman and her family must fully appreciate the possibility of complications and be prepared to transport her to the hospital immediately. In properly selected patients, there appears to be no benefit to inpatient versus outpatient management of placenta previa (Mouer, 1994; Neilson, 2003). And Drost and Keil (1994) demonstrated a 50-percent reduction in hospitalization and maternal costs, as well as a 40-percent reduction in costs for mother–infant pairs when outpatient was compared with inpatient management.

Importantly, there are no differences in maternal or fetal morbidity rates with outpatient versus inpatient observation. Wing and colleagues (1996a) reported preliminary results from their randomized clinical trial of inpatient versus home management of 53 women with a bleeding previa from 24 to 36 weeks. Maternal and perinatal morbidities were similar in each group, but home management saved $15,000 per case in 1996 dollars. Despite this, 62 percent of these 53 women had recurrent bleeding, and 52 percent required expeditious cesarean delivery.

Delivery

Cesarean delivery is necessary in practically all women with placenta previa. Most often, a transverse uterine incision is possible. However, because fetal bleeding may result from a transverse incision into an anterior placenta, a vertical incision is sometimes employed. But, even when the incision extends through the placenta, maternal or fetal outcomes are rarely compromised.

Ward (2003) described an alternative surgical technique in which a cleavage plane is developed following the uterine incision. The operator undermines the placenta toward the closest edge until the membranes are palpable and they are then ruptured with the fetus delivered *around* the intact placenta. This approach has not yet been evaluated in controlled studies.

Because of the poorly contractile nature of the lower uterine segment, there may be uncontrollable hemorrhage following placental removal. When bleeding from the placental bed cannot be controlled by conservative means, other methods can be attempted. Oversewing the implantation site with 0-chromic sutures may provide hemostasis. In some women, bilateral uterine or internal iliac artery ligation described on page 796 may provide hemostasis. Cho and colleagues (1991) described placing interrupted 0-chromic sutures one centimeter apart and forming a sutured circle around the bleeding portion of the lower segment. This method controlled hemorrhage in all eight women in whom it was employed. Druzin (1989) described four cases in which the lower uterine segment was tightly packed with gauze that successfully arrested hemorrhage. The pack was removed transvaginally 12 hours later. Pelvic artery embolization as discussed on page 797 also has gained acceptance.

If such conservative methods fail, and bleeding is brisk, then hysterectomy is necessary (see Chap. 25, p. 555). *For women whose placenta previa is implanted anteriorly in the site of a prior hysterotomy incision, there is an increased likelihood of associated placenta accreta and need for hysterectomy.* During the year ending in February 2006, 40 percent of 318 peripartum hysterectomies in the United Kingdom were done for abnormally adhered placentation (Knight, 2007).

Maternal and Perinatal Outcomes

A marked reduction in maternal mortality rates from placenta previa was achieved during the last half of the 20th century. Still, as shown in Figure 35-1, placenta previa is an important cause of maternal morbidity and mortality. In their recent review, Oyelese and Smulian (2006) cite an approximately threefold increased maternal mortality ratio of 30 per 100,000.

Preterm delivery as a result of placenta previa is a major cause of perinatal death. Using 1997 linked birth and infant death data sets for the United States, Salihu and associates (2003) reported the neonatal mortality rate to be threefold increased in pregnancies complicated by placenta previa. This was primarily because of increased preterm birth rates. In another large series, Ananth and associates (2003b) reported a comparably increased risk of neonatal death even for those fetuses delivered at term. Some of this risk appears related to fetal-growth restriction and limited prenatal care. And although suspected by some investigators, an association of increased congenital malformations and previa was not confirmed until relatively recently by Crane and co-workers (1999). Importantly, they controlled for maternal age, and for reasons that are unclear, fetal anomalies were increased 2.5-fold in pregnancies complicated by placenta previa.

The association of fetal-growth restriction with placenta previa is less certain. Brar and colleagues (1988) reported the incidence to be nearly 20 percent, but Crane and co-workers (1999) found no increased incidence after controlling for gestational age. Ananth and associates (2001a) examined this relationship in a population-based cohort of more than 500,000 singleton births. They found that most of the association between placenta previa and low birthweight was from preterm birth, and only to a lesser extent from growth impairment.

Third-Stage Bleeding

Some bleeding is inevitable during the third stage of labor as the result of transient partial separation of the placenta. As the placenta separates, blood from the implantation site may escape into the vagina immediately—the *Duncan mechanism* of placental separation. Alternately, it may be concealed behind the placenta and membranes until the placenta is delivered—the *Schultze mechanism.*

In the presence of any external hemorrhage during the third stage, the uterus should be massaged if it is not contracted firmly. If the signs of placental separation have appeared, expression of the placenta should be attempted by manual fundal pressure as described in Chapter 17 (p. 398). Descent of the placenta is indicated by the cord becoming slack. If bleeding continues, manual removal of the placenta may be necessary. *Delivery of the placenta by cord traction, especially when the uterus is atonic, may cause uterine inversion.* Prevention and management of this complication are discussed in detail on page 780.

Bleeding with Prolonged Third Stage

In some cases, the placenta does not separate promptly. There is still no definite answer to the question concerning the length of

time that should elapse in the absence of bleeding before the placenta is removed manually. Obstetrical tradition has set somewhat arbitrary limits on third-stage duration in attempts to define *abnormally retained placenta* and thus, to reduce blood loss from prolonged placental separation. Combs and Laros (1991) studied 12,275 singleton vaginal deliveries and reported the median third-stage duration to be 6 minutes, and for 3.3 percent of these women, it was more than 30 minutes. Several measures of hemorrhage, including curettage or transfusion, increased when the third stage was approximately 30 minutes or longer. Prolonged third-stage labor is discussed in Chapter 17 (p. 397).

Technique of Manual Placental Removal

Adequate analgesia is mandatory, and aseptic surgical technique should be used. After grasping the fundus through the abdominal wall with one hand, the other hand is introduced into the vagina and passed into the uterus, along the umbilical cord. As soon as the placenta is reached, its margin is located, and the border of the hand is insinuated between it and the uterine wall (**Fig. 35-16**). Then with the back of the hand in contact with the uterus, the placenta is peeled off its uterine attachment by a motion similar to that used in separating the leaves of a book. After its complete separation, the placenta should be grasped with the entire hand, which is then gradually withdrawn. Membranes are removed at the same time by carefully teasing them from the decidua, using ring forceps to grasp them as necessary. Another method is to wipe out the uterine cavity with a laparotomy sponge.

Management after Placental Delivery

The fundus should always be palpated following either spontaneous or manual placental delivery to confirm that the uterus is well contracted. If it is not firm, vigorous fundal massage is indicated. Most evidence suggests that uterine massage prevents postpartum hemorrhage from atony (Hofmeyr and associates, 2008). Typically, 20 U of oxytocin in 1000 mL of lactated Ringer or normal saline proves effective when administered intravenously at approximately 10 mL/min—200 mU of oxytocin per minute—simultaneously with effective uterine massage. Oxytocin should never be given as an undiluted bolus dose, because serious hypotension or cardiac arrhythmias may occur (see Chap. 17, p. 399).

Uterine Atony

Failure of the uterus to contract properly following delivery is the most common cause of obstetrical hemorrhage. In many women, uterine atony can at least be anticipated well in advance of delivery (Table 35-2). Although risk factors are well known, the ability to identify which individual woman will experience atony is limited. Rouse and colleagues (2006) studied 23,900 women undergoing primary cesarean delivery and reported that half of those women experiencing atony had no risk factors.

The *overdistended uterus* is prone to be hypotonic after delivery. Thus, women with a large fetus, multiple fetuses, or hydramnios are prone to uterine atony. The woman whose labor is characterized by *uterine activity* that is either remarkably vigorous or barely effective is also likely to bleed excessively from postpartum atony. Similarly, labor either initiated or augmented with *oxytocics* is more likely to be followed by atony and hemorrhage.

High parity may be a risk factor for uterine atony. Fuchs and colleagues (1985) described outcomes of nearly 5800 women para 7 or greater. They reported that the 2.7-percent incidence of postpartum hemorrhage was increased fourfold compared with that of the general obstetrical population. Babinszki and colleagues (1999) reported the incidence of postpartum hemorrhage to be 0.3 percent in women of low parity, but it was 1.9 percent in those para 4 or greater.

Another risk is if the woman has had a *prior postpartum hemorrhage*. Finally, attempts to *hasten placental delivery* may incite

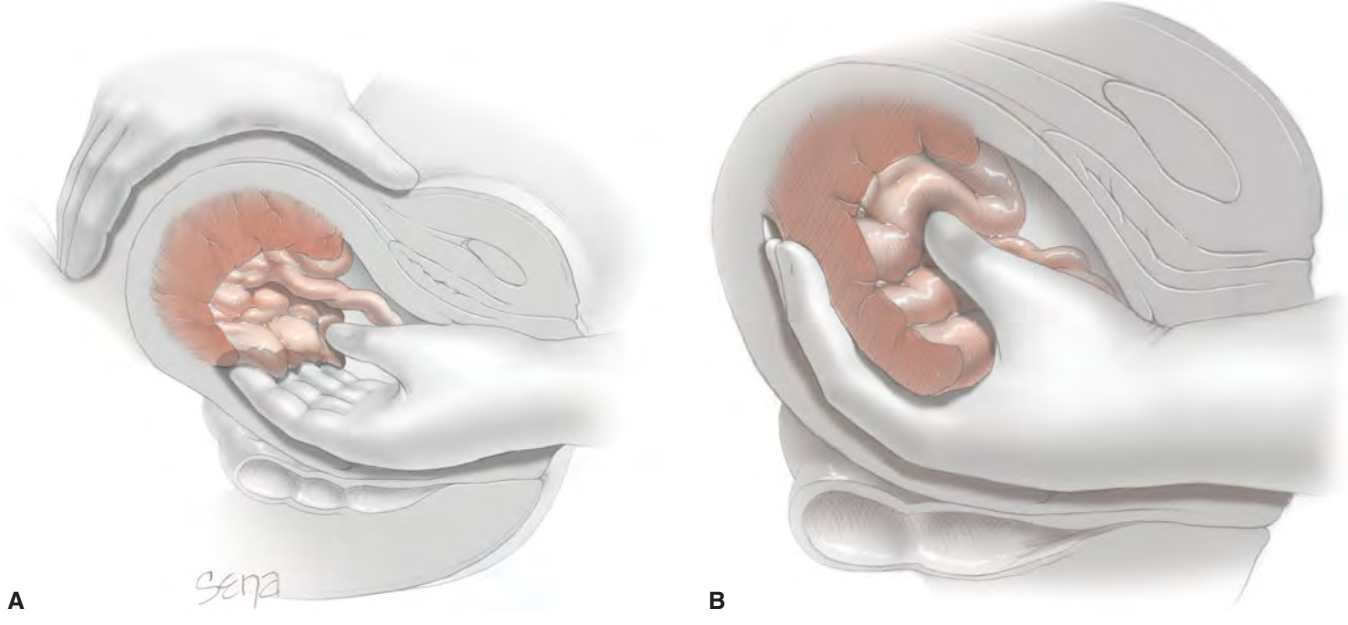

FIGURE 35-16 Manual removal of placenta is accomplished as the fingers are swept from side to side and advanced **(A)** until the placenta is detached, grasped, and removed **(B)**.

atony. *Constant kneading and squeezing of the uterus that already is contracted likely impedes the physiological mechanism of placental detachment, causing incomplete placental separation and increased blood loss.*

Retained Placental Fragments

Immediate postpartum hemorrhage is seldom caused by retained placental fragments, but a remaining piece of placenta is a common cause of bleeding late in the puerperium. Inspection of the placenta after delivery should be routine. If a portion is missing, the uterus should be explored and the fragment removed, particularly with continuing postpartum bleeding. Retention of a *succenturiate lobe* is an occasional cause of postpartum hemorrhage (see Chap. 27, p. 577). The late bleeding that may result from a placental polyp is discussed in Chapter 30 (p. 648).

Uterotonic Agents

A number of compounds are used to cause the postpartum uterus to contract.

Oxytocin. In most units, after placental delivery is accomplished, oxytocin is given intravenously or intramuscularly, as described in Chapter 17 (p. 399). This or other oxytocics will prevent most cases of uterine atony.

Ergot Derivatives. If oxytocin does not prove effective to reverse uterine atony, we usually administer 0.2 mg of methylergonovine intramuscularly. This may stimulate the uterus to contract sufficiently to control hemorrhage. Any superior therapeutic effects of ergot derivatives compared with those of oxytocin are speculative. Importantly, if ergot agents are intravenously administered, they may cause dangerous hypertension, especially in women with preeclampsia.

Prostaglandin Analogs. The 15-methyl derivative of prostaglandin $F_{2\alpha}$–carboprost tromethamine–has been approved since the mid-1980s for treatment of uterine atony. The initial recommended dose is 250 μg (0.25 mg) given intramuscularly. This is repeated if necessary at 15- to 90-minute intervals up to a maximum of eight doses. Oleen and Mariano (1990) studied its use for postpartum hemorrhage at 12 obstetrical units. Arrest of bleeding was considered successful in 88 percent of 237 women treated. Another 7 percent required other oxytocics for control of hemorrhage. The remaining 5 percent required surgical intervention.

Carboprost is associated with side effects in approximately 20 percent of women (Oleen and Mariano, 1990). In descending order of frequency, these include diarrhea, hypertension, vomiting, fever, flushing, and tachycardia. We have encountered serious hypertension in a few women so treated. And Hankins and colleagues (1988) observed that intramuscular carboprost was followed within 15 minutes by arterial oxygen desaturation that averaged 10 percent. They concluded that this was due to pulmonary airway and vascular constriction.

Rectally administered prostaglandin E_2 20-mg suppositories are used for uterine atony but have not been studied in clinical trials. A few reports have suggested that synthetic prostaglandin E_1 analog—misoprostol or Cytotec—may be effective for the treatment of atony (Abdel-Aleem and associates, 2001; O'Brien and colleagues, 1998). In a recent Cochrane review, however, Mousa and Alfirevic (2007) reported no benefit to misoprostol compared with standard therapy with oxytocin and ergometrine. Only three studies met the stringent criteria for inclusion, and all dosing regimens were different.

Misoprostol has also been evaluated for prophylaxis of postpartum hemorrhage. In a randomized trial, Derman and coworkers (2006) compared a 600-μg oral dose with placebo given at delivery. Postpartum hemorrhage was significantly reduced from 12 to 6 percent, and severe hemorrhage from 1.2 to 0.2 percent with misoprostol use. However, based on their study of 325 women, Gerstenfeld and Wing (2001) concluded that 400 μg of misoprostol administered rectally was no more effective than intravenous oxytocin in preventing postpartum hemorrhage. And in their systematic review, Villar and coworkers (2002) reported that oxytocin and ergot preparations administered during third-stage labor were more effective than misoprostol for prevention of postpartum hemorrhage.

Bleeding Unresponsive to Oxytocics

Continued bleeding after multiple administrations of oxytocics may be from unrecognized genital tract lacerations, including in some cases uterine rupture. Thus, if bleeding persists, no time should be lost in haphazard efforts to control hemorrhage, but the following management steps should be initiated immediately:

1. Initiate bimanual uterine compression, a simple procedure that controls most uterine hemorrhage (**Fig. 35-17**). This technique consists of massage of the posterior aspect of the uterus with a hand on the abdomen and massage through the vagina of the anterior uterine wall with the other hand made into a fist.
2. Call for help!

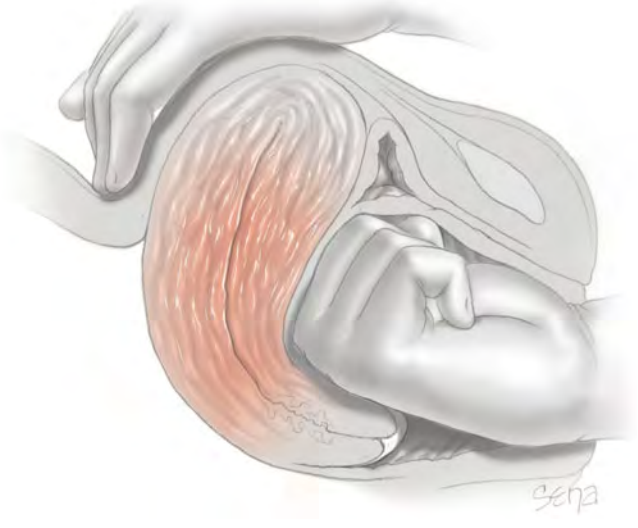

FIGURE 35-17 Bimanual compression of the uterus between the fist in the anterior fornix and the abdominal hand, which is also used for uterine massage. This usually controls hemorrhage from uterine atony.

3. Add a second large-bore intravenous catheter so that crystalloid with oxytocin may be continued at the same time blood is given.
4. Begin blood transfusions. The blood group of every obstetrical patient should be known, if possible, before labor, and an indirect Coombs test done to detect erythrocyte antibodies. If the latter is negative, then crossmatching of blood is not necessary (see p. 793). In an extreme emergency, type O, D-negative "universal donor" blood is given.
5. Explore the uterine cavity manually for retained placental fragments or lacerations.
6. Thoroughly inspect the cervix and vagina for lacerations after adequate exposure.
7. Insert a Foley catheter to monitor urine output, which is a good measure of renal perfusion.
8. Begin volume resuscitation as described subsequently on page 791.

Blood transfusion should be considered in any woman with postpartum hemorrhage in whom abdominal uterine massage and oxytocic agents fail to control bleeding. With transfusion and simultaneous manual uterine compression and intravenous oxytocin, additional measures are rarely required.

Surgical Management of Uterine Atony

With intractable atony unresponsive to the above measures, surgical intervention can be lifesaving. In our experience, *uterine artery ligation*—discussed on page 795—is less helpful for hemorrhage from uterine atony compared with its use for hysterotomy extensions at cesarean delivery. It is also debatable whether *internal iliac artery ligation* is beneficial for uterine atony (Clark and colleagues, 1985). From India, Joshi and co-workers (2007) described 36 women who had the procedure for postpartum atony—a third of those required hysterectomy. Our concern, in addition to an inherently high failure rate, is that the procedure, discussed on page 796, is technically difficult and consumes valuable time if hysterectomy is necessary.

Uterine Compression Sutures. In 1997, B-Lynch and colleagues described a surgical technique for severe postpartum atony in which a pair of vertical brace, #2-chromic sutures were secured around the uterus. When tightened and tied, they give the appearance of suspenders—or braces—that compress the anterior and posterior walls together (**Fig. 35-18**). Price and B-Lynch (2005) summarized 17 reports in which 44 of 46 procedures were successful. In another preliminary report, B-Lynch (2005) cited 948 cases with only seven failures. Our experiences are not nearly so successful, but the technique certainly is effective in some cases. A number of modifications of the B-Lynch technique have been described (Bhal, 2005; Cho, 2000; Ghezzi, 2007; Hayman, 2002; Pereira, 2005, and all their colleagues).

Reports of complications from compression sutures have been slowly emerging. At this time, their incidence is unknown but is likely low. Uterine ischemic necrosis with peritonitis has been described in several case reports (Gottlieb, 2008; Joshi, 2004; Ochoa, 2002; Treloar, 2006, and all their colleagues). The women described by Akoury and Sherman (2008) had one B-Lynch suture and two Cho sutures and were found to have one large triangular and two smaller defects in the uterine wall in a subsequent pregnancy. Total ischemic uterine necrosis developed in a woman described by Friederich and associates (2007). In addition to B-Lynch compression sutures, the woman also had bilateral ligation of uterine, uterovarian, and round ligament arteries.

Uterine Packing

This technique should be considered in women with refractory postpartum hemorrhage related to uterine atony who wish to preserve fertility. Popular during the first half of the 20th century, uterine packing subsequently fell from favor because of concerns about concealed bleeding and infection (Hsu and coworkers, 2003). Newer techniques, however, have allayed some of these concerns (Roman and Rebarber, 2003). In one technique, the tip of a 24F Foley catheter with a 30-mL balloon is guided into the uterine cavity and filled with 60 to 80 mL of saline. The open tip permits continuous drainage from the uterus. If bleeding subsides, the catheter is typically removed after 12 to 24 hours. Alternatively, the uterus or pelvis may be packed directly with gauze (Gilstrap, 2002).

Placenta Accreta, Increta, and Percreta

In most instances, the placenta separates spontaneously from its implantation site during the first few minutes after delivery of the infant. Infrequently, detachment is delayed because the placenta is unusually adhered to the implantation site. In these cases, the decidua is scanty or absent, and the physiological line of cleavage through the decidual spongy layer is lacking. As a consequence, one or more placental lobules, also termed *cotyledons*, are firmly bound to the defective decidua basalis or even to the myometrium. When the placenta is densely anchored in this fashion, the condition is called placenta accreta. Varying degrees of accreta cause significant morbidity and at times, mortality from severe hemorrhage, uterine perforation, and infection.

Definitions

The term *placenta accreta* is used to describe any implantation in which there is abnormally firm adherence to the uterine wall. As the consequence of partial or total absence of the decidua basalis and imperfect development of the fibrinoid or *Nitabuch layer*, placental villi are attached to the myometrium in placenta accreta (**Fig. 35-19A**). With *placenta increta*, villi actually invade into the myometrium (**Fig. 35-19B**). Finally, with *placenta percreta*, villi penetrate through the myometrium (**Fig. 35-19C**). The abnormal adherence may involve all lobules—*total placenta accreta*—as was the case in **Figure 35-20A**. Or, it may involve only a few to several lobules—*partial placenta accreta*—such as shown in **Figure 35-20B**. All or part of a single lobule may be attached—*focal placenta accreta*. According to Benirschke and colleagues (2006), histological diagnosis cannot be made from the placenta alone, and the entire uterus or curettings with myometrium are necessary for histopathological confirmation.

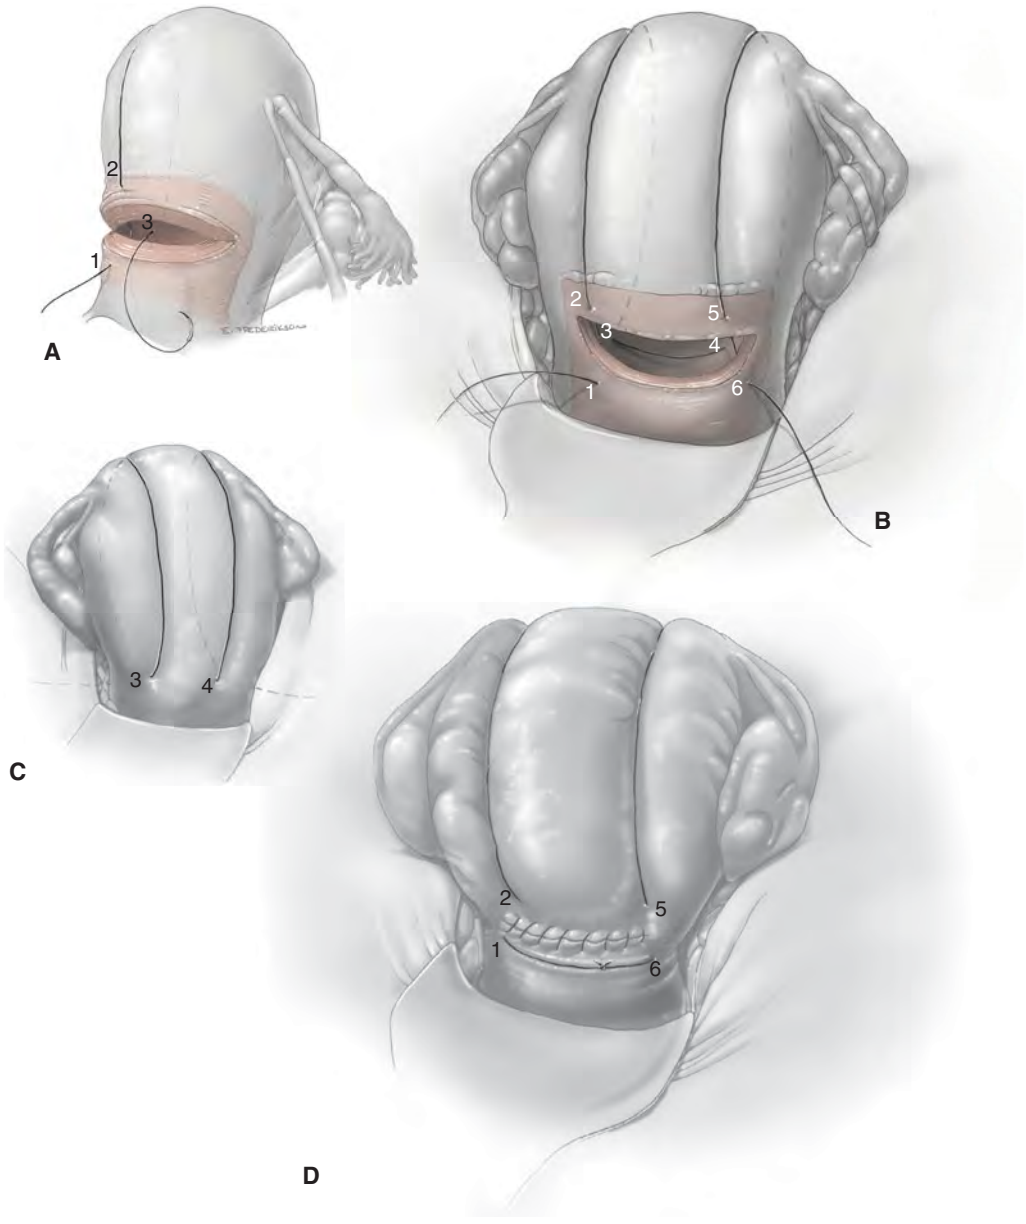

FIGURE 35-18 The B-Lynch uterine compression suture technique. Figures **(A)**, **(B)**, and **(D)** demonstrate an anterior view of the uterus. Figure **(C)** is a posterior view. Numbers denote the sequential path of the suture and are shown in more than one figure. In step 1, beginning below the incision, the needle pierces the lower uterine segment to enter the uterine cavity. In step 2, the needle exits the cavity above the incision. The suture then loops up and around the fundus to the posterior uterine surface. Here, in step 3, the needle pierces the posterior uterine wall to reenter the uterine cavity. The suture then traverses from left to right within the cavity. In step 4, the needle exits the uterine cavity through the posterior uterine wall. From the back of the uterus, the suture loops up and around the fundus to the front of the uterus. In step 5, the needle pierces the myometrium above the incision to reenter the uterine cavity. In step 6, the needle exits below the incision. Finally, the sutures at points 1 and 6 are tied below the incision.

Incidence

Over the past few decades, the incidences of placenta accreta, increta, and percreta have increased. This is because of the increasing cesarean delivery rate (see Chap. 25, p. 544). The American College of Obstetricians and Gynecologists (2002) estimated that placenta accreta complicates 1 in 2500 deliveries. From their review, Stafford and Belfort (2008) cite the incidence of approximately 1 in 2500 in the 1980s, 1 in 535 in 2002, and 1:210 in 2006. For some time, it has been a leading cause of intractable postpartum hemorrhage requiring emergency peripartum hysterectomy (Zelop and colleagues, 1993). And as shown in Figure 35-1, various forms of accreta are a substantive cause of maternal deaths from hemorrhage.

Associated Conditions

Decidual formation is commonly defective in the lower uterine segment over a previous cesarean delivery scar or after uterine curettage. In a review of 622 cases of placenta accreta collected between 1945 and 1969, Fox (1972) reported that: (1) a third of cases had placenta previa, (2) a fourth had a prior cesarean delivery,

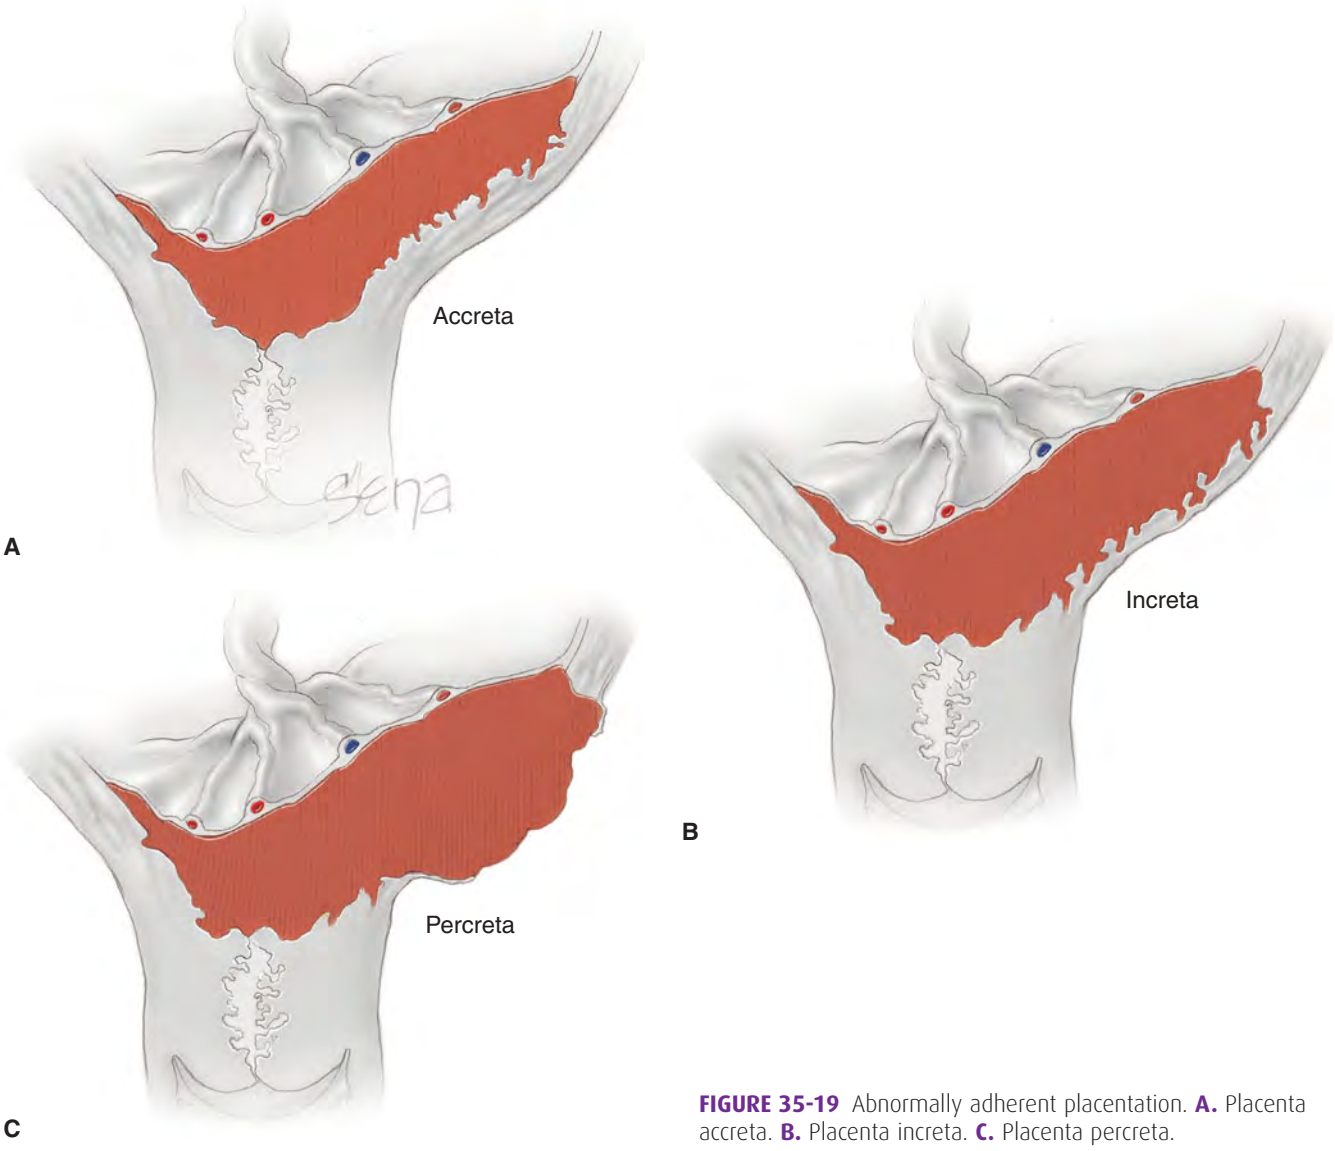

FIGURE 35-19 Abnormally adherent placentation. **A.** Placenta accreta. **B.** Placenta increta. **C.** Placenta percreta.

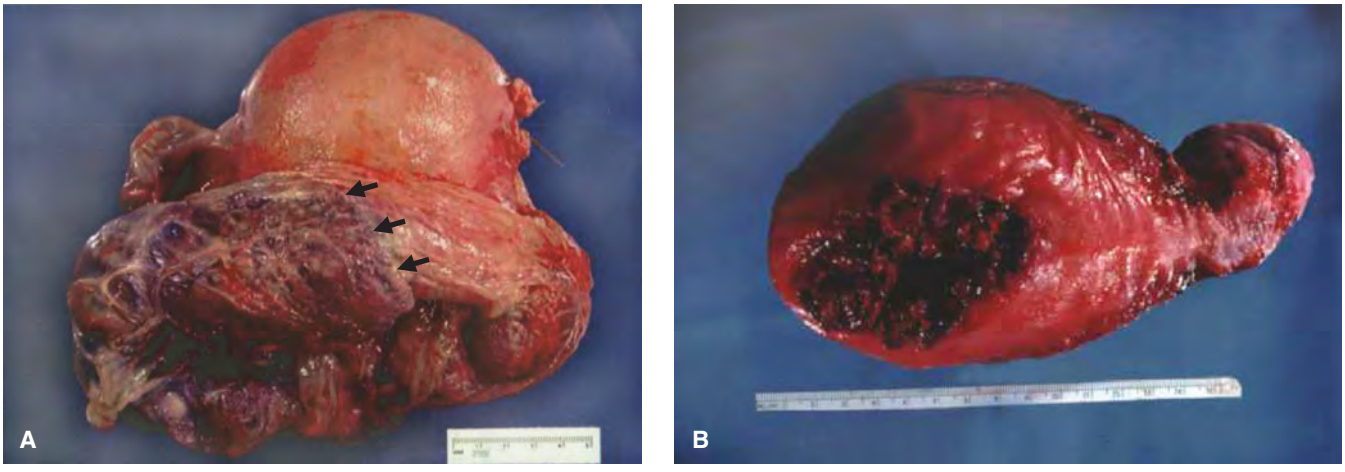

FIGURE 35-20 Cesarean hysterectomy specimens with placenta percreta. **A.** Total placenta previa with percreta involving the lower uterine segment and cervical canal. (3) nearly a fourth had previously undergone curettage, and (4) a fourth were gravida 6 or more. Zaki and associates (1998) found that 10 percent of 112 consecutive cases of placenta previa had associated accreta. Hardardottir and colleagues (1996) observed that almost 50 percent of placentas in women with a prior cesarean delivery had adhered myometrial fibers detected microscopically.

There are risk factors for placenta accreta that have come to light with MSAFP screening for neural-tube defects and aneuploidies (see Chap. 13, p. 289). Hung and co-workers (1999) analyzed outcomes of more than 9300 women screened for Down syndrome at 14 to 22 weeks. They reported a 54-fold increased risk for accreta in women with placenta previa. The risk for accreta was increased eightfold when MSAFP levels exceeded 2.5 MoM; it was increased fourfold when maternal free β-hCG levels were greater than 2.5 MoM; and it was increased threefold when maternal age was 35 years or older.

Clinical Course and Diagnosis

In the first trimester, as discussed in Chapter 10 (p. 253), abnormal myometrial invasion may manifest as a *cesarean scar pregnancy* (Ash and associates, 2007). According to their review, Rotas and colleagues (2006) reported this type of ectopic pregnancy to be increasing in frequency and cited an incidence of approximately 1 in 2000 pregnancies. If pregnancy advances, placental villi at the site of a previous cesarean scar may lead to uterine rupture before labor (Liang and co-workers, 2003). Antepartum hemorrhage with placenta accreta is common and usually the consequence of coexisting placenta previa. In many cases, placenta accreta is not identified until third-stage labor. In this setting, an adhered placenta, as described on page 775, is encountered.

Perioperative Evaluation

Efforts are ongoing to better identify placental ingrowth antepartum. Lam and colleagues (2004) found that sonography was only 33-percent sensitive for detecting placenta accreta. With sonographic Doppler color flow mapping-such as shown in **Figure 35-21**, Twickler and colleagues (2000) reported that two factors were highly predictive of myometrial invasion: (1) a distance less than 1 mm between the uterine serosa-bladder interface and the retroplacental vessels, and (2) identification of large intraplacental lakes. These had a sensitivity of 100 percent and positive-predictive value of 78 percent. Chou and co-workers (2001) also described successful use of three-dimensional color Doppler imaging for diagnosis of placenta percreta.

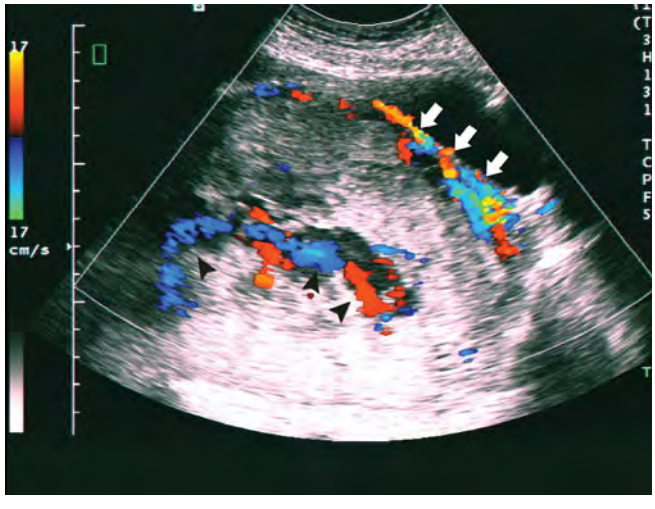

FIGURE 35-21 Transabdominal sonogram of placental invasion. Retroplacental vessels (*white arrows*) invade the myometrium and obscure the bladder-serosal interface. Abnormal intraplacental venous lakes (*black arrows*) are commonly seen in this setting.

Magnetic resonance (MR) imaging is used as an adjunct to sonography when there is strong clinical suspicion of an accreta. Warshak and colleagues (2006) described a two-step protocol in which MR imaging was used if sonography was inconclusive. They reported that 23 of 26 cases of placenta accreta were accurately predicted, and 14 of 14 were correctly excluded. Lax and co-workers (2007) identified three MR imaging findings that suggested accreta: (1) uterine bulging, (2) heterogeneous signal intensity within the placenta, and (3) presence of dark intraplacental bands on T2-weighted imaging.

Baxi and associates (2004) found that elevated serum D-dimer levels may predict significant blood loss and morbidity in women with placenta accreta. This perhaps reflects trophoblastic invasion into the myometrium and adjacent tissues.

Management

Thorough preoperative assessment allows better planning. Exigencies to be considered are appropriate surgical and blood banking facilities, as well as availability of gynecological oncological, surgical, or urological consultation (Bauer and Bonanno, 2009; Stafford and Belfort, 2008). Transfer to a level III facility should be considered (Worley and colleagues, 2008).

Preoperative Arterial Catheter Placement. Experience has accrued with preoperative placement of pelvic arterial catheters. Balloon-tipped catheters are placed before surgery into the internal iliac arteries and are inflated after the fetus is delivered to decrease blood loss during placental delivery and hysterectomy, if indicated. Alternatively, the catheters can be injected with a substance to embolize the arterial sites. Yu and colleagues (2009) presented data from 11 women with abnormal placentation during late gestation in whom uterine artery embolization was done after fetal but before placental delivery. They reported favorable outcomes. From France, Sentilhes and co-workers (2009) described successes in four of 17 women. Oyelese and Smulian (2006) reviewed the limited reported results in the literature and reached no firm conclusions concerning efficacy. Greenburg and colleagues (2007) described a woman who developed thrombolic occlusion of the common and left iliac arteries and advise caution with embolization use.

Delivery of the Placenta. Problems associated with delivery of the placenta and subsequent developments vary appreciably, depending on the site of implantation, depth of myometrial penetration, and number of lobules involved. It is likely that focal placenta accreta with implantation in the upper uterine segment develops more often than recognized. Either the involved lobule is pulled off the myometrium with perhaps somewhat excessive bleeding, or the lobule is torn from the placenta and adheres to the implantation site with increased bleeding, immediately or later. According to Benirschke and Kaufmann (2006),

this may be one mechanism for formation of a so-called *placental polyp* (see Chap. 30, p. 648).

With more extensive involvement, hemorrhage becomes profuse as delivery of the placenta is attempted. Successful treatment depends on immediate blood replacement therapy as subsequently described, and nearly always prompts hysterectomy. *This may be aided by fully developing the bladder flap and dissecting it around the percreta if possible prior to delivery.* Other measures include uterine or internal iliac artery ligation, balloon occlusion, or embolization as discussed above. Karam and colleagues (2003) described use of argon beam coagulation for hemostasis in a woman with placenta percreta and bladder invasion.

With total placenta accreta, there may be very little or no bleeding, at least until manual placental removal is attempted. At times, traction on the umbilical cord inverts the uterus. Mostly, however, usual attempts at manual removal do not succeed because a cleavage plane between the placenta and uterine wall cannot be developed. In the past, "conservative" management included manual removal of as much placenta as possible followed by uterine packing. Unfortunately, 25 percent of women managed conservatively died (Fox, 1972). Thus, the safest treatment in this circumstance is hysterectomy.

At cesarean delivery, another option for a woman who is not bleeding significantly is to leave the entire placenta in place without attempts to extract it and to close the cesarean hysterotomy incision. Leaving the placenta in situ has also been attempted with advanced gestational-age extrauterine pregnancies (Worley and associates, 2008). Currently, there is minimal experience with this approach, and these are chronicled in case reports. Several scenarios have been described. In most, methotrexate was given at the time of surgery. In some, pelvic arterial embolization was also performed (Kayem and colleagues, 2002; Lee and co-workers, 2008). In a few cases, the placenta spontaneously resorbed (Henrich and co-workers, 2002; Kayem and associates, 2002). Subsequent hysterectomy—either planned or prompted by bleeding or infection—is performed several weeks postpartum when blood loss may be less torrential (Hays, 2008; Lee, 2008; Nijman, 2002, and all their colleagues).

Management Outcomes. Most reported outcomes with abnormal placentation are retrospective observational studies of limited size. These are usually reported to describe successes with one particular management method such as some of the ones cited above. Eller and co-workers (2009) reviewed outcomes in 76 cases of placenta accreta cared for at the University of Utah. They found that preoperative identification with scheduled cesarean hysterectomy without placental removal was associated with significantly reduced morbidity—36 versus 67 percent—compared with those of attempted placental removal. They also reported that preoperative bilateral ureteral stenting significantly reduced morbidity—18 versus 55 percent—compared with no stenting. Finally, internal iliac artery ligation did not lower morbidity. Although such a primary surgical approach can be technically difficult in some cases, at Parkland Hospital we have found this management to be preferable, except that we do not routinely perform preoperative ureteral catheterization, and instead, place such catheters transvesically during surgery if necessary. The use of preoperative arterial catheterization as described may be useful in some cases.

Leaving the placenta in situ may prevent massive hemorrhage requiring hysterectomy with the goal of fertility preservation and potential damage to pelvic structures. Timmermans and co-workers (2007) reviewed 48 publications from 1985 through 2006 and described so-called conservative management in 60 such women. Initially, the placenta was either only partially removed or left completely intact. Approximately half were treated with either adjuvant methotrexate or uterine artery embolization. The overall success rate—defined as fertility prevention—was 80 percent. The most common complication was vaginal bleeding in a third that began hours to 3 months' postpartum. A third of these—15 percent of the whole group—required hysterectomy to arrest hemorrhage. Of 11 women with puerperal infection, two required hysterectomy. Serial serum β-hCG measurements were not found to be predictive, and the authors recommend serial imaging with sonography or MR imaging.

Inversion of the Uterus

Complete uterine inversion after delivery of the infant is almost always the consequence of strong traction on an umbilical cord attached to a placenta implanted in the fundus (**Fig. 35-22**). Incomplete uterine inversion may also occur (**Fig. 35-23**). Contributing to uterine inversion is a sturdy cord that does not readily break away from the placenta, combined with fundal pressure and a relaxed uterus, including the lower segment and cervix. Placenta accreta may be implicated as in the case in Figure 35-22, although uterine inversion can occur without a firmly adhered placenta.

The incidence of uterine inversion varies, and in three reports totaling approximately 116,500 deliveries, it averaged 1 in 3000 (Achanna and colleagues, 2006; Baskett, 2002; Platt and Druzin, 1981). This is consistent with experiences from the obstetrical service at Parkland Hospital, in which we encounter several cases annually among approximately 15,000 deliveries. Perhaps ironically, most are seen with "low-risk" deliveries.

FIGURE 35-22 Uterine inversion associated with a fundal placenta accreta during a home delivery was fatal for this woman.

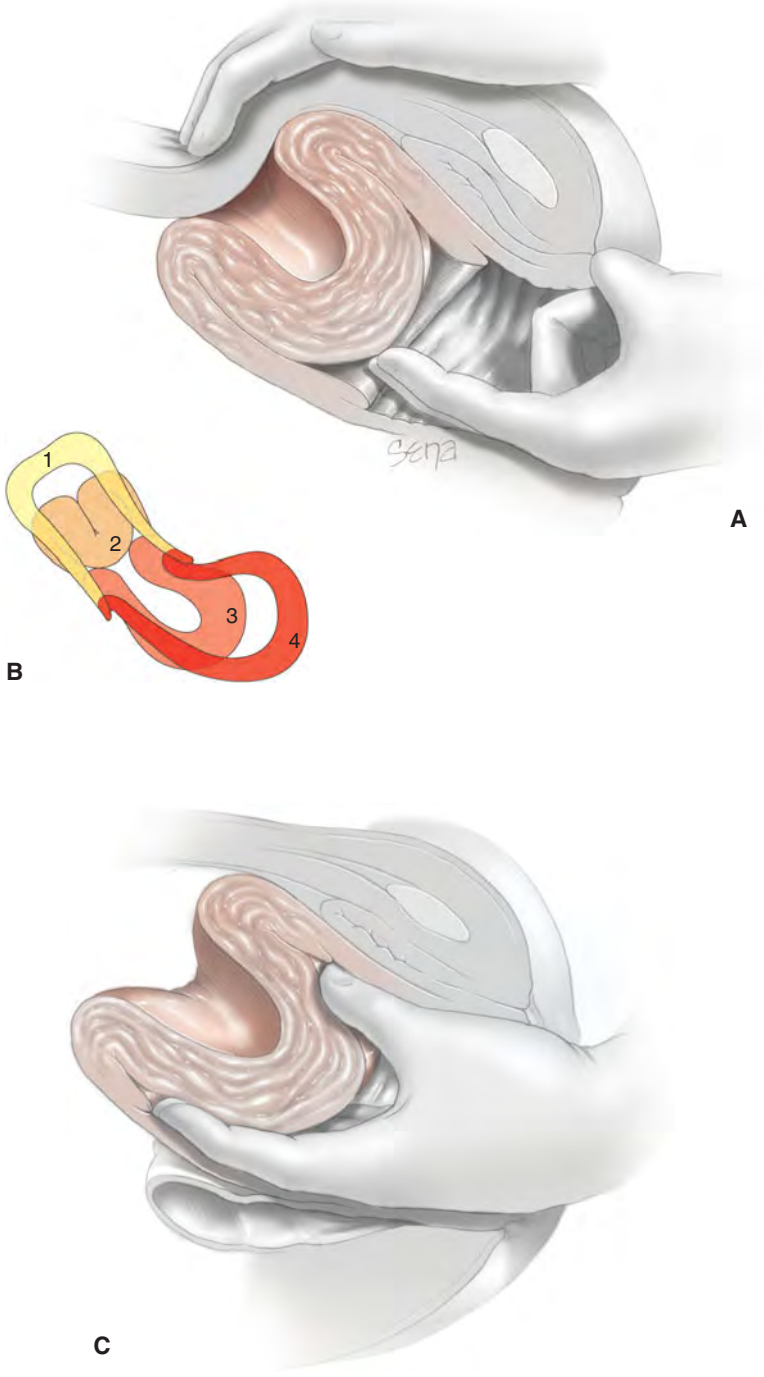

FIGURE 35-23 A. Incomplete uterine inversion is diagnosed by abdominal palpation of a crater-like depression and vaginal palpation of the fundal wall in the lower segment and cervix. **B.** Progressive degrees of inversion are shown in the inset. **C.** To replace the uterus, the palm is placed on the center of the inverted fundus, while fingers identify the cervical margins. Upward pressure by the palm restores the uterus and elevates it past the level of the cervix.

Management

Uterine inversion is most often associated with immediate life-threatening hemorrhage. In the past, it was taught that shock was disproportionate to blood loss, possibly mediated by parasympathetic stimulation caused by stretching of tissues. Careful evaluation of the need in many cases for transfusion of large volumes of blood, however, illustrates that blood loss is usually massive and greatly underestimated (Watson and associates, 1980).

Delay in treatment increases the mortality rate appreciably. It is imperative that a number of steps be taken urgently and simultaneously:

- Immediate assistance is summoned to include anesthesia personnel and other physicians
- The recently inverted uterus with placenta already separated from it may often be replaced simply by pushing up on the fundus with the palm of the hand and fingers in the direction of the long axis of the vagina
- Adequate large-bore intravenous infusion systems are established, and crystalloid and blood are given to treat hypovolemia
- If still attached, the placenta is not removed until infusion systems are operational, fluids are being given, and a uterine-relaxing anesthetic such as a halogenated inhalation agent has been administered. Other tocolytic drugs such as terbutaline, ritodrine, magnesium sulfate, and nitroglycerin have been used successfully for uterine relaxation and repositioning (Hong and colleagues, 2006; You and Zahn, 2006). In the meantime, if the inverted uterus has prolapsed beyond the vagina, it is replaced within the vagina
- After removing the placenta, steady pressure with the fist is applied to the inverted fundus in an attempt to push it up into the dilated cervix. Alternatively, two fingers are rigidly extended and are used to push the center of the fundus upward. *Care is taken not to apply so much pressure as to perforate the uterus with the fingertips.* As soon as the uterus is restored to its normal configuration, the tocolytic agent is stopped. An oxytocin infusion is begun while the operator maintains the fundus in its normal anatomical position.

Initially, bimanual compression as shown in Figure 35-17 aids in control of further hemorrhage until uterine tone is recovered. After the uterus is well contracted, the operator continues to monitor the uterus transvaginally for any evidence of subsequent inversion.

Surgical Intervention

Most often, the inverted uterus can be restored to its normal position by the techniques described. Occasionally, the uterus cannot be reinverted by vaginal manipulation because of a dense constriction ring (Kochenour, 2002). In this case, laparotomy is imperative. The configuration seen at surgery is shown in Figure 35-24. The fundus may be simultaneously pushed upward from below and pulled from above. A deep traction suture well placed in the inverted fundus may be of aid. If the constriction ring still prohibits reposition, it is carefully incised posteriorly to expose the fundus (Van Vugt and associates, 1981). A variant using tissue forceps to grasp the top of the fundus has been described by Robson and colleagues (2005). After replacement of the fundus, the

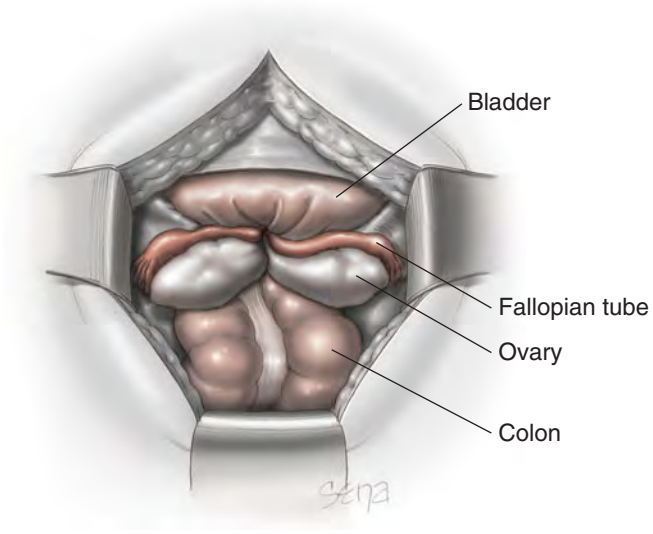

FIGURE 35-24 Completely inverted uterus viewed from above at laparotomy and showing pelvic viscera and landmarks.

anesthetic agent used to relax the myometrium is stopped, oxytocin infusion is begun, and the uterine incision is repaired.

Genital Tract Lacerations

Perineal Lacerations

All except the most superficial perineal lacerations are accompanied by varying degrees of injury to the lower portion of the vagina. Such tears may reach sufficient depth to involve the anal sphincter and may extend to varying depths through the vaginal walls. Bilateral lacerations into the vagina are usually unequal in length and separated by a tongue-shaped portion of vaginal mucosa.

Vaginal Lacerations

Isolated lacerations involving the middle or upper third of the vagina, but unassociated with lacerations of the perineum or cervix, are encountered less commonly. These are usually longitudinal and frequently result from injuries sustained during a forceps or vacuum delivery. However, they may even develop with spontaneous delivery. Such lacerations frequently extend deep into the underlying tissues and may give rise to significant hemorrhage, which usually is controlled by appropriate suturing. They may be missed unless thorough inspection of the upper vagina is performed. *Bleeding while the uterus is firmly contracted is strong evidence of genital tract laceration, retained placental fragments, or both.*

Lacerations of the anterior vaginal wall in close proximity to the urethra are relatively common. They are often superficial with little to no bleeding, and repair is usually not indicated. If such lacerations are large enough to require extensive repair, difficulty in voiding can be anticipated, and an indwelling catheter is placed.

Injuries to Levator Ani Muscles

These result from overdistension of the birth canal (see Figs. 2-25 and 2-26, p. 33). Muscle fibers are separated, and diminution in their tonicity may be sufficient to interfere with pelvic diaphragm function. In such cases, pelvic relaxation may develop. If the injuries involve the pubococcygeus muscle, urinary incontinence also may result (see Chap. 30, p. 649).

Injuries to the Cervix

The cervix is lacerated in more than half of all vaginal deliveries (Fahmy and associates, 1991). Most of these are less than 0.5 cm, although deep cervical tears may extend to the upper third of the vagina. In rare instances, the cervix may be entirely or partially avulsed from the vagina. Such colporrhexis may occur in the anterior, posterior, or lateral fornices. These injuries sometimes follow difficult forceps rotations or deliveries performed through an incompletely dilated cervix with the forceps blades applied over the cervix. Rarely, cervical tears may reach to involve the lower uterine segment and uterine artery and its major branches, and even extend through the peritoneum. They may be totally unsuspected, but more often, they manifest as excessive external hemorrhage or as hematomas.

Extensive tears of the vaginal vault should be explored carefully. If there is question of peritoneal perforation or of retroperitoneal or intraperitoneal hemorrhage, laparotomy should be considered. With damage of this severity, intrauterine exploration for possible rupture is also indicated. Surgical repair is usually required, and effective analgesia or anesthesia, vigorous blood replacement, and capable assistance are mandatory.

Cervical lacerations up to 2 cm must be regarded as inevitable in childbirth. Such tears heal rapidly and are rarely the source of complications. In healing, they cause a significant change in the round shape of the external os, from circular before labor to appreciably widened after delivery (see Fig. 2-12, p. 24). As the consequence of such tears, there may be eversion with exposure of the mucus-producing endocervical epithelium.

Occasionally, the edematous anterior lip of the cervix may be caught during labor and compressed between the fetal head and maternal symphysis pubis. If ischemia is severe, the cervical lip may necrose and separate. Rarely, the entire vaginal portion may be avulsed from the rest of the cervix—termed *annular* or *circular detachment of the cervix*.

Diagnosis. A deep cervical tear should always be suspected in women with profuse hemorrhage during and after third-stage labor, particularly if the uterus is firmly contracted. Thorough examination is necessary, and the flabby cervix often makes digital examination alone unsatisfactory. Thus, the extent of the injury can be fully appreciated only after adequate exposure and visual inspection of the cervix. Visualization is best accomplished when an *assistant* applies firm downward pressure on the uterus while the operator exerts traction on the lips of the cervix with ring forceps. Right-angle vaginal wall retractors are often helpful.

In view of the frequency with which deep tears follow major operative vaginal deliveries, the cervix should be inspected routinely at the conclusion of the third stage after all difficult deliveries, even if there is no bleeding.

Management. Deep cervical tears usually require surgical repair. When the laceration is limited to the cervix, or even when it extends somewhat into the vaginal fornix, satisfactory results

FIGURE 35-25 Repair of cervical laceration with appropriate surgical exposure.

are obtained by suturing the cervix after bringing it into view at the vulva (Fig. 35-25). Because the hemorrhage usually comes from the upper angle of the wound, the first suture is placed proximal to the angle. Suturing proceeds outward toward the operator. Associated vaginal lacerations may be tamponaded with gauze packs to retard hemorrhage while cervical lacerations are repaired. Either interrupted or running absorbable sutures are suitable. Overzealous suturing in an attempt to restore the normal cervical appearance may lead to subsequent stenosis during uterine involution. Alternatively, Lichtenberg (2003) described the successful use of angiographic embolization for treatment of a high cervical tear after failed surgical repair.

Puerperal Hematomas

In a review of seven series, the incidence of puerperal hematomas was found to vary from 1 in 300 to 1 in 1000 deliveries (Cunningham, 2002). Nulliparity, episiotomy, and forceps delivery are the most commonly associated risk factors (Propst and Thorp, 1998; Ridgway, 1995). In other cases, hematomas may develop following rupture of a blood vessel without laceration of superficial tissues. These may occur with spontaneous or operative delivery, and hemorrhage may be delayed. Finally, coagulopathies, such as von Willebrand disease, are rarer causes.

Puerperal hematomas may be classified as vulvar, vulvovaginal, paravaginal, or retroperitoneal. Vulvar hematomas most often involve branches of the pudendal artery, including the posterior rectal, transverse perineal, or posterior labial artery (see Fig. 2-5, p. 20). Paravaginal hematomas may involve the descending branch of the uterine artery (Zahn and Yeomans, 1990). Infrequently, a torn vessel lies above the pelvic fascia. In that event, the hematoma develops above it. In its early stages, the hematoma forms a rounded swelling that projects into the upper portion of the vaginal canal and may almost occlude its lumen. If the bleeding continues, it dissects retroperitoneally, and thus, may form a tumor palpable above the inguinal ligament. Alternatively, it may dissect upward, eventually reaching the lower margin of the diaphragm.

Vulvar Hematomas

These hematomas, such as the one shown in Figure 35-26, and particularly those that develop rapidly, may cause excruciating pain. This often is the first symptom noticed. Moderate-sized hematomas may be absorbed spontaneously. The tissues overlying the hematoma may rupture as a result of pressure necrosis, and profuse hemorrhage may follow. In others, the contents of the hematoma may be discharged in the form of large clots. In the subperitoneal variety, extravasation of blood beneath the peritoneum may be massive and occasionally fatal. Some of these dissect behind the ascending colon up to the hepatic flexure.

Diagnosis. A vulvar hematoma is readily diagnosed by severe perineal pain and usually rapid appearance of a tense, fluctuant, and sensitive swelling of varying size covered by discolored skin. When the mass develops adjacent to the vagina, it may escape detection temporarily. Symptoms of pressure, if not pain or inability to void, should prompt a vaginal examination with discovery of a round, fluctuant mass encroaching on the lumen. When a hematoma extends upward between the folds of the broad ligament, it may escape detection unless a portion of the hematoma can be felt on abdominal palpation or unless hypovolemia develops. These are worrisome because they can be fatal. Sonographic or CT imaging may be helpful to assess the location and extent of these hematomas.

Treatment. Smaller vulvar hematomas identified after leaving the delivery room may be treated expectantly (Propst and Thorp, 1998). But if pain is severe or the hematoma continues

FIGURE 35-26 Right-sided vulvar hematoma associated with a vaginal laceration following spontaneous delivery in a woman with consumptive coagulopathy from fatty liver of pregnancy.

to enlarge, the best treatment is prompt incision and drainage. This is done at the point of maximal distension along with evacuation of blood and clots and ligation of bleeding points. The cavity may then be obliterated with mattress sutures. Often, no sites of bleeding are identified after the hematoma has been drained. In such cases, the cavity is surgically closed, and the vagina is packed for 12 to 24 hours. **With hematomas of the genital tract, blood loss is nearly always considerably more than the clinical estimate.** Hypovolemia and severe anemia should be prevented by adequate blood replacement. Half of women with hematomas requiring surgical repair also require transfusions (Zahn and Yeomans, 1990).

Subperitoneal and supravaginal hematomas are more difficult to treat because of difficult surgical access. Some can be evacuated by vulvar or vaginal incision, but unless there is complete hemostasis, laparotomy is advisable.

Angiographic Embolization. This technique has become popular for management of intractable puerperal hematomas. Embolization can be used primarily or most often when hemostasis is not obtained by surgical methods. It is described further on page 797. Ojala and co-workers (2005) described three women with a vulvovaginal hematoma in which it was used.

Rupture of the Uterus

Uterine rupture may develop as a result of preexisting injury or anomaly, it may be associated with trauma, or it may complicate labor in a previously unscarred uterus. A classification of the etiology of uterine rupture is presented in Table 35-5.

The most common cause of uterine rupture is separation of a previous cesarean hysterotomy scar. With decreasing interest in a trial of labor following a prior cesarean delivery, rupture of an unscarred uterus may now be associated with up to half of cases of uterine rupture (Porrecco and co-workers, 2009). This is discussed in detail in Chapter 26 (p. 573). Other common predisposing factors to uterine rupture are previous traumatizing operations or manipulations such as curettage, perforation, or myomectomy (Kieser and Baskett, 2002; Pelosi and Pelosi, 1997). Excessive or inappropriate uterine stimulation with oxytocin, a previously frequent cause, has become uncommon. Mishra and colleagues (1995) described a 43-year-old woman who suffered a ruptured vertical cesarean incision associated with inhaled crack cocaine that produced tetanic contractions.

Morbidity and Mortality

Prenatal morbidity and mortality rates can be substantive with rupture of a prior uterine incision during labor (see Chap. 26, p. 573). Rachagan and colleagues (1991) reported the fetal mortality rate to be almost 70 percent with either spontaneous or traumatic uterine rupture. In 24 women with uterine rupture principally unassociated with prior incisions, Eden and associates (1986) reported one maternal death and a 46-percent perinatal loss rate. As discussed above, Porrecco and co-workers (2009) reported a 46-percent incidence of perinatal mortality or severe morbidity in 37 women who suffered a uterine rupture with a viable-aged fetus. Hysterectomy may be necessary to control hemorrhage.

Traumatic Rupture

Although the uterus is surprisingly resistant to blunt trauma, pregnant women sustaining such trauma to the abdomen should be watched carefully for signs of a ruptured uterus (see

TABLE 35-5. Classification of Causes of Uterine Rupture

Uterine Injury or Anomaly Sustained before Current Pregnancy	Uterine Injury or Abnormality During Current Pregnancy
Surgery involving the myometrium:	**Before delivery:**
Cesarean delivery or hysterotomy	Persistent, intense, spontaneous contractions
Previously repaired uterine rupture	Labor stimulation—oxytocin or prostaglandins
Myomectomy incision through or to the endometrium	Intra-amnionic instillation—saline or prostaglandins
Deep cornual resection of interstitial oviduct	Perforation by internal uterine pressure catheter
Metroplasty	External trauma—sharp or blunt
Coincidental uterine trauma:	External version
Abortion with instrumentation—curette, sounds	Uterine overdistension—hydramnios, multifetal pregnancy
Sharp or blunt trauma—accidents, bullets, knives	**During delivery:**
Silent rupture in previous pregnancy	Internal version
Congenital anomaly:	Difficult forceps delivery
Pregnancy in undeveloped uterine horn	Rapid tumultuous labor and delivery
	Breech extraction
	Fetal anomaly distending lower segment
	Vigorous uterine pressure during delivery
	Difficult manual removal of placenta
	Acquired:
	Placenta increta or percreta
	Gestational trophoblastic neoplasia
	Adenomyosis
	Sacculation of entrapped retroverted uterus

Chap. 42, p. 938) as well as a placental abruption, described on page 761. Miller and Paul (1996) found that trauma accounted for a ruptured uterus in only 3 of more than 150 women. In the past, internal podalic version and extraction often caused traumatic rupture during delivery. Other causes of traumatic rupture include difficult forceps delivery, unusual fetal enlargement such as hydrocephaly, and breech extraction.

Spontaneous Rupture

In the study by Miller and Paul (1996), the incidence of spontaneous uterine rupture was only approximately 1 in 15,000 deliveries. The investigators also found that spontaneous rupture is more likely in women of high parity (Miller and colleagues, 1997). Oxytocin stimulation of labor has been commonly associated with uterine rupture, especially in women of high parity (Fuchs and coworkers, 1985; Rachagan and associates, 1991). Other uterotonic agents are also implicated. Uterine rupture has resulted from labor induction with prostaglandin E_2 gel or E_1 vaginal tablets (Bennett, 1997; Maymon and associates, 1991). For these reasons, all uterotonic agents should be given with great caution to induce or stimulate labor in women of high parity. Similarly, in women of high parity, a trial of labor with suspected cephalopelvic disproportion, high cephalic presentation, or abnormal presentation, such as a brow, must be undertaken with caution.

Pathological Anatomy

Rupture of the previously intact uterus at the time of labor most often involves the thinned-out lower uterine segment. The rent, when it is in the immediate vicinity of the cervix, frequently extends transversely or obliquely. Usually, the tear is longitudinal when it occurs in the portion of the uterus adjacent to the broad ligament (**Fig. 35-27**). Although developing primarily in the lower uterine segment, it is not unusual for the laceration to extend further upward into the body of the uterus or downward through the cervix into the vagina. At times, the bladder may also be lacerated (Rachagan and colleagues, 1991). After complete rupture, the uterine contents escape into the peritoneal cavity. In cases in which the presenting part is firmly engaged, however, then only a portion of the fetus may be extruded from the uterus. In uterine rupture in which the peritoneum remains intact, hemorrhage frequently extends into the broad ligament. This may result in a large retroperitoneal hematoma and exsanguination.

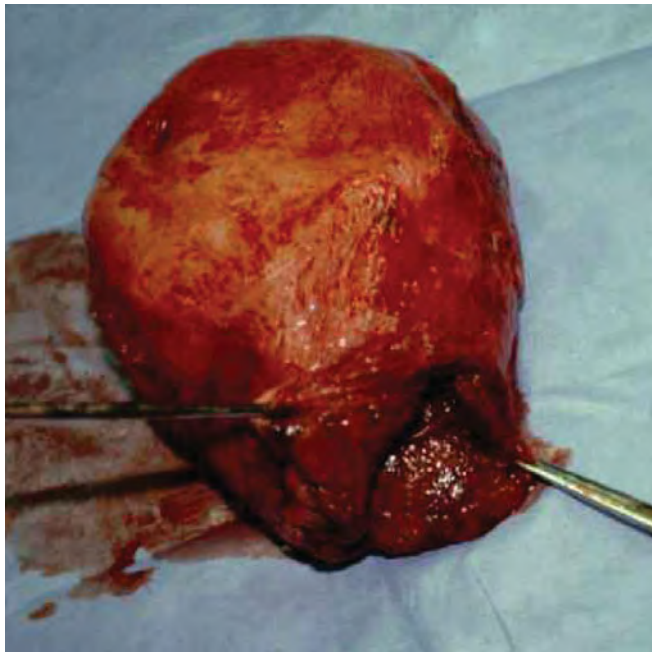

FIGURE 35-27 Spontaneously ruptured uterus at left lateral edge of lower uterine segment.

Clinical Course and Treatment

A discussion of the various clinical presentations of uterine rupture as well as treatment approaches is covered in detail in Chapter 26 (p. 573).

CONSUMPTIVE COAGULOPATHY

In 1901, DeLee reported that "temporary hemophilia" developed in a woman with a placental abruption and in another with a long-dead macerated fetus. Observations that extensive placental abruption and other accidents of pregnancy were frequently associated with hypofibrinogenemia stimulated interest in causes of intense intravascular coagulation. Although these observations were initially almost totally confined to obstetrical cases, subsequently they were made for almost all areas of medicine (Baglin, 1996). These syndromes are commonly termed *consumptive coagulopathy* or *disseminated intravascular coagulation (DIC).*

Pregnancy Hypercoagulability

Pregnancy normally induces appreciable increases in the concentrations of coagulation factors I (fibrinogen), VII, VIII, IX, and X (see Chap. 5, p. 116). Many of these are shown in the Appendix. Other plasma factors and platelets do not change so remarkably. Plasminogen levels are increased considerably, yet plasmin activity antepartum is normally decreased compared with that of nonpregnancy. At the same time, in pregnancy, there does appear to be increased activation of platelet, clotting, and fibrinolytic mechanisms (Baker and associates, 2009). Specifically, there are significant increases in fibrinopeptide A, β-thromboglobulin, platelet factor 4, and fibrinogen-fibrin degradation products. Gerbasi and colleagues (1990) concluded that this compensated, accelerated intravascular coagulation may serve to maintain the uteroplacental interface.

Pathological Activation of Coagulation

In pathological states, an abnormal cycle of coagulation and fibrinolysis may be initiated. Coagulation may be activated via the extrinsic pathway by thromboplastin from tissue destruction and perhaps via the intrinsic pathway by collagen and other tissue components when there is loss of endothelial integrity (**Fig. 35-28**). Tissue factor is released and complexes with factor VII. This in turn activates tenase (factor IX) and prothrombinase (factor X) complexes. As a result, fibrin is deposited in

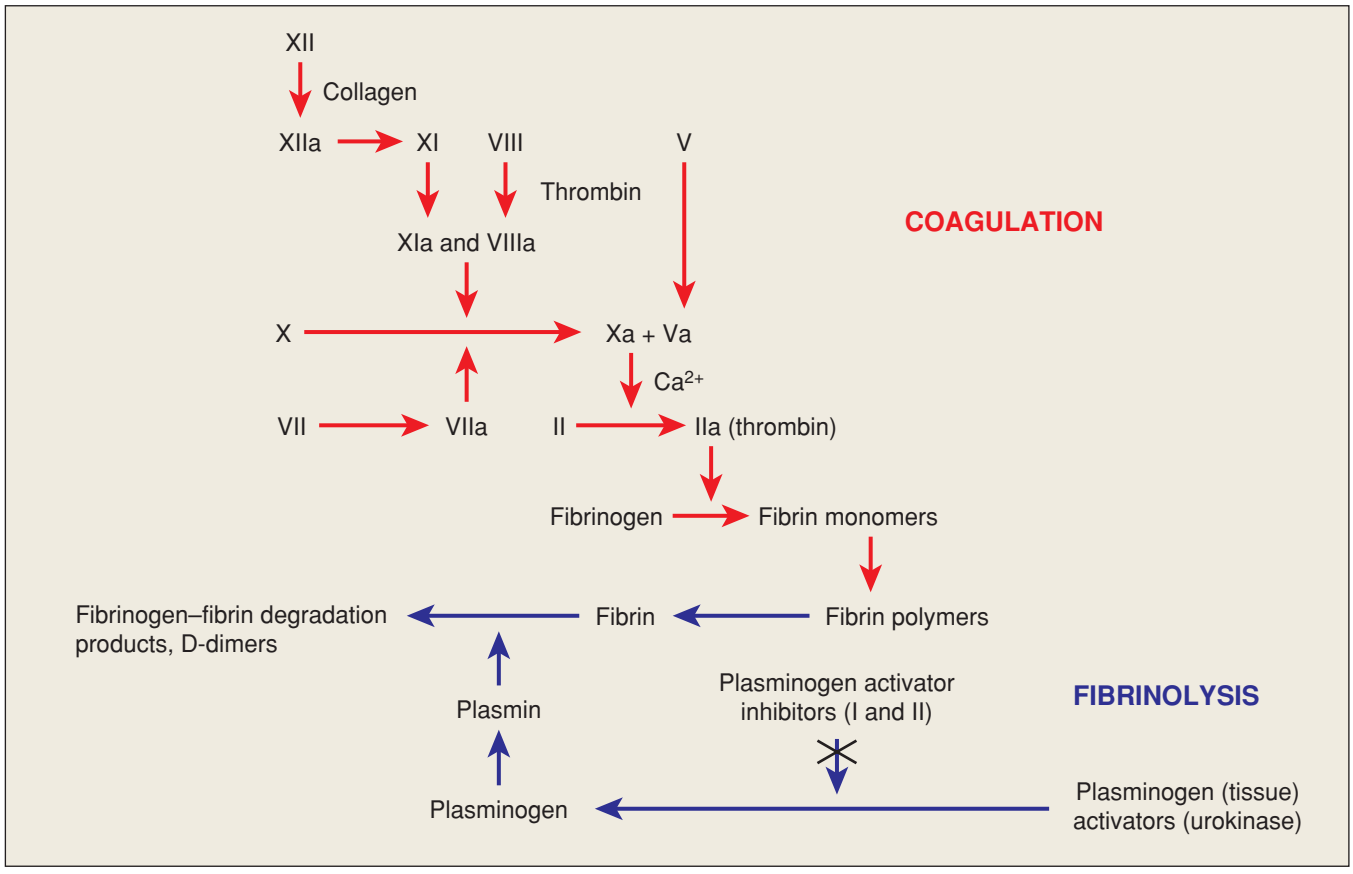

FIGURE 35-28 The coagulation and fibrinolysis cascades.

small vessels of virtually every organ system. However, this seldom causes organ failure. Small vessels are protected because of fibrinolysis. Coagulation releases fibrin monomers. These monomers combine with tissue plasminogen activator and plasminogen, which releases plasmin as shown in Figure 35-28. In turn, plasmin lyses fibrinogen, fibrin monomer, and fibrin polymers to form a series of fibrinogen-fibrin derivatives. Measured by immunoassay, these are known as *fibrin degradation products* or *fibrin split products* that include D-dimers. With this pathological cycle of consumption and fibrinolysis, there is depletion of platelets and coagulation factors in variable quantities. As a consequence, bleeding results.

Common inciting factors for consumptive coagulation in obstetrics include thromboplastin from placental abruption as well as endotoxin and exotoxins. Another mechanism is direct activation of factor X by proteases, for example, as present in mucin or as produced by neoplasms. Amnionic fluid contains abundant mucin from fetal squames, and this likely causes the rapid defibrination found with amnionic fluid embolism. Zhou and associates (2009) have presented evidence that in addition to tissue factor, phosphatidylserine expressed by the amnionic cell membrane is an inciting factor.

Consumptive coagulopathy is almost always seen as a complication of an identifiable, underlying pathological process against which treatment must be directed to reverse defibrination. Thus, identification and prompt elimination of the coagulopathy source is the first priority.

Significance

In addition to bleeding and circulatory obstruction, which may cause ischemia from hypoperfusion, consumptive coagulopathy may be associated with microangiopathic hemolysis. This is caused by mechanical disruption of the erythrocyte membrane within small vessels in which fibrin has been deposited. Varying degrees of hemolysis with anemia, hemoglobinemia, hemoglobinuria, and erythrocyte morphological changes are produced. According to Pritchard and colleagues (1976), this likely causes or contributes to the hemolysis encountered with the so-called *HELLP syndrome—hemolysis, elevated liver enzymes, low platelets* (see Chap. 34, p. 720).

In obstetrical syndromes involving consumptive coagulopathy, the importance of vigorous restoration and maintenance of the circulation to treat hypovolemia and persistent intravascular coagulation cannot be overemphasized. With adequate perfusion of vital organs, activated coagulation factors and circulating fibrin and fibrin degradation products are promptly removed by the reticuloendothelial system. At the same time, hepatic and endothelial synthesis of procoagulants is promoted.

The likelihood of life-threatening hemorrhage in obstetrical situations complicated by defective coagulation depends not only on the extent of the coagulation defects but—of great importance—on whether the vasculature is intact or disrupted. With gross derangement of blood coagulation, there may be fatal hemorrhage when vascular integrity is disrupted, yet no hemorrhage as long as all blood vessels remain intact.

Clinical and Laboratory Evidence of Defective Hemostasis

Bioassay is an excellent method to clinically detect or suspect significant coagulopathy. *Excessive bleeding at sites of modest trauma characterizes defective hemostasis.* Persistent bleeding from venipuncture sites, nicks from shaving the perineum or abdomen, trauma from insertion of a catheter, and spontaneous bleeding from the gums or nose are signs of possible coagulation defects. Purpuric areas at pressure sites such as blood pressure cuffs may indicate incoagulable blood, or more commonly, clinically significant thrombocytopenia. A surgical procedure provides the ultimate bioassay for coagulation. Continuous generalized oozing from the skin, subcutaneous and fascial tissues, the retroperitoneal space, or episiotomy site should at least suggest coagulopathy.

Hypofibrinogenemia

In late pregnancy, plasma fibrinogen levels typically are 300 to 600 mg/dL. With consumptive coagulopathy, these high levels may sometimes serve to protect against clinically significant hypofibrinogenemia. To promote clinical coagulation, fibrinogen levels must be approximately 150 mg/dL. If serious *hypofibrinogenemia* is present, the clot formed from whole blood in a glass tube may initially be soft but not necessarily remarkably reduced in volume. Then, over the next half hour or so, as platelet-induced clot retraction develops, it becomes quite small, so that many of the erythrocytes are extruded, and the volume of liquid clearly exceeds that of clot.

Fibrin and Fibrinogen Derivatives

Serum fibrin degradation products may be detected by a number of sensitive test systems. Monoclonal antibodies to detect D-dimers are commonly used. With clinically significant consumption coagulopathy, these measurements are always abnormally high.

Thrombocytopenia

Serious thrombocytopenia is likely if petechiae are abundant, if clotted blood fails to retract over a period of an hour or so, or if platelets are rare in a stained blood smear. Confirmation is provided by platelet count. With severe preeclampsia and eclampsia, there may also be *qualitative platelet dysfunction* (see Chap. 34, p. 717).

Prothrombin and Partial Thromboplastin Times

Prolongation of these standard coagulation tests may result from appreciable reductions in those coagulants essential for generating thrombin, from fibrinogen concentrations below a critical level—approximately 100 mg/dL, or from appreciable amounts of circulating fibrinogen-fibrin degradation products. Prolongation of the prothrombin time and partial thromboplastin time need not be the consequence of consumptive coagulopathy.

Coagulation- and Fibrinolysis-Directed Agents

Heparin

The infusion of heparin to try to block disseminated intravascular coagulation associated with placental abruption or other situations in which the integrity of the vascular system is compromised is mentioned only to condemn its use.

Epsilon-Aminocaproic Acid

This agent has been administered in an attempt to control fibrinolysis by inhibiting the conversion of plasminogen to plasmin. Epsilon-aminocaproic acid inhibits the proteolytic action of plasmin on fibrinogen, fibrin monomer, and fibrin polymer (clot). Failure to clear fibrin polymer from the microcirculation could result in organ ischemia and infarction, such as renal cortical necrosis. Its use in most types of obstetrical coagulopathy has not been efficacious and is not recommended.

Placental Abruption

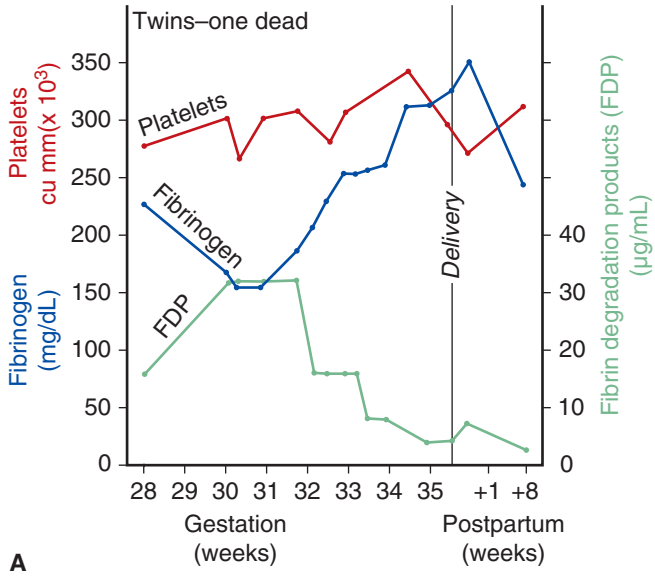
This is the most common cause of severe consumptive coagulopathy in obstetrics and is discussed on page 761.

Fetal Death and Delayed Delivery

In the past, in most women with fetal death, spontaneous labor eventually ensued, most often within 2 weeks. Studies indicated that gross disruption of the maternal coagulation mechanism rarely developed within 1 month after fetal death (Pritchard, 1959, 1973). If the fetus was retained longer, however, approximately 25 percent of the women developed a coagulopathy. Today, because of certainty with which fetal death can be confirmed with sonography and because highly effective methods are available to induce labor, coagulopathy from a retained dead fetus is unusual.

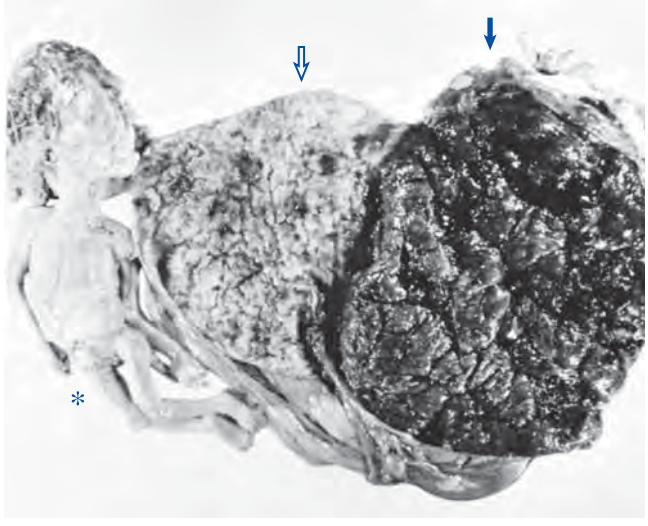
Coagulopathy

The fibrinogen concentration typically falls over 6 weeks or more to levels that are normal for the nonpregnant state—and in some cases, it falls to critical concentrations of 100 mg/dL or less. Simultaneously, fibrin degradation product levels become elevated in serum (Pritchard, 1973). These changes are presumably mediated by thromboplastin from the dead products of conception (Jimenez and Pritchard, 1968; Lerner and associates, 1967). The platelet count tends to decrease in these instances, but severe thrombocytopenia is uncommon even if the fibrinogen level is quite low. Although coagulation defects may correct spontaneously before evacuation, this is unusual and happens slowly (Pritchard, 1959).



Heparin

Correction of coagulation defects in this circumstance has been accomplished using low doses of heparin—5000 U, two to three times daily—under carefully controlled conditions *in women with an intact circulation* (Pacheco and colleagues, 2004). Heparin appropriately administered can block further pathological consumption of fibrinogen and other clotting factors, thereby slowing or temporarily reversing the cycle of consumption and fibrinolysis. Such correction should be undertaken only if the patient is not actively bleeding and with simultaneous steps to effect delivery.



Fetal Death in Multifetal Pregnancy

It is uncommon that an obvious coagulation derangement develops in a multifetal pregnancy complicated by the death of at least one fetus and survival of another (Landy and Weingold, 1989). Petersen and Nyholm (1999) followed 22 women with a multifetal pregnancy with one fetal death after the first trimester and did not detect a coagulopathy in any of these cases.

Chescheir and Seeds (1988) reported a woman in whom, following the death of one twin fetus, there was a progressive but transient fall in the plasma fibrinogen concentration and rise in the level of fibrin degradation products. Most cases are seen in monochorionic twins with vascular anastomoses (see Chap. 39, p. 878). We have encountered a few such cases at Parkland Hospital, and one is shown in **Figure 35-29**. Coagulation changes ceased spontaneously, and the surviving fetus, when delivered near term, was healthy. The placenta of the long-dead fetus was filled with fibrin.

A

B

FIGURE 35-29 A. Death of one twin was confirmed sonographically at 28 weeks' gestation. Serial studies then demonstrated decreasing plasma fibrinogen concentration and abnormally elevated serum fibrin degradation products that reached a nadir 4 weeks later. After this, spontaneously, the fibrinogen concentration rose, and the fibrin degradation product levels fell in mirror-like fashion. When delivered at 36 weeks, the liveborn co-twin was healthy and had normal coagulation studies and normal appearing placenta (*blue arrow*). **B.** The fibrin-filled placenta of the long-dead fetus is apparent (*clear arrow*). Presumably, the fibrin curtailed the escape of thromboplastin from the dead products into the maternal circulation. FDP = fibrin degradation products.

Amnionic Fluid Embolism

This is a complex disorder classically characterized by the abrupt onset of hypotension, hypoxia, and consumptive coagulopathy. There is great individual variation in its clinical manifestation. Thus, women are encountered in whom one of these three clinical hallmarks dominates or is entirely absent. Although uncommon in an absolute sense, amnionic fluid embolism was implicated as the cause of death in 9 percent of the 3201 pregnancy-related maternal deaths ascertained by the Centers for Disease Control and Prevention from 1991 through 1997 (Berg and colleagues, 2003). Similarly, Clark and associates (2008) reported that 14 percent of 95 maternal deaths in a 1.46-million delivery database were due to amnionic fluid embolism.

Using data from 3 million deliveries in the United States from 1999 and 2003, Abenhaim and colleagues (2008) estimated a frequency of approximately 7.7 cases per 100,000 births. Risk factors included advanced maternal age, minority race, placenta previa, preeclampsia, and forceps or cesarean delivery. The case-fatality rate was 22 percent.

In obvious cases, the clinical picture is dramatic. Classically, a woman in the late stages of labor or immediately postpartum begins gasping for air, and then rapidly suffers seizure or cardiorespiratory arrest complicated by consumptive coagulopathy, massive hemorrhage, and death. These are unquestionably the most dramatic cases. But there appears to be variation in the clinical presentation of this condition. For example, we have managed a number of women in whom otherwise uncomplicated vaginal delivery was followed by severe acute consumptive coagulopathy without cardiorespiratory symptoms. Thus, in some women, consumptive coagulopathy appears to be the *forme fruste* of amnionic fluid embolism (Awad and Shorten, 2001; Davies, 1999; Porter and colleagues, 1996). Other features common to amnionic fluid embolism are meconium staining and rapid labor.

Pathogenesis

Amnionic fluid embolism was originally described in 1941 by Steiner and Lushbaugh. Subsequent studies by Adamsons and associates (1971) and Stolte and co-workers (1967) demonstrated that amnionic fluid is innocuous, even when infused in large amounts.

Amnionic fluid enters the circulation as a result of a breach in the physiological barrier that normally exists between maternal and fetal compartments. Such events appear to be common, if not universal, with both squames of presumed fetal origin and trophoblasts being commonly found in the maternal circulation (Clark and colleagues, 1986; Lee and co-workers, 1986). There may be maternal exposure to various fetal elements during pregnancy termination, following amniocentesis or trauma, or more

TABLE 35-6. Clinical Findings in 84 Women with Amnionic Fluid Embolism

Clinical Findings	Clark et al (1995) (n = 46)	Weiwen (2000) (n = 38)
Hypotension	43	38
Fetal distress	30/30	NS
Pulmonary edema or ARDS	28/30	11
Cardiopulmonary arrest	40	38
Cyanosis	38	38
Coagulopathy	38	12/16
Dyspnea	22/45	38
Seizure	22	6

ARDS = acute respiratory distress syndrome; NS = not stated.

commonly during labor or delivery as small lacerations develop in the lower uterine segment or cervix. Alternatively, cesarean delivery affords ample opportunity for mixture of maternal blood and fetal tissue.

In most cases, these events are innocuous. In certain women, however, such exposure initiates a complex series of physiological reactions that are listed in Table 35-6. A similar process has been shown for traumatic fat embolism (Peltier, 1984). A complete understanding of the precise pathophysiological cascade remains elusive. In a case-controlled study of nine women with presumed amnionic fluid embolism, Benson and associates (2001) found that levels of some indicators of anaphylaxis—serum tryptase and urinary histamine—were increased in some of the women, yet none had evidence of mast cell degranulation. Of note, complement levels were decreased uniformly, suggesting that complement activation may play an important role. Because such activation also occurs in seriously ill patients with acute respiratory distress syndrome, however, it is not known whether complement activation is a primary or secondary result of amnionic fluid embolism. A number of chemokines and cytokines likely are also important in the pathogenesis. For example, Khong (1998) found intense expression of endothelin-1 in fetal squames recovered from the lungs of two fatal cases.

Pathophysiology

Studies in primates using homologous amnionic fluid injection, as well as a carefully performed study in the goat model, have provided important insights into central hemodynamic aberrations (Adamsons and co-workers, 1971; Hankins and colleagues, 1993; Stolte and colleagues, 1967). The initial phase consists of pulmonary and systemic hypertension. Indeed, in a remarkable case report, Stanten and associates (2003) described the results of a transesophageal echocardiogram performed within 10 minutes of circulatory collapse related to amnionic fluid embolism. The findings included a massively dilated akinetic right ventricle and a small, vigorously contracting, cavity-obliterated left ventricle. These were all consistent with failure to transfer blood from the right to the left heart because of catastrophic pulmonary vasoconstriction. Transient but profound oxygen desaturation is often seen in the initial phase, resulting in neurological injury in most survivors (Harvey and associates, 1996).

Decreased systemic vascular resistance and left ventricular stroke work index occur following this initial phase (Clark and colleagues, 1988). In women who live beyond the initial cardiovascular collapse, a secondary phase of lung injury and coagulopathy often ensues.

The association of uterine hypertonus with cardiovascular collapse appears to be the effect of amnionic fluid embolism rather than the cause (Clark and co-workers, 1995). Indeed, uterine blood flow ceases completely when intrauterine pressures exceed 35 to 40 mm Hg (Towell, 1976). Thus, a hypertonic contraction is the *least* likely time for fetal–maternal exchange to take place. Similarly, there is no causal association between oxytocin use and amnionic fluid embolism (American College of Obstetricians and Gynecologists, 1993).

Diagnosis

In the past, the detection of squamous cells or other debris of fetal origin in the central pulmonary circulation was believed to be pathognomonic for amnionic fluid embolism. Indeed, in fatal cases, histopathological findings may be dramatic, especially in those involving meconium-stained amnionic fluid (Fig. 35-30). The detection of such debris, however, may require extensive special staining, and even then it is often not seen. For example, Hankins and colleagues (2002) injected raw amnionic fluid into eight goats. Using special staining, there was microscopic evidence of pulmonary embolization in only 25 percent. Interestingly, of seven other animals who were injected with fluid stained with *meconium*, all had histopathological evidence of embolization.

In a study by Clark and associates (1995), fetal elements were detected in 75 percent of autopsies and in 50 percent of specimens prepared from concentrated buffy coat aspirates taken antemortem from a pulmonary artery catheter. Further, several studies have demonstrated that squamous cells, trophoblasts, and other debris of fetal origin may commonly be found in the central circulation of women with conditions other than amnionic fluid embolism. Thus, this finding is neither sensitive nor specific, and the diagnosis is generally made by identifying clinically characteristic signs and symptoms. In

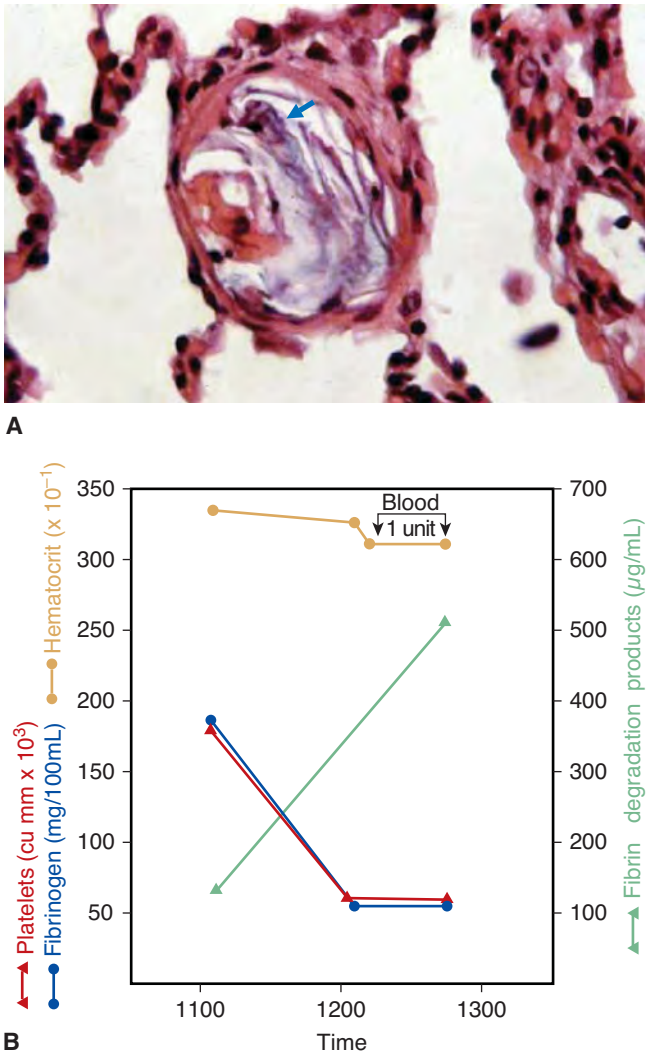


FIGURE 35-30 Fatal amnionic fluid embolism. **A.** Fetal squames (*arrow*) packed into a small pulmonary artery. Most of the empty spaces within the vessel were demonstrated by special lipid stains to be filled with vernix caseosa. **B.** Acute and rapid defibrination in the same woman showing levels of fibrinogen, fibrinogen–fibrin degradation products, and platelets.

less typical cases, diagnosis is contingent on careful exclusion of other causes.

Management

Although an initial period of systemic and pulmonary hypertension appears to be involved in amnionic fluid embolism, this phase is transient. Women who survive long enough to receive any treatment other than cardiopulmonary resuscitation should receive therapy directed at oxygenation and support of the failing myocardium. Circulatory support and blood and component replacement are paramount. *There are no data that any type of intervention improves maternal prognosis with amnionic fluid embolism.* In undelivered women suffering cardiac arrest, consideration should be given to emergency perimortem cesarean delivery in an effort to improve newborn outcome. Such decision making is more complex in a woman who is hemodynamically unstable, but who has not suffered cardiac arrest (see Chap. 42, p. 942).

Prognosis

The dismal outcomes with amnionic fluid embolism are undoubtedly related to reporting biases. Also, the syndrome likely is underdiagnosed in all but the most severe cases. In the report by Clark and co-workers (1995), there was a 60-percent maternal mortality rate. In the California database of 1.1 million deliveries by Gilbert and Danielsen (1999), only 25 percent of reported cases were fatal. Weiwen (2000) has provided preliminary data from 38 cases in the Suzhou region of China, and almost 90 percent of these women died. Death can be amazingly rapid, and of the 34 women who died in the series from China, 12 died within 30 minutes.

Profound neurological impairment is common in survivors. *In the cases reported by Clark and colleagues (1995), only 8 percent of women who had a cardiac arrest in conjunction with initial symptoms survived neurologically intact.* Outcome is also poor for fetuses and is related to the cardiac arrest-to-delivery interval. Overall, the neonatal survival rate is 70 percent, but almost half suffer residual neurological impairment.

Sepsis Syndrome

Infections that lead to bacteremia and septic shock in obstetrics are most commonly due to septic abortion, antepartum pyelonephritis, or puerperal sepsis. Other aspects of sepsis syndrome and septic shock are discussed in Chapter 42 (p. 932).

Abortion

Remarkable blood loss may occur as the consequence of abortion. Hemorrhage during early pregnancy is less likely to be severe unless abortion was induced and the procedure was traumatic. When pregnancy is more advanced, the mechanisms responsible for hemorrhage are most often the same as those described for placental abruption and placenta previa—that is, the disruption of a large number of maternal blood vessels at the site of placental implantation.

Coagulopathy

Serious disruption of the coagulation mechanism as the consequence of abortion may develop in the following circumstances:

- Prolonged retention of a dead fetus
- Sepsis syndrome—a notorious cause
- Labor induction with a prostaglandin
- Instrumented termination of the pregnancy
- Intrauterine instillation of hypertonic saline or urea solutions

The kinds of changes in coagulation that have been identified with abortion induced with *hypertonic solutions* imply at least that thromboplastin is released from placenta, fetus, decidua, or all three by the necrobiotic effect of the hypertonic solutions, which then initiates coagulopathy within the maternal circulation (Burkman and associates, 1977). Coagulation defects have been observed to develop rarely during induction of abortion with prostaglandin. Saraiya and colleagues (1999) reviewed 62 spontaneous abortion–related deaths reported to the Pregnancy Mortality Surveillance System. Almost 60 percent of

the deaths were caused by infection, and half of these women had consumptive coagulopathy.

Consumptive coagulopathy has been an uncommon but serious complication among women with *septic abortion*. The incidence of coagulation defects in the past at Parkland Hospital was highest in those with *Clostridium perfringens* sepsis and intense intravascular hemolysis (Pritchard and Whalley, 1971). Management consists of prompt restoration and maintenance of the circulation, and appropriate steps to control the infection, including evacuation of the infected products (see Chap. 9, p. 222).

MANAGEMENT OF HEMORRHAGE

Hypovolemic Shock

Shock from hemorrhage evolves through several stages. Early in the course of massive bleeding, there are decreases in mean arterial pressure, stroke volume, cardiac output, central venous pressure, and pulmonary capillary wedge pressure. Increases in arteriovenous oxygen content difference reflect a relative increase in tissue oxygen extraction, although overall oxygen consumption falls.

Blood flow to capillary beds in various organs is controlled by arterioles, which are resistance vessels that in turn are partially controlled by the central nervous system. At least 70 percent of total blood volume is contained in venules, which are passive resistance vessels controlled by humoral factors. Catecholamine release during hemorrhage causes a generalized increase in venular tone, resulting in an autotransfusion from this capacitance reservoir (Barber and colleagues, 1999). These changes are accompanied by compensatory increases in heart rate, systemic and pulmonary vascular resistance, and myocardial contractility. In addition, there is redistribution of cardiac output and blood volume by selective, centrally mediated arteriolar constriction. This results in diminished perfusion to the kidneys, splanchnic beds, skin, and uterus, but relative maintenance of blood flow to the heart, brain, adrenal glands, and organs that autoregulate their own flow.

As the blood volume deficit exceeds 25 percent, compensatory mechanisms usually are inadequate to maintain cardiac output and blood pressure. At this point, additional small losses of blood result in rapid clinical deterioration. Despite an initial increase in *total oxygen extraction* by maternal tissue, maldistribution of blood flow results in *local* tissue hypoxia and metabolic acidosis, producing a vicious cycle of vasoconstriction, organ ischemia, and cellular death. Hemorrhage also activates lymphocytes and monocytes, which in turn cause endothelial cell activation. As with sepsis syndrome, these events lead to loss of capillary membrane integrity and additional loss of intravascular volume. There is also increased platelet aggregation in hypovolemic shock, resulting in the release of a number of vasoactive mediators that cause small vessel occlusion and further impairment of microcirculatory perfusion.

Often overlooked is the importance of extracellular fluid and electrolyte shifts in both the pathophysiology and successful treatment of hypovolemic shock. This involves changes in the cellular transport of various ions, in which sodium and water enter skeletal muscles and cellular potassium is lost to the extracellular fluid. Replacement of extracellular fluid is thus an important component of therapy in hypovolemic shock. *Survival is reduced in acute hemorrhagic shock when blood alone, compared with blood and lactated Ringer solution, is administered.*

Estimation of Blood Loss

Visual inspection is notoriously inaccurate, and clinical estimates can average half the measured loss. Importantly, in obstetrics, part or all of the hemorrhage may be concealed. It is important to realize that in a situation of acute hemorrhage, the immediate hematocrit may not reflect actual blood loss. After the loss of 1000 mL, the hematocrit typically falls only 3 volume percent in the first hour. When resuscitation is given with rapid infusion of intravenous crystalloids, there is prompt equilibration. **During an episode of acute significant hemorrhage, the initial hematocrit is always the highest.** This is true whether it is measured in the delivery room, operating room, or recovery room.

Urine output is one of the most important "vital signs" to follow in the woman with obstetrical hemorrhage. *Renal blood flow is especially sensitive to changes in blood volume. Thus, in the absence of diuretics, the rate of urine formation, when carefully measured, reflects the adequacy of renal perfusion and in turn, the perfusion of other vital organs.* Urine flow of at least 30 mL, and preferably 60 mL per hour, should be maintained. With potentially serious hemorrhage, an indwelling bladder catheter should be inserted promptly to measure urine flow. Potent diuretics such as furosemide invalidate the relationship between urine flow and renal perfusion. This need not be a problem in the management of the woman who is hemorrhaging, because diuretics should be avoided in a hypovolemic patient. Another effect of furosemide is venodilation, which further reduces cardiac venous return, thereby further compromising cardiac output.

Resuscitation and Acute Management

Whenever there is any suggestion of excessive blood loss after delivery, it is essential to immediately identify uterine atony, retained placental fragments, or genital tract lacerations. It is imperative that at least one or two intravenous infusion systems of large caliber be established promptly to allow rapid administration of crystalloid solutions and blood. An operating room, surgical team, and anesthesiologist should always be immediately available. Specific causes of postpartum hemorrhage are managed as discussed earlier in this chapter.

Fluid Replacement

Treatment of serious hemorrhage demands prompt and adequate refilling of the intravascular compartment. Crystalloid solutions typically are used for initial volume resuscitation. Such solutions rapidly equilibrate into the extravascular space and only 20 percent of crystalloid remains in the circulation of critically ill patients after 1 hour (Shoemaker and Kram, 1991). Because of such equilibration, initial fluid infusion should involve about three times as much crystalloid as the estimated blood loss.

There is debate concerning fluid resuscitation of hypovolemic shock with colloid versus crystalloid solutions. Perel and Roberts (2007) performed a Cochrane review for resuscitation

of nonpregnant critically ill patients. They found equivalent benefits but concluded that colloid solutions were more expensive. The Saline versus Albumin Fluid Evaluation (SAFE) trial of almost 7000 randomized nonpregnant patients reported similar results (Finfer and co-workers, 2004). Because of this, we concur with Bonnar (2000) that fluid resuscitation should be with crystalloid and blood.

Blood Replacement

Considerable debate also surrounds the hematocrit level or hemoglobin concentration that mandates blood transfusion. According to deliberations of a Consensus Development Conference (1988), cardiac output does not substantively decrease until the hemoglobin concentration falls to approximately 7 g/dL or hematocrit of 20 volumes percent. Although the committee reported that otherwise healthy anesthetized animals survived isovolemic anemia with hematocrit decreases to 5 volumes percent, they further cited that there was significant functional deterioration well before that point. It is difficult to define a universal hematocrit or hemoglobin value below or above which transfusion is either mandatory or contraindicated. That said, recommendations of the Consensus Conference should be considered in clinical decision making. According to these guidelines, red blood cells are not infused for moderate anemia in stable women.

For the woman acutely bleeding, we recommend rapid blood infusion if the hematocrit is less than 25 volumes percent. This decision is obviously dependent on whether there is imminent surgery, acute operative blood loss, acute hypoxia, vascular collapse, or other factors present. In Iraq, U.S. Military Combat Trauma Units aim for a hematocrit of 21 volumes percent (Barbieri, 2007).

Hebert and associates (1999) reported results from the Canadian Critical Care Trials Group. A total of 838 critically ill nonpregnant patients were randomly assigned to restrictive red cell transfusions to maintain hemoglobin concentration above 7 g/dL or to liberal transfusions to maintain the hemoglobin 10 to 12 g/dL. The 30-day mortality rate was similar—19 versus 23 percent in the restrictive versus liberal groups, respectively. In patients who were not as ill—defined by Acute Physiology and Chronic Health Evaluation (APACHE) scores of 20 or less—the 30-day mortality rate was significantly lower in the restrictive group—9 versus 26 percent. Morrison and colleagues (1991) reported no benefits of red cell transfusions given to women who had suffered postpartum hemorrhage and who were *isovolemic but anemic* with a hematocrit between 18 and 25 volumes percent. *Clearly, the level to which a woman is transfused depends not only on the present red cell mass, but also on the likelihood of additional blood loss.*

Whole Blood and Blood Components

Contents and effects of transfusion of various blood components are shown in Table 35-7. *Compatible whole blood is ideal for treatment of hypovolemia from catastrophic acute hemorrhage.* It has a shelf life of 40 days, and 70 percent of the transfused red cells function for at least 24 hours following transfusion. One unit raises the hematocrit by 3 to 4 volume percent. Whole blood replaces many coagulation factors, especially fibrinogen, and its plasma expands hypovolemia. Importantly, women with severe hemorrhage are resuscitated with fewer blood donor exposures than with packed red cells and components. For example, after their review, Shaz and co-workers (2009) recommended that plasma, platelets, and red cells be given in a 1:1:1 ratio for trauma patients undergoing massive transfusions. Drawbacks of such a scheme are exposure to many more donors. In a randomized study of 33 nonpregnant patients undergoing liver transplantation, Laine and colleagues (2003) found that whole blood, compared with component therapy, was associated with fewer donor exposures yet provided equally

TABLE 35-7. Blood Products Commonly Transfused in Obstetrical Hemorrhage

Product	Volume per Unit	Contents per Unit	Effect(s) in Obstetrical Hemorrhage
Whole blood	About 500 mL; Hct ~ 40 percent	RBCs, plasma, 600–700 mg of fibrinogen, no platelets	Restores blood volume and fibrinogen, increases Hct 3–4 volume percent per unit
Packed RBCs ("packed cells")	About 250 mL plus additive solutions; Hct ~ 55–80 percent	RBCs only, no fibrinogen, no platelets	Increases Hct 3–4 volume percent per unit
Fresh-frozen plasma (FFP)	About 250 mL; 30-minute thaw needed before use	Colloid plus 600–700 mg fibrinogen, no platelets	Restores circulating volume and fibrinogen
Cryoprecipitate	About 15 mL, frozen	About 200 mg fibrinogen plus other clotting factors, no platelets	About 3000–4000 mg total is needed to restore fibrinogen to > 150 mg/dL
Platelets	About 50 mL, stored at room temperature	One unit raises platelet count about 5000/μL (single-donor apheresis "6-pack" is preferable)	6–10 units usually transfused (single-donor 6-pack preferable)

Hct = hematocrit; RBCs = red blood cells.
Modified from Leveno and colleagues (2003).

effective therapy for blood loss. Freshly donated whole blood has also been used for casualties with life-threatening massive hemorrhage at combat support hospitals in Iraq (Spinella and co-workers, 2008).

Our experiences at Parkland Hospital also favor whole blood for massive hemorrhage. In a recent audit of more than 66,000 women delivered at Parkland Hospital, Alexander and associates (2009) reported significantly decreased incidences of renal failure, adult respiratory distress syndrome, pulmonary edema, hypofibrinogenemia, admission to an intensive care unit, and maternal death when whole blood transfusions were compared with packed red cell transfusions or combinations of blood products.

For women who are more stable and do not have massive blood loss, packed red blood cell transfusions are suitable. According to the National Institutes of Health (1993), component therapy provides better treatment because only the specific component needed is given. Accordingly, the infusion of whole banked blood is usually not necessary and is rarely available.

Dilutional Coagulopathy

When blood loss is massive, replacement with crystalloid solutions and packed red blood cells usually results in a relative depletion of platelets and soluble clotting factors. This leads to a dilutional coagulopathy that clinically is indistinguishable from disseminated intravascular coagulopathy (see p. 785). Such dilution impairs hemostasis and further contributes to blood loss.

The most frequent coagulation defect found in women with blood loss and multiple transfusions is thrombocytopenia (Counts and colleagues, 1979). Stored whole blood is deficient in platelets and in factors V, VIII, and XI. Moreover, all soluble clotting factors are absent from packed red blood cells. Thus, severe hemorrhage without factor replacement may also cause hypofibrinogenemia and prolongation of the prothrombin and partial thromboplastin times. In some women, frank consumptive coagulopathy may accompany shock and confuse the distinction between dilutional and consumptive coagulopathy. Fortunately, in most situations encountered in obstetrics, treatment of both types of coagulopathy is the same.

The impact of massive transfusion with resultant coagulopathy has been studied recently by both civilian trauma groups and military combat hospitals (Bochicchio, 2008; Borgman, 2007; Gonzalez, 2007; Johansson, 2007, and all their co-workers). Patients undergoing massive transfusion—defined as 10 or more units of blood—had much higher survival rates as the ratio of plasma:red cell units was closer to 1:1.4, that is, one unit of plasma for each unit of packed red cells. The highest mortality group had a 1:8 ratio. *Component replacement is rarely necessary with acute replacement of 5 to 10 units of packed red blood cells or less.* When blood loss exceeds this amount, consideration should be given to evaluation of platelet count, clotting studies, and plasma fibrinogen concentration.

In the woman with obstetrical hemorrhage, the platelet count should be maintained above 50,000/μL with the infusion of platelet concentrates. A fibrinogen level of less than 100 mg/dL or sufficiently prolonged prothrombin or partial thromboplastin times in a woman with surgical bleeding is an indication for fresh-frozen plasma administration in doses of 10 to 15 mL/kg.

Type and Screen versus Crossmatch

In any woman at significant risk for hemorrhage, typing and screening or crossmatching is essential. The screening procedure involves mixing the maternal serum with standard reagent red cells that carry the antigens with which most of the common clinically significant antibodies react. A crossmatch, on the other hand, involves the use of actual donor erythrocytes rather than standard red cells.

Only 0.03 to 0.07 percent of patients who are determined not to have antibodies in a type-and-screen procedure subsequently have antibodies as determined by crossmatch (Boral and colleagues, 1979). Thus, administration of screened blood rarely results in adverse clinical sequelae. Not performing a crossmatch also decreases blood bank costs. Moreover, blood that is crossmatched is held exclusively for that single potential recipient. With type-and-screening, blood is available for any potential recipient and blood wastage is reduced. For all of these reasons, type and screen is preferred in most obstetrical situations.

Packed Red Blood Cells

Cells packed from a unit of whole blood have a hematocrit of 55 to 80 volumes percent, depending on the method used for preparation and storage. A unit of packed red blood cells contains the same volume of erythrocytes as whole blood and also raises the hematocrit by 3 to 4 volumes percent. Packed red blood cell and crystalloid infusion are the mainstays of transfusion therapy for most cases of obstetrical hemorrhage.

Platelets

When needed, it is preferable to transfuse platelets obtained by apheresis from one donor. In this scheme, the equivalent of platelets from six individual donors is given as a one-unit one-donor transfusion. Such units generally cannot be stored more than 5 days.

If single-donor platelets are not available, random donor platelet packs are used. These are prepared from individual units of whole blood by centrifugation, and then resuspended in 50 to 70 mL of plasma. One unit of random donor platelets contains about 5.5×10^{10} platelets, and 6 to 10 such units are generally transfused. Each unit transfused should raise the platelet count by 5000/μL (National Institutes of Health, 1993). The donor plasma must be compatible with recipient erythrocytes. Further, because some red blood cells are invariably transfused along with the platelets, only platelets from D-negative donors should be given to D-negative recipients. Even so, Lin and colleagues (2002) found that transfusion of ABO-nonidentical platelets in nonpregnant patients undergoing cardiovascular surgery was not associated with adverse effects. Platelet transfusion is considered in a bleeding patient with a platelet count below 50,000/μL. In the *nonsurgical patient*, bleeding is rarely encountered if the platelet count exceeds 5000 to 10,000/μL (Sachs, 1991).

Fresh-Frozen Plasma

This component is prepared by separating plasma from whole blood and then freezing it. Approximately 30 minutes are required for the frozen plasma to thaw. It is a source of all stable

and labile clotting factors, including fibrinogen. Thus, it is often used in the acute treatment of women with consumptive or dilutional coagulopathy as discussed previously. Fresh-frozen plasma is not appropriate for use as a volume expander in the absence of specific clotting factor deficiency. It should be considered in a bleeding woman with a fibrinogen level below 100 mg/dL or with abnormal prothrombin and partial thromboplastin times.

Cryoprecipitate

This component is prepared from fresh-frozen plasma. Cryoprecipitate is composed of factor VIII:C, factor VIII:von Willebrand factor, 200 mg of fibrinogen, factor XIII, and fibronectin, all combined in less than 15 mL of the plasma from which it was derived (American Association of Blood Banks, 1994). Cryoprecipitate is an ideal source of fibrinogen if levels are dangerously low and there is oozing from surgical incisions. There is no advantage to the use of cryoprecipitate for general clotting factor replacement in the bleeding woman instead of fresh-frozen plasma. The exception to this is in states of general factor deficiency where potential volume overload is a problem, and in a few conditions involving deficiency of specific factors.

Recombinant Activated Factor VII

This synthetic vitamin K-dependent protein was approved by the Food and Drug Administration (FDA) principally for treatment of bleeding in individuals with hemophilia. Recombinant activated factor VII—*rFVIIa* or *NovoSeven*—acts by binding to exposed tissue factor at the site of tissue and vascular injury. Thrombin so generated activates platelets and the coagulation cascade. Over the past 10 years, rFVIIa has been used successfully to help control hemorrhage from surgery, trauma, and other causes (Mannucci and Levi, 2007). A number of reports of successful treatment for obstetrical hemorrhage in women with hemophilia have accrued.

Recombinant FVIIa has also been used to control severe obstetrical hemorrhage in women *without* hemophilia who have severe hemorrhage from complications of pregnancy. In their review of 65 published cases, Franchini and associates (2007) reported that two thirds of women underwent cesarean delivery, and in a third of treated women, postpartum atony was the cause of bleeding. Overall, half of all 65 women also underwent hysterectomy. Alfirevic and co-workers (2007) described 113 women with postpartum hemorrhage treated with rFVIIa and reported to the Northern European Registry. Over half had uterine atony, a third lacerations, and a fourth had placenta previa or abruption. Almost 35 percent underwent hysterectomy and 10 percent had uterine artery embolization. Bleeding was diminished or arrested in over 80 percent with no complications due to rFVIIa. Lewis and co-workers (2009) caution that rFVIIa administration will not be effective if plasma fibrinogen is depleted and levels are around 50 mg/dL or less.

The specter of thrombosis with rFVIIa use is of concern (Mannucci and Levi, 2007). In a review of the FDA adverse event reporting system by O'Connell and associates (2006), there were 185 thrombotic events in 168 nonpregnant patients, and most were with off-label use of rFVIIa, mainly for hemorrhage. These events may affect as many as 7 percent of treated patients, but appear so far to be uncommon in obstetrical patients.

Autotransfusion

There are no convincing data that intraoperative blood salvage and autotransfusion is safe in obstetrical patients. A few small studies have uncovered no obvious problems (Rainaldi and colleagues, 1998). In their contemporaneous review, Allam and associates (2008) document the lack of prospective trials, but found no serious reported complications.

Autologous Transfusion

Under some circumstances, autologous blood storage for transfusion may be considered. In general, however, this has been disappointing. For example, McVay and colleagues (1989) reported observations from 273 pregnant women in whom blood was drawn in the third trimester. Minimal requirements were a hemoglobin concentration 11 g/dL or a hematocrit of 34 volumes percent. Unfortunately, almost three fourths of these women donated only one unit, a volume of questionable value.

In many cases, the need for transfusion cannot be predicted. Sherman and colleagues (1992) studied 27 women given two or more transfusions in more than 16,000 deliveries. In only 40 percent was an antepartum risk factor identified. Similar findings were reported by Reyal and associates (2004). Andres and co-workers (1990) and Etchason and associates (1995) concluded that autologous transfusions were not cost effective.

Complications of Blood Transfusion

Each unit of blood or any component is associated with risk of exposure to blood-borne infections. During the past several decades, substantial advances have been achieved in blood transfusion safety. Currently, the most serious known risks are administrative error leading to ABO-incompatible blood transfusion, transfusion-related acute lung injury (TRALI), and bacterial and viral transmission (Goodnough, 2003).

Hemolytic Transfusion Reaction. The transfusion of an incompatible blood component may result in acute hemolysis characterized by disseminated intravascular coagulation, acute renal failure, and death. Preventable errors, such as mislabeling of a specimen or transfusing an incorrect patient, are responsible for most reactions. Although the rate of such errors in the United States is estimated to be 1 in 14,000 units, it is likely greater due to underreporting (Goodnough, 2003; Linden and co-workers, 2001).

Signs and symptoms of a transfusion reaction include fever, hypotension, tachycardia, dyspnea, chest or back pain, flushing, severe anxiety, and hemoglobinuria. Immediate supportive measures include stopping the transfusion, treating hypotension and hyperkalemia, administering a diuretic, and alkalinizing the urine. Assays for urine and plasma hemoglobin concentration and an antibody screen help confirm the diagnosis.

Transfusion-Related Acute Lung Injury (TRALI). This is a life-threatening complication characterized by severe dyspnea, hypoxia, and noncardiogenic pulmonary edema that develops within 6 hours of transfusion (Silliman and associates, 2003). It is estimated to complicate at least 1 in 5000 transfusions. Although the pathogenesis of TRALI is incompletely understood, the mechanisms of injury to the pulmonary capillaries appear to involve lipid products from stored components as well as

leukocyte reactions (Kopko and co-workers, 2002; Silliman and associates, 2003). More recently, the delayed TRALI syndrome has been described as having an onset 6 to 72 hours following transfusion (Marik and Corwin, 2008). Management is discussed in Chapter 42 (p. 930).

Bacterial Contamination. The transfusion of a contaminated blood component is associated with a 60-percent mortality rate. The most commonly implicated contaminant of red cells is *Yersinia enterocolitica*. In the United States, the risk of bacterial contamination is less than 1 per million units. Currently, the greatest risk of transfusion-transmitted disease is bacterial contamination of platelets, which is estimated to affect as many as 1 in 2000 units (Goodnough, 2003).

Viral Transmission. Fortunately, the most feared infection—*human immunodeficiency virus (HIV)*—is the least common. With current screening methods using nucleic acid amplification testing, the time between infection and the first appearance of viral RNA is 11 days for HIV-1 and 8 to 10 days for hepatitis C (Busch and colleagues, 2003). As a result, the risk of HIV infection in screened blood is currently estimated to be less than 1 per 2 million units transfused. Only four transfusion-transmitted HIV infections have been identified since 1999 (Dodd, 2003). Similarly, the risk of hepatitis C infection is approximately 1 in 2 million units transfused (Stramer and associates, 2004).

The likelihood of *HIV-2* infection is even less. After implementation of a combined HIV-1/HIV-2 screening of blood donors in 1992, only three units of 74 million tested through 1995 were positive for HIV-2 (Centers for Disease Control and Prevention, 1995). The risk of *hepatitis B* transmission is higher, although it is estimated to be less than 1 per 100,000 units transfused (Jackson and colleagues, 2003). The risk of transmitting other infectious diseases with transfusion, such as malaria and cytomegalovirus, is estimated to be less than 1 in 1 million (National Institutes of Health, 1993). There have been reports of West Nile virus infection acquired via transfusion. Pealer and colleagues (2003) identified 23 confirmed cases between August 2002 and April 2003.

Red-Cell Substitutes

There are three varieties of these substitutes, and their history and development have been recently reviewed by Ness and Cushing (2007) as well as by Spiess (2009).

- Perfluorochemicals are fluoridated hydrocarbons that are biologically inert liquids with relatively high oxygen solubility. The use of such emulsions allows oxygen to be transported and delivered to tissues by simple diffusion. The only approved substitute, *Fluosol*, was removed from the market. *Oxygant* is a second-generation perfluorochemical that was suspended from Phase III studies.
- Liposome-encapsulated hemoglobin has not proved promising.
- Hemoglobin-based oxygen carriers are still in development. One is *diaspirin cross-linked hemoglobin (DCLHb)*, which proved to be dangerous (Sloan and colleagues, 1999).

SURGICAL MANAGEMENT OF HEMORRHAGE

Uterine Artery Ligation

Used primarily for lacerations at the lateral part of the hysterotomy incision, this technique is shown in **Figure 35-31**.

Uterine Compression Sutures

Several modifications of the vertical brace suture described by B-Lynch and colleagues (1997) have been described for intractable postpartum atony. These are discussed on page 777 and shown in Figure 35-18.

Internal Iliac Artery Ligation

Ligation of the internal iliac arteries can reduce hemorrhage appreciably (Allahbadia, 1993; Joshi and colleagues, 2007). The procedure may be technically difficult, however, and is successful in only approximately half of patients in whom it is attempted (American College of Obstetricians and Gynecologists, 1998).

Technique

With adequate exposure, ligation is accomplished by opening the peritoneum over the common iliac artery and dissecting

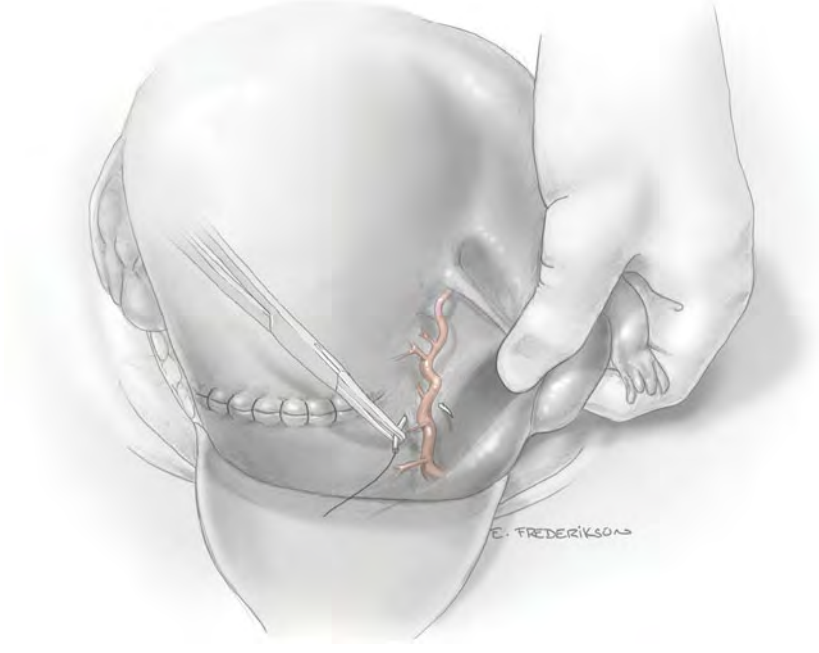

FIGURE 35-31 Uterine artery ligation. The suture goes through the lateral uterine wall anteriorly, curves around posteriorly, then re-enters anteriorly. When tied, it encompasses the uterine artery.

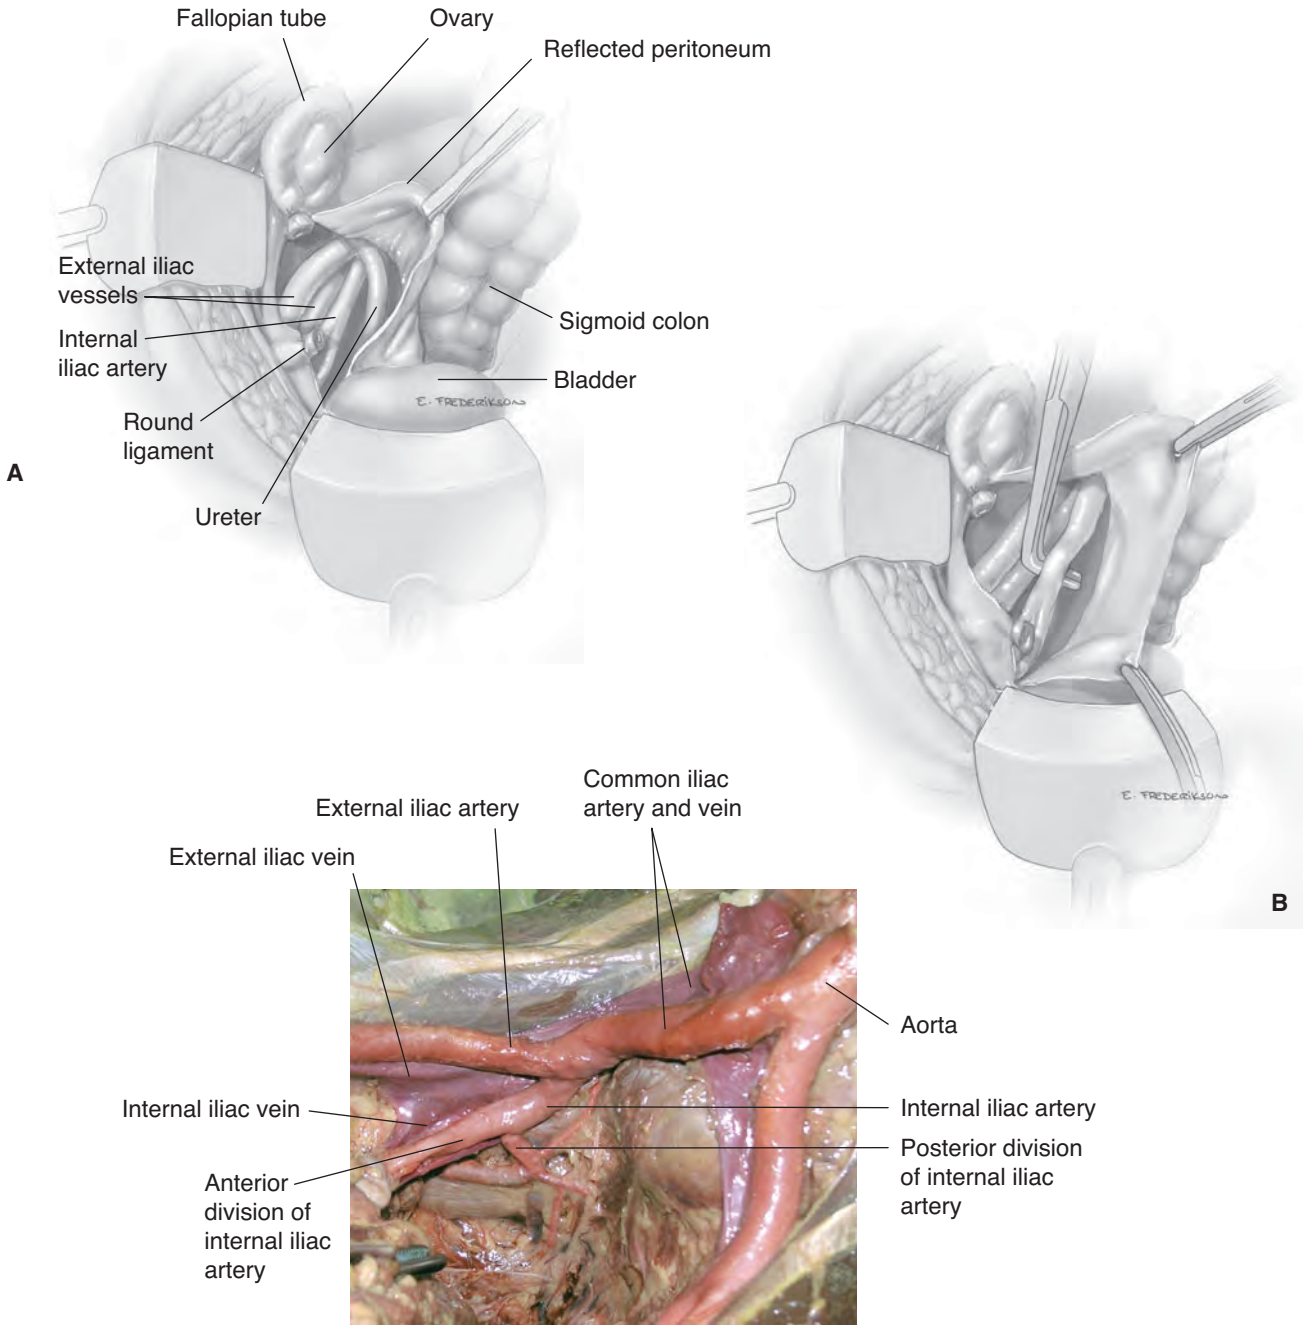

FIGURE 35-32 Ligation of the right internal iliac artery. **A.** The peritoneum covering the right iliac vessels is opened and reflected. **Inset.** Unembalmed cadaveric dissection shows the most common location of the internal iliac vein, which lies lateral to the artery. Ideally, the ligature is place around the anterior division of the internal iliac artery to spare tissues supplied by its posterior division. (Inset, reprinted from *American Journal of Obstetrics & Gynecology,* Vol. 197, No. 6, AT Bleich, DD Rahn, CK Wieslander, et al., Posterior division of the internal iliac artery: Anatomic variations and clinical applications, pp. 658.e1–658.e5, Copyright 2007, with permission from Elsevier.) **B.** Ligation of the right internal iliac artery. A ligature is carried beneath the artery from laterally to medially with a right-angle clamp and firmly tied.

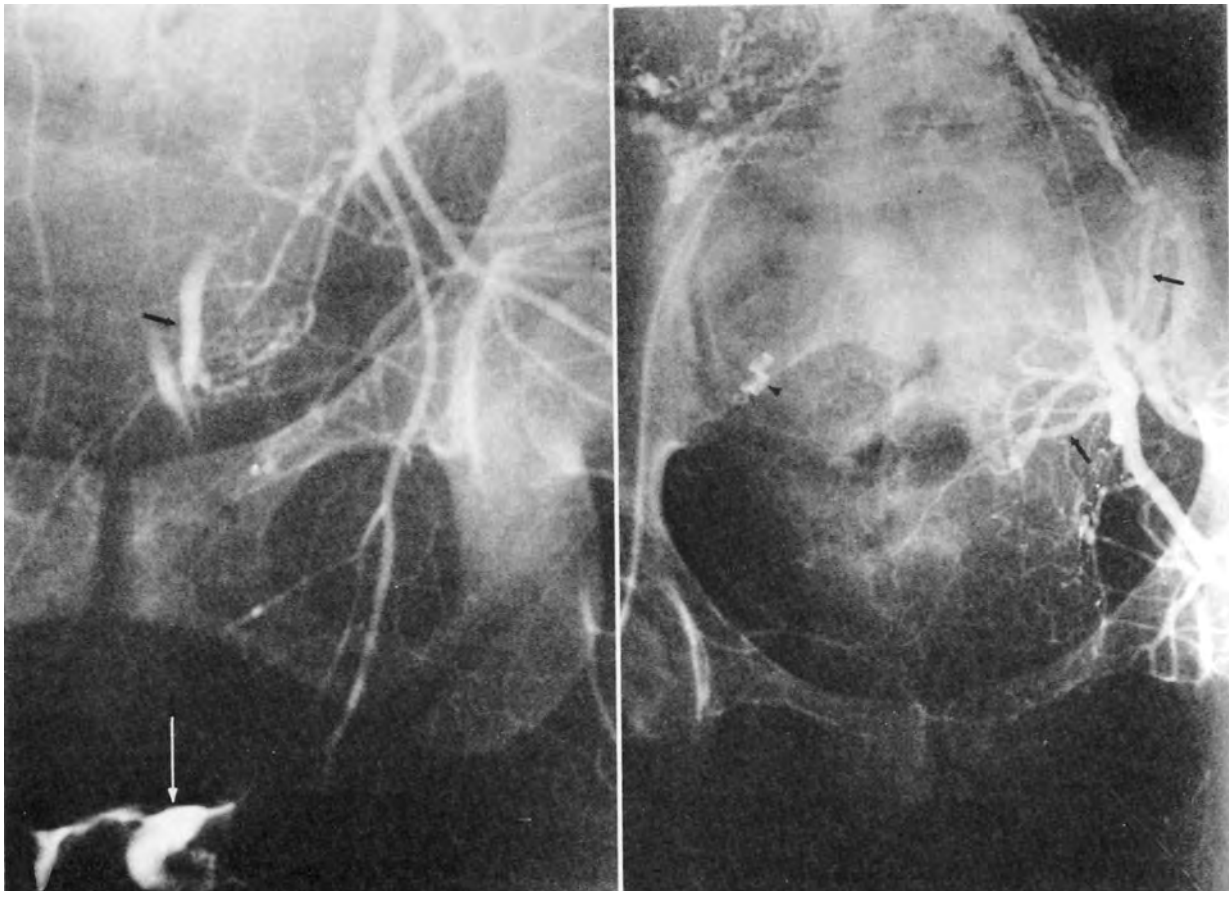
down to the bifurcation of the external and internal iliac arteries as shown in Figure 35-32. Bleich and associates (2007) have shown in dissections of nonpregnant female cadavers that ligation of the internal iliac artery 5 cm distal to the common iliac bifurcation should avoid the posterior division branches. The areolar sheath covering the internal iliac artery is incised longitudinally, and a right-angle clamp is carefully passed just beneath the artery from the lateral side to the medial side. Care must be taken not to perforate contiguous large veins, especially the internal iliac vein. Suture, usually nonabsorbable, is then inserted into the open clamp, the jaws are locked, and the suture is carried around the vessel. The vessel is then securely ligated. Pulsations in the external iliac artery, if present before tying the ligature, should be present afterward as well. If not, pulsations must be identified after arterial hypotension has been successfully treated to ensure that the blood flow through the external iliac artery has not been compromised by the ligature.

The most important mechanism of action with internal iliac artery ligation is an 85-percent reduction in pulse pressure in those arteries distal to the ligation (Burchell, 1968). This converts

an arterial pressure system into one with pressures approaching those in the venous circulation and more amenable to hemostasis via simple clot formation. Fortunately, bilateral ligation of these arteries does not appear to interfere with subsequent reproduction. Nizard and associates (2003) documented 21 pregnancies in 17 women after bilateral internal iliac artery ligation including three abortions, three miscarriages, two ectopic pregnancies, and 13 normal pregnancies.

Angiographic Embolization



Perhaps used most commonly for puerperal hematomas, angiographic embolization may be used if surgical access to bleeding pelvic vessels is difficult (**Fig. 35-33**). These techniques have been advanced over the past 10 years, and a number of reports describe their use for various causes of intractable hemorrhage (Bodner, 2006; Chung, 2003; Sentilhes, 2009; Steinauer, 2008, and all their colleagues). In these cited, embolization was successful in 90 percent of 180 women. Fertility is not impaired, and many of these women have had subsequent successful pregnancies (Chauleur, 2008; Fiori, 2009; Goldberg, 2002; Kolomeyevskaya, 2009; Ornan, 2003, and all their associates). Its use has even been described during pregnancy by Rebarber and co-workers (2009), who used it to embolize a large lower uterine segment arteriovenous malformation at 20 weeks. In most of these reports, complications were few, but at least two cases of ischemic necrosis have been described (Cottier and colleagues, 2002; Sentilhes and associates, 2009).

Preoperative Arterial Catheter Placement

Balloon-tipped catheters are inserted into the iliac arteries preoperatively, and they can be inflated or embolization performed when heavy blood loss is encountered (Oyelese and Smulian, 2006; Yu and co-workers, 2009). In addition to their use for placenta percreta and its variants, it has been described for abdominal pregnancy (see Chap. 10, p. 249). Adverse effects are limited, but one case each of associated postoperative iliac and popliteal artery thrombosis has been described (Greenberg and associates, 2007; Sewell and colleagues, 2006).

Pelvic Umbrella Pack

Described by Logothetopulos (1926), the umbrella or parachute pack is placed for continuing pelvic hemorrhage following

A B

FIGURE 35-33 A. Selective left internal iliac arteriogram before embolization. Note marked extravasation from vaginal artery (*black arrow*) and vulvar branches (*white arrow*) of the left internal pudendal artery. **B.** After embolization, the branches of the left internal pudendal artery are occluded. Patency of the left uterine artery (*arrows*) and coils in the right internal iliac artery (*arrowhead*) are noted. (This figure was published in *American Journal of Obstetrics & Gynecology,* Vol. 160, No. 2, HG Chin, DR Scott, R Resnik, et al., Angiographic embolization of intractable puerperal hematomas, pp. 434–438, Copyright Elsevier 1989)

FIGURE 35-34 Assembly of a pelvic pressure pack to control hemorrhage. A sterile x-ray cassette cover drape (plastic bag) is filled with gauze rolls tied end-to-end. The length of gauze is then folded into a ball **(A)** and placed within the cassette bag in such a way that the gauze can be unwound eventually with traction on the tail **(D)**. Intravenous tubing **(E)** is tied to the exiting part of the neck **(C)** and connected to a 1-liter bag **(G)**. Once in place, the gauze pack **(A)** fills the pelvis to tamponade vessels and the narrow upper neck **(B)** passes to exit the vagina **(C)**. The IV bag is suspended off the foot of the bed to sustain pressure of the gauze pack on bleeding sites.

hysterectomy (Howard and associates, 2002). It more commonly has been used for gynecological surgery, and usually internal iliac artery ligation or pelvic artery embolization was also used. The pack is constructed of a sterile x-ray cassette bag, filled with gauze rolls knotted together to provide enough volume to fill the pelvis as shown in Figure 35-34. The pack is introduced transabdominally with the stalk exiting the vagina. Mild traction is applied by tying the stalk to a 1-liter fluid bag which is hung over the foot of the bed. An indwelling urinary catheter is used to monitor urinary output and to prevent urinary obstruction. Placement of percutaneous pelvic drains should be considered to monitor ongoing bleeding within the peritoneal cavity. Broad-spectrum antimicrobials should be administered, and the umbrella pack is removed vaginally after 24 hours.

Dildy and colleagues (2006) presented their results with 11 women in whom the pack was used to arrest hemorrhage following hysterectomy. These women were given 7 to 77 units of packed red cells. The pack was successful to stop bleeding in nine of 11 women. Over the years, we have had mixed results with this technique but recommend it as a "last-ditch" attempt.
